RELATIVE VALUE OF TESTS FOR RENAL INEFFICIENCY.

IT is manifest to all clinicians that not one of the very numerous tests in use for renal permeability possesses value for the general practitioners as a class. None can be carried out properly without apparatus, strictest regulation of diet, trained assistants, etc. They belong to the resources of hospitals. In a discussion on this subject before the Aertzlicher Verein at Frankfort (*Münchener medizinische Wochenschrift*, February 22) von Noorden expressed himself as above. At the same time he enumerated in the order of their value to him those tests which he naturally employs. The iodine test, one of the oldest known, he has used with great profit from the first of his career. Its chief value is in prognosis, for it tends to reveal the progressive deterioration of the kidneys when this is present. Next in order come alimentary or tolerance tests with necessary ingredients of the diet—water, sodium chloride, and nitrogen (as urea). These three tests are also of value for regulating the diet. The fifth test, that for the amount of N retention in the blood is of course an indirect method for examining the functions of the kidneys. To be of value it must be made at repeated intervals. The recent method of Bary enables us to get a rapid result with only a few drops of blood.

A LEGISLATIVE ATTEMPT TO CURTAIL THE POWERS OF THE BOARDS OF HEALTH.

IN the turmoil and hurry of the closing hour of the New York Legislature a bill was passed amending the public service commissions law in such a way as to give to the commissions exclusive power to regulate overcrowding in public conveyances and specifically taking that power away from the local boards of health throughout the State. No attempt was made on the part of the legislators to find out how public opinion would react to such an encroachment upon the jurisdiction and powers of the health boards of this State; no public hearing was called when a measure of such vital concern to the welfare of the commonwealth was under consideration. If this bill is signed by the Governor and becomes law, it will establish a dangerous precedent which, if availed of generally, may undermine the effectiveness of the State health law and cripple the powers of the boards of health so conservatively and beneficially exercised throughout all these years. There is no good reason for depriving health boards of their power to regulate overcrowding in public conveyances and to protect the public from a well recognized mode of spreading communicable diseases through close personal contact with infected individuals. If the regulation of the overcrowding in cars is left exclusively in the hands of the public service commissions, it never will be effective for the reasons that the personnel of the commissions does not include sanitary experts or physicians, that the commissions will not consider the problem from the same viewpoint as the health authorities, and that even if they do attempt to regulate overcrowding they will have to invoke the penal statute in punishing offenders. This will necessitate drawn-out litigation and proof on their part that the offence committed had a criminal motive or intent. It could never be proved that when a person coughed or sneezed in an overcrowded car and disseminated pathogenic organisms he had a purpose of infecting others. Under the public health law proof of such a motive is not required to stop at once a nuisance or to remove immediately a source of danger to the community. The bill, known as the Simpson bill, Assembly Int. 496, is now in the hands of the Governor. It is hoped that the Governor, who on many occasions has shown such an enlightened interest in public health, will veto this measure.

SENATOR WORKS' RESOLUTION.

ETERNAL vigilance seems to be strongly indicated and most necessary for the protection of the community when legislative bodies are in session, for there is evidently no end to the long array of preposterous measures that are tolerated by them. The resolution recently introduced by Mr. John D. Works of California, in the Senate of the United States, may be cited as an illustration of this mischievous kind of legislative meddling with rules of reason. The Christian Science Senator evidently became uneasy when he learned of the election of the Surgeon General of the United States Public Health Service to the presidency of the American Medical Association, and determined to save the country from the calamity that threatened it. Accordingly he introduced a resolution forbidding the officers of the service to join any medical, public health, or other organization, explaining in the preamble that the American Medical Association is a

body of men belonging to but one school of medicine and interested in the promotion of their selfish ends. It is hardly conceivable that such a bill will be reported out of the committee to which it was referred. It will undoubtedly die of dry rot in the archives of the committee, and it will in this form serve as a lasting monument to its introducer. It affords us, however, an opportunity to pay tribute to the efficiency of the Service and its head, to the contributions to medical and public health science which the officers of the service have made, and to the intellectual and scientific stimulus their membership in the various medical and public health associations gives to the great body of physicians comprising these associations. Emphatic protests against this outrageous bill of Senator Works should be sent to the members of Congress, for the bill is a direct insult to the intelligence of the people.

News of the Week.

City Death Rate.—During the week ending April 22 there were reported in New York City 1,515 deaths, giving a death rate of 14.15 per 1,000, as compared with a total of 1,748 deaths and a rate of 16.68 for the corresponding week of last year. Because of the growth of population since last year, this decrease of 2.53 in the weekly rate is equivalent to a saving of 271 lives. The death rate for the first seventeen weeks of 1916 is 15.48 as compared with 15.65 for the corresponding period of last year. The disease showing important decreases in mortality were: Measles, scarlet fever, diphtheria, spinal meningitis, digestive (other than diarrhea), pneumonia, influenza, and pulmonary tuberculosis. There was no noteworthy increase in the mortality of any disease.

Quarantine Bill Signed.—On April 27 Governor Whitman of New York signed the Adler bill transferring the Quarantine Station at Rosebank, N. Y., to the Federal Government. The new law creates a commission, consisting of the Governor, the Lieutenant-Governor, the Attorney-General, the Comptroller, and the State Engineer and Surveyor, to negotiate the transfer.

Dr. White's Brain.—In accordance with his wish, the brain of Prof. J. William White of Philadelphia, who died on April 24, was removed shortly after death and deposited in the Wistar Institute for Anatomy, University of Pennsylvania, where it will be used for scientific study.

Study of Internal Secretions.—The formation of an Association for the Study of the Internal Secretions has recently been suggested by a number of American physicians interested in the subject, and it is now desired to learn whether there is sufficient interest in the matter to warrant its further consideration. Some of the advantages of such an association are set forth as (1) the assembling of those interested in the subject; (2) the facilitating of the exchange of ideas, inquiries, and reprints on the internal secretions; (3) the enabling of those who are without facilities to keep in touch with the literature of the subject—possibly by the preparation of a monthly list of articles with a brief résumé; (4) the facilitating of concerted clinical study of the subject and of the measures brought forward in organotherapy. It is, therefore, requested that any physician who may be interested and would approve the establishment of such an association send his name and address on a postal card to Dr. Henry H. Harrower, 715-719 Baker-Detwiler Building, Los Angeles, Cal.

Street Accidents.—The Police Commissioner of New York reports a considerable decrease in the number of street accidents in the city during the first quarter of this year as compared with the same period of 1915. The establishments of car-stop safety zones, the designation of play streets for school children, and an increase in the traffic force are believed to be responsible for the decrease. During the first quarter of 1915 the accidents numbered 4,664, the fatal accidents numbering 119, as compared with 4,277 accidents, and 105 fatalities for the first three months of 1916. There was a drop of almost 40 per cent. in the number of children under 16 who were injured, the figures being 1,181 for January, February, and March of 1915, and 761 for the same months of this year. During the same quarter 46 children were killed in 1915 and 28 in 1916. The number of persons injured by accident in the streets during the entire year 1915 was 22,540, death resulting in 659 cases. Of these 659 106 were children under six years of age, and 184 were between six and sixteen years. In the list of dead there were 149 females and 510 males. The largest number of accidents occurred in July—2,291—and the smallest in February—1,359. Passenger motor vehicles were responsible for the greatest number of accidents, 4,865 persons being struck, of whom 177 died. Street cars injured 1,771 persons, of whom 77 died; delivery motor vehicles, 1,212 persons, with 105 deaths, and motor cycles 377 persons with no fatalities. Horse-drawn passenger and delivery vehicles, trucks, etc., struck 2,587 persons, causing 103 deaths. To falls and miscellaneous accidents suffered while riding on, boarding, or alighting from vehicles were ascribed 3,026 injuries, of which 47 were fatal.

Baby Week.—Saturday, May 6, and Sunday, May 7, have been designated as Baby Sabbath and Baby Sunday, respectively, as a fitting end to the Baby Week in New York. The committee in charge of arrangements of the week called attention to the fact that during 1915 there died in New York City alone 13,866 children under one year of age, and that in fully one-half of the cases death was due to preventable disease.

Addition to Hospital.—The addition to the New York Nursery and Child's Hospital, which has just been completed and furnished, was opened for use this week.

President Encourages Red Cross.—The plan of the American Red Cross to enroll 100,000 new members in the Metropolitan district by Decoration Day, has been approved by President Wilson who, in a message to the committee in charge, says: "It is both a patriotic and a humane service that is rendered by every citizen who becomes a member. A large, well organized, and efficient Red Cross is essential."

American Association for Promoting Hygiene and Public Baths.—The next conference of this association will be held in Baltimore on May 9, under the presidency of Dr. Simon Baruch. The program includes "Dock Baths" by Dr. Franzack of Buffalo, "Floating Baths" by Col. Frank Hines of New York, "Effect of Baths in Training the Feeble-Minded" by Dr. Eleanor Keller of the Vanderbilt Clinic, and "Comparison of Methods for Disinfecting Swimming Pools" by Dr. Wallace Mannheimer of Columbia University. An address will be delivered by the president, Dr. Baruch, on "Hygienic Preparedness and School Baths." The secretary of the association is Mr. J. Leonard Mason, 587 City Hall, Philadelphia.

American Gynecological Society.—The forty-first annual meeting of this society will be held in Washington on May 9, 10, and 11, under the presidency of Dr. J. Wesley Bovée. The program contains the titles of thirty papers to be read in addition to a discussion on the "Production of Painless Labor by Other Means Than Morphine-Scopolamine." The secretary of the society is Dr. LeRoy Brown, 148 W. 77th Street, New York.

American Association of Immunologists.—The third annual meeting of this association will be held in Washington on May 11 and 12, under the presidency of Dr. James W. Jobling. The program contains the announcement of twenty-six papers.

Medical Society Elections.—TOLLAND COUNTY (CONN.) MEDICAL SOCIETY: Annual meeting at Rockville on April 17. Officers elected: *President*, Dr. Thomas F. Rockwell, Rockville; *Vice-President*, Dr. Donald L. Ross, Mansfield; *Secretary-Treasurer*, Dr. Eli P. Flint, Rockville.

PLYMOUTH DISTRICT (MASS.) MEDICAL SOCIETY: Annual meeting at Brockton on April 20. Officers elected: *President*, Dr. Nathaniel K. Moyes, Duxbury; *Vice-President*, Dr. Gilman Osgood, Rockland; *Secretary-Treasurer*, Dr. Alfred C. Smith, Brockton.

TANGIPAHOA PARISH (LA.) MEDICAL ASSOCIATION: Annual meeting at Amite City on April 13. Officers elected: *President*, Dr. Edward L. McGehee, Hammond; *Vice-President*, Dr. James L. Le Noir, Amite; *Secretary-Treasurer*, Dr. Anthony J. Strange, Independence.

MEDICAL SOCIETY OF THE STATE OF NORTH CAROLINA: Sixty-fourth annual meeting at Durham on April 18 to 20. Officers elected: *President*, Dr. Charles O. H. Laughinghouse, Greenville; *Vice-Presidents*, Dr. David J. Hill, Lexington, Dr. Joseph L. Spruill, Columbia, and Dr. J. H. Shuford, Hickory. The next meeting will be held in Asheville in April, 1917.

SOUTH CAROLINA MEDICAL ASSOCIATION: Annual meeting at Charleston on April 18 to 20. Officers elected: *President*, Dr. Curran B. Earle, Greenville; *Vice-Presidents*, Dr. Charles R. May, Bennettsville, and Dr. Clarence L. Kibler, Columbia; *Secretary-Treasurer*, Dr. Edgar A. Hines, Seneca. Spartanburg was elected as the place for the next meeting.

Obituary Notes.—Dr. THEOPHILE J. ELLINGER died in Philadelphia on April 29 at the age of 60 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1879, and he served a term as intern in the Philadelphia Hospital. He was a police surgeon for ten years. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, of the Medical Examiners' Association, of the West Philadelphia Medical Society, of the Physicians' Motor Club, and of the American Medical Association.

Dr. FRED K. PORTER of Southwick, Mass., a graduate of the Medico-Chirurgical College of Philadelphia in 1898, died at his home, on April 12, aged 42 years.

Dr. GEORGE H. GODSON of Harmon, N. Y., a graduate of the New York University Medical College in 1892, and a member of the Medical Society of the State of New York, the Westchester County Medical Society, the Harlem Medical Society, and the Greater New York Medical Association, died at his home, on April 21, aged 55 years.

Dr. WILFORD B. HARDIN of Dallas, Tex., a graduate of the medical college of the Southern Meth-

odist University in 1911, and professor of gynecology at that university, died at El Paso, on April 10, aged 28 years.

Dr. CHARLES A. FERNALD of Boston, Mass., a graduate of Harvard University Medical School in 1872, and a member of the American Medical Association, the Massachusetts Medical Society, and the Suffolk County Medical Society, died at his home, on March 15, aged 68 years.

Dr. ABRAHAM HERZLICH of New York, a graduate of the University and Bellevue Hospital Medical College, New York, in 1905, assistant surgeon at the Hospital for Deformities and Joint Diseases, and a member of the Eastern Medical Society of the City of New York, the New York Physicians' Association, and the Harlem Medical Association, died on April 16, aged 32 years.

Dr. THOMAS C. MOORE of Smyrna, Del., died at Cheswold, on April 12, at the age of 62 years. He was graduated from Hahnemann Medical College and Hospital in the class of 1884.

Dr. NORTON DOWNS died at Three Tuns, Pa., on April 15, at the age of 52 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1888. He was a member of the Montgomery County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. EDWARD WACHTEL PALMER of Greencastle, Pa., died at Chambersburg, on April 18, at the age of 46 years. He was graduated from Baltimore Medical College in the class of 1902.

Dr. FRANKLIN D. WORCESTER of Keene, N. H., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1887, died at his home, on March 30, aged 64 years.

Correspondence.

NINE MONTHS IN A GERMAN HOSPITAL.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—THE following observations were made during a period of military activity on the Russo-German (Silesia-Polish) border and vicinity. I was staff-surgeon of the American National Red Cross European Relief Expedition, departing from New York in September, 1914, on the *S.S. Red Cross*, which proceeded abroad to Pauillac, France, and Falmouth, England, and through Holland to Austria and Germany. Hospital supplies and units of surgeons and nurses were distributed to the warring countries. The German and Austrian units were placed in hospitals in October, 1914, at Cosel and Gleiwitz, Silesia, Germany, and at Vienna and Budapest.

Dr. Breiger, the leitender artz of Cosel, appointed me surgeon-in-charge (haupt-artz) of an improvised hospital, previously a modern schoolhouse, with a capacity of 120 to 130 beds. The hospital staff comprised two German assistant surgeons, a German medical student doing his fourth year in lieu of military service, a nursing staff of nuns consisting of Grauschwestern and German Red Cross sisters and helpsisters, also a squad of sanitary troops.

Since returning to the United States in July, 1915, I have found a scarcity of reports in the literature in reference to German war hospitals.

The Polish-German town Cosel is situated on the Oder River near the line of union of Germany, Austria, and Russia, called Drei Kaiser's Ecke.

Battles at Bendzin and engagements in the corner's vicinity and South Russian-Polish towns during the fall and winter of 1914 were the sources of wounded. In the spring of 1915 the sources were more distant—from Warsaw and the Carpathian mountains. Transportation by hospital trains took one or two days in the former and three to seven days in the latter distributing places. A main trunk railroad connected Cosel with Breslau and Mysłowitz, and at the latter place three main lines emptied: one from Russian Poland draining the Warsaw region via Radom, another line from Kielce and South Poland, and a third from the Northern Austria border draining the Carpathians from Przemyśl and Lemberg. Field hospitals were numbered. Radom was a chief distributing point for the Germans in the Warsaw attacks. It rapidly developed under the German rule, and rail communication was established with Lille, France.

Private hospital trains, as well as the regular army trains, were used in transportation to Cosel; also, hospital ships on the Oder carried convalecents away from Cosel to points along the river as far as Stettin on the coast.

There were eleven other hospitals in Cosel, the majority being improvised (Turnhall, School, Barracks), but a garrison hospital built in 1807 and a civil hospital were permanent ones.

The Sixty-second Regiment of infantry was stationed here; its barracks were dated and used by Bismarck. Recruits and Landsturm filled the town. Night exercises, marches, departure of detachments at regular periods for the front, incoming transports, an all-pervading military atmosphere made life here eventful and interesting. Military funerals were daily occurrences. Russian prisoners wounded were treated under careful guard, too, at a Schutzenhaus. Sentries were constantly posted throughout the city, at the provision houses, and at the bridges on the Oder. At nine o'clock at night all civilians were off the streets, doctors and sanitary troops coming and going to their various stations (hospitals). During the night sentries signaled one another by a peculiar whistle, "all's well," on the hour.

The hospital capacity was 1,200 beds. It averaged 1,000 all the time.

First-aid dressings were noted on half the wounded. Others had been put up in casts at field hospitals. The filthy condition of many wounds was accounted for by delay in transit through Russia; maggots and lice developed, especially in fractures within casts.

The men were, in general, well nourished, but filthy and bewhiskered. The field treatment was noted to be: Arrest of hemorrhage. Immobilization of fractures, using starch bandages, boards, straw, long side board with hoops half encircling the trunk, pelvis, thigh, or leg; wire sieve for arm. Plaster (gypsum) was applied lavishly, some casts being one and a half inches thick and of fine quality; straw and aluminum in half-inch strips were incorporated in the casts. No windows were made in the cast, but the site of the wound was marked. Many of these were saturated by purulent exudate coming from the wounds. The first dressings consisted of applications of 5 per cent. tincture of iodine and sublimated gauze made adherent to the wound (and dirt free) by masticol (mastich and benzol).

Hospital cases were divided at the railroad station as light and heavy wounded, and sick. The

and later paralysis in extension or flexion; less severe in the former than the latter. One should use great caution in admitting the existence of a complete transverse lesion.

Capt. E. Adams had fourteen cases in hospital with evidence of damage to nerve tissue; three ended fatally, two from urinary sepsis, the third from bronchopneumonia. In three others there was no improvement; in eight there was progress. He thought bedsores and catheters were to blame for some fatalities, and doubted if it was right to hand over cases to male nurses for regular catheterization.

Capt. E. F. Buzzard agreed almost entirely with the two previous speakers. When an operation was done it was not enough to remove a foreign body—a proper laminectomy was wanted.

Maj. Newton Pitt had been disappointed with laminectomy. In cystitis he had seen improvement follow suprapubic cystotomy.

Dr. Wilson referred to cases of shock, and spoke of one caused by a shell bursting in front of a youth without hitting him, but bringing on symptoms of transverse lesion at the level of the ninth dorsal segment. Lieut.-Col. Sargent, in case of doubt, would give the patient the chance of benefit from an exploratory operation.

The Harveian lecture was delivered on the 16th inst. by Dr. James Taylor, who took for subject, "Nervous and Other Medical Disorders as Seen at an Eye Hospital." He illustrated a number of points with lantern slides, and carried on the work which he had begun in connection with the late Hughlings Jackson, who was one of the first to show the great importance of eye symptoms in relation to disease of the nervous system. Dr. Taylor has enjoyed unique opportunities of observing such cases at the leading eye hospital, and has begun to realize how large is the number of patients who seek advice at such institutions on account of some eye trouble which on examination proves to be an indication of a general condition. He commented on the cases he had had at Moorfields in groups, the largest comprising those who came on account of failing sight, which proved to be associated with optic atrophy; this was found in most cases to be connected with other conditions. In over 200 out of 233 cases there were distinct signs of tabes or of general paralysis of the insane; in some only Argyll-Robertson pupil—in one on one side only; in others only absence of knee jerks and lightning pains; in others, again, both these conditions, occasionally gastric crises. Ataxy only rarely occurs in tabes with optic atrophy—a fact long known and confirmed by these 200 cases, for it was found in only two, and very marked in only one of them. Signs of general paralysis were noted in only three or four, but it is not uncommon for mental symptoms indicative of this to appear some years after patients have been quite blind.

The next largest group applied on account of some defect in the ocular movements. Dr. Taylor commented separately on myasthenia gravis, albuminuric and glycosuric retinitis, Graves' disease, hemiopia, retinal embolism and thrombosis, and optic neuritis. They illustrated the extraordinarily varied medical interests to be seen at an eye hospital as well as the need for a broad general basis on which to build as to different forms of diseases, in addition to the ocular and visual signs which may indicate variations in the progress of physiological or pathological processes.

PRACTICE IN ALASKA.

SOME TRANSPORTATION DIFFICULTIES.

(From Our Special Correspondent.)

ST. MICHAEL, ALASKA, March 10, 1916.

IN this modern age of rapid transportation of the sick and injured, the profession compares the various methods in the relative number of minutes consumed and at the same time lays great stress on the facility of taking patients to and from these various vehicles and the smoothness with which the vehicles run. This has come about partly through the advancement in the profession, but largely through competition on the part of the several manufacturers and operators of these carriages for the sick.

Persons living in Alaska, particularly in northern Alaska, know of these conveniences and luxuries through visits to the United States proper and through literature, but when tragedy falls upon them they must resort to such transportation as is available. This transportation in summer may be a boat, usually home made, wooden or kyak (native Eskimo boat made of skins stretched over very light timbers), or perchance a passenger or freight boat passing in the right direction on the Yukon River or some of its tributaries. In this connection it may be interesting to note that almost all persons in Alaska live on or near some water that is navigable, at least by small boats. In winter the transportation is by means of the sled drawn by the reindeer or by Eskimo dogs; in this immediate section by dogs only. These dogs are used in this section exclusively for all forms of overland transportation; are used in odd numbers, hitched in pairs with one in front as leader. The sled is strongly made of hickory or oak with broad runners, sides to hold the cargo (whatever it may be), two handles and a brake at the back, where the "musher" (driver) rides or runs along after the dogs. It is surprising what these animals can pull on a good trail and on how little they live. For example, eleven average Malamute dogs will pull 1,000 pounds at the rate of 60 miles a day; they can keep this up for day after day, and with an occasional day's rest can keep going the entire season, which is about seven months out of the year. They will live, work hard, and keep fat on one dried salmon fish a day per dog, which is thrown out to each animal in the evening after the day's work is over.

During the period in which the "freeze" is commencing (fall) and during the period when the thaw is taking place (summer) the trails are bad, and it is at this time that transportation is most difficult in Alaska, as neither the boats nor the sleds can be used. To travel overland at this time, particularly on the coast, and make any headway is almost impossible on account of the tundra. The tundra is a peculiar soil, probably of glacial origin, flat or rolling in contour, covered with wild grasses or reindeer moss, found in northern and northwestern Alaska from the coast to many miles inland. There is a humus on the surface which is almost impervious to water, and the grasses grow in very tough bunches about 10 inches in diameter and as high as 18 inches. These bunches are called "nigger heads," are very elastic, and dot the surface of the tundra in great numbers. As warm weather comes on, the snow and ice melt, water collects between these "nigger heads," and the surplus flows away according to the contour of the ground. The tundra thaws down about 8 inches, but remains frozen

always beneath this plane, and on digging below this point one finds ice mixed with the earth.

It can readily be seen that traveling overland during the early fall or early summer is very difficult, as you are either stepping in water or on a "nigger head." Should you step on a "nigger head," it will bend over and the foot slip off. It was during this transition period in the fall of 1915 that a man named Mr. W. D., aged 49, had to be brought from Iditarod to St. Michael, Alaska. This man had been working all summer, and was making the "clean up" (gold dredging) preparatory to returning to the States before navigation closed. The day prior to the proposed date of taking a gasoline launch for St. Michael, this man was struck on the back of the neck by a steam shovel. He developed paraplegia as the result of this injury, even lost control over his urine and feces.

The last over-the-sea ship was scheduled to leave St. Michael seven days after this injury. There were twenty-one persons in the party, including three women, and they must make St. Michael by that date or remain in Alaska over winter. All of these persons had remained in Iditarod until after the close of navigation on the Iditarod and Yukon Rivers in order to reap the full proceeds in gold at the clean-up from their summer's hard work. The question naturally arose: "What can we do, now that W. D. is paralyzed? His wife and children are waiting and expecting him on this last ship, bringing with him the gold of a prosperous summer." W. D. said: "We will go." There was no doctor, but his friends packed him into the gasoline launch, and the party of twenty-one started north on the Iditarod. Traveling was satisfactory until they reached the Yukon River. There was an early freeze-up, earlier than in previous years, and the party encountered ice. They proceeded on the Yukon but a short distance when it became impossible to go farther on account of the dense ice, so the party had to land. They succeeded in getting to a native Eskimo village, procured a sled and brought W. D. in. The launch turned back and made its way to Iditarod before being caught in the ice, and the tragedy was reported to St. Michael by wireless. A rescue party started out from St. Michael in a large tug boat, thinking that it would be possible to force the new ice. On reaching the mouth of the Yukon the ice was so thick that the tug could make no headway, and was compelled to return without the party, but brought news that there were now one paralyzed man, one man with pneumonia, and a woman with heart failure, and had also learned that the party would attempt the remaining portion of the trip overland. There was some snow, but the trails were bad, and although the sloughs were covered with ice, it was thin and dangerous.

Persons well versed with local conditions expressed the opinion that it was very doubtful whether or not enough dogs and sleds could be procured to transport so large a party with their necessary luggage, so the army fort at St. Michael sent out three sleds of eleven dogs each, fur robes, and the necessary number of soldiers, in charge of Sergeant Rector, U. S. Signal Corps, to assist the party in every way they could. Sergeant Rector is an old soldier and reliable. He directed his mushing (sledging) party so as to reach the Iditarod persons in the shortest possible time, and with this additional assistance and the scientific leadership of the soldier, the twenty-one persons were safely

landed in St. Michael sixteen days after beginning their journey. The three sick were put in the hospital, and the others found comfortable quarters in the town. None of them had had the proper kind or amount of food since leaving the launch on the Yukon River, but W. D. was cheerful, always with a smile and a joke, and his paralytic condition the same as when leaving Iditarod.

Even after the many hardships that this party had encountered to reach St. Michael, they were too late to connect with the last ship touching this port for the United States. They were not down-spirited as the sick were improving, especially W. D., whose condition was diagnosed as concussion of the cervical spine, and he made great improvement in a few days of proper rest and treatment.

It was learned that there was to be one more ship to Nome, Alaska, a distance of 120 miles by water, and it was further learned that the U. S. Coast Guard Cutter *Bear* was in Arctic waters, so the U. S. Deputy Marshal wired the captain of the *Bear* about the stranded party and the sick. Captain Cochran of the *Bear* promptly answered: "Will be there to-morrow morning at eight o'clock to take the party to Nome."

W. D.'s troubles were not over yet! Bering Sea (Norton Sound) was frozen over two miles out from shore; so how was the party going to get aboard? This ice, too, was new and dangerous. The *Bear* arrived in due time and penetrated the ice until about one mile from shore. The Iditarod party had seen the smoke of their friend, the *Bear*, coming, and were waiting on shore until they could determine the point where the cutter would stop. Sleds, kyaks, and snowshoes had been procured to use in making the proposed trip from shore to ship, but again the ice was new, untried, and broken in spots by the tide. "How safe is it?" asked one of the ladies. "I do not know," said W. D., "but we must make it." The party crept along slowly over the ice, pulling the sick in sleds by means of long ropes. Those walking were using snowshoes. At the same time the trained crew was launching boats from the *Bear* on the ice. As the party reached these boats they were pulled alongside, and safely and scientifically landed on board the ship. It took one hour and thirty-five minutes to accomplish this boarding, which was carried out without incident and with the greatest of precision. The party landed in Nome in due time to connect with the steamer for Seattle, Wash., and a wireless en route stated "All doing well."

Progress of Medical Science.

Boston Medical and Surgical Journal.

April 20, 1916.

1. Preventable Forms of Mental Disease and How to Prevent Them. E. Stanley Abbot.
2. Pellagra. A Review of the Subject. Charles A. Howland.
3. Acid Auto-intoxication in Infancy and Childhood. John Lovett Morse.
4. The Frequency of Epilepsy in the Offspring of Epileptics. D. A. Thom.
5. False Aneurysm of the Brachial Artery. D. Pearce Penhallow.

1. Preventable Forms of Mental Disease and How to Prevent Them.—E. Stanley Abbot discusses the more common forms of mental disease and says that some of these are wholly, some partly, and some not at all, preventable in the present state of our knowledge. Of the insane admitted to our hospitals about 24 per cent. are cases of dementia præcox; 16 to 20 per cent.

are cases of manic-depressive psychosis, and in this class the writer believes that fatigue plays a large part as a causative factor; 16 per cent. are cases of organic brain disease, and 14 to 15 per cent. may be classed as toxic psychoses. Alcoholic insanity, a wholly preventable psychosis, forms by far the largest part of this group. About 15 to 20 per cent. of the admissions are made up of small groups of miscellaneous psychoses, such as paranoia, epileptic insanity, etc., and many others are of doubtful diagnosis. The writer concludes that an indeterminate but very large amount of feeble-mindedness can be prevented; that of the insanities proper, the alcoholic and drug psychoses, and general paralysis can be absolutely prevented; that of the fatigue psychoses a large proportion, possibly half or three-quarters, might be avoided; that possibly a small proportion of the dementia præcox and arteriosclerosis psychoses might be obviated, and that a small proportion of the remaining forms might also be prevented. By proper attention to the requirements of eugenics, by the avoidance of undue fatigue and worry, by the prevention of syphilis and by a suppression of the general use of alcoholic drinks it would happen in the course of a generation that there would occur yearly, at a conservative estimate, a quarter to a third less insanity than at present and perhaps three-fourths less feeble-mindedness. The indirect benefits to the community in lessened cost to the State, in lessened crime and dependency, in better health and better efficiency, better standards of living, and better morality would be incalculable.

3. Acid Autointoxication in Infancy and Childhood.—

John Lovett Morse sums up his review of the nature and origin of the acetone bodies by stating that they are formed from fat in the absence of carbohydrates or when the metabolism of carbohydrates is abnormal. They may also under certain conditions be formed from protein, the amount formed from protein being relatively unimportant in comparison with that formed from fat. The acetone bodies are not formed in the digestive tract. The deleterious effect of the acetone bodies is not due to any specific toxic properties which they possess, but to their acid character in general and to the power which they possess as acids in withdrawing alkali from the organism. Few who have not examined the urine of children regularly for the presence of acetone and diacetic acid realize how frequently they are present. They are found so often that no attention is paid to their presence unless there are some symptoms of acid intoxication. In making a diagnosis of acid intoxication better tests are the examination of the blood for the presence of abnormal acids, the determination of the amount of ammonia excreted in the urine and its relation to the total nitrogen excretion, and the determination of the carbon dioxide coefficient in the expired air. The most characteristic symptom of acid intoxication in infancy and childhood, outside of the presence of considerable amounts of acetone bodies in the urine, is a peculiar type of dyspnea, or rather hypernea, without cyanosis. Another evidence of acid intoxication which is very frequent in infancy is a diminution in the output of urine, complete anuria being not at all uncommon. A number of other symptoms may be present but are not pathognomonic of acidosis. The writer refers to the reports with reference to an epidemic of acidosis in Boston and the vicinity and says that it is evident from what we know of the etiology of acidosis that an epidemic of primary acidosis is an impossibility. In the vast majority of cases thus reported there was no justification for the diagnosis of acidosis. It was true, however, that some strange and unusual cases occurred during this period. It is also true that in a

number of these cases large amounts of acetone bodies were found in the urine, and that, when these cases recovered, the acetone bodies first disappeared from the urine, while in the fatal cases they persisted. Dr. Morse cites several illustrative cases. He says that little or nothing is known as to the pathological changes. Degenerative changes have been found in the parenchymatous organs but nothing in any way pathognomonic. The logical treatment is the introduction of alkalies into the system, the best for this purpose being bicarbonate of sodium. This may be given by the mouth, by rectum, subcutaneously, or intravenously. The writer prefers to give it by mouth if it can be retained, making the concentration 1:30 or 1:60. In urgent cases dextrose in strength of 2½ per cent. in physiological saline solution may be given intravenously. It must be remembered that this treatment is simply for the condition of acid intoxication, and that the condition is not a primary but a secondary one.

1. Orthodontia and the General Physical Health.—

Bernhard Wolf Weinberger discusses more particularly the subject of malocclusion, with reference to its etiology, effects, and treatment, and concludes that modern orthodontia requires a thorough knowledge of the physiological development of the dental arches and associated structures, the remote as well as the local etiological factors; proper diagnosis, classification, and treatment, based not only upon mechanical principles, but on physiological principles as well. A study of normal occlusion teaches that the full complement of teeth is absolutely necessary in order that the teeth may perform their proper function; extraction of teeth to accomplish this result is not only unnecessary but even criminal. Where the dental arches are arrested in their development, the development of the associated structures is also hindered. Therefore the orthodontist is dependent upon the rhinologist, and the rhinologist needs the assistance of the orthodontist. The disturbances of development begin early in life, consequently orthodontic treatment should be begun early, in order that cure may be completed by the time the second molars are in their proper position. Marked facial deformities can be corrected, allowing every child to develop normally, permitting functions of nutrition, digestion, and respiration.

2. Obstruction of the Pylorus in Infants.—E. Mather

Sill reports six cases, three of pylorospasm and three of pyloric stenosis, and says that we are forced to admit that pyloric spasm plays a most important part in each group of these cases, because the symptoms in the great majority of cases are abrupt in their onset. Then again in a number of cases the symptoms will subside and the child will recover. He calls attention to the cardinal points in diagnosis—sudden onset, persistent projectile vomiting, constipation or obstipation, and steady loss in weight. He thinks a palpable tumor is not necessary for a diagnosis and is not always felt.

If a distinct tumor of the pylorus is felt surgery probably offers the best chance of recovery. Medical treatment offers much better hopes for cases in private practice than for dispensary or hospital cases. Such treatment should consist in breast milk from the mother or wet nurse, dilution of which may be necessary. When breast milk is not obtainable, suitably modified cow's milk may be given every half hour in small amounts at first and the amounts increased at lengthened intervals of feeding as symptoms improve. A milk formula low in fat and sugar should be given in the beginning. Unsweetened evaporated milk diluted with barley gruel is best suited for this purpose. The stomach should be washed twice daily with normal saline solution, 5 per cent. of bicarbonate, the temperature of the water being 110° F. Small doses of opium and atropine may act favorably in allaying the spasm. On the whole it is best not to rely too much on drugs in these cases. Posture is important. The head of the bed should be raised, or a pillow placed under the child so that it lies on a marked incline. After feeding the child must be kept quiet for at least an hour. The postoperative treatment consists in giving breast milk alternately with boiled water. Three hours after operation two teaspoonfuls of breast milk are given, followed in one hour by two teaspoonfuls of water. The next day one-half ounce is administered every three hours. Colon irrigations of a physiological saline solution are given after twenty-four hours, but sooner if there is distention with gas.

6. Ischiorectal Abscess from a Fish Bone.—J. F. Saphir relates the history of a patient who consulted a physician complaining of pain in the anus, chills, and some fever, aching in all parts of the body, and general malaise. His condition was finally diagnosed as ischiorectal abscess, for which he was operated upon. He continued to have a fistulous opening, for which he received treatment, and was finally subjected to another operation four months after the first when, in curetting the fistulous tract, a fish bone was discovered about two and one-half inches in length and triply bent upon itself. The writer points out that this case emphasizes the necessity in fistula cases for early diagnosis; for more frequent rectal examinations on the part of the family physician; for complete and more thorough opening of the canal, and probing of affected areas for branch canals, pockets, and foreign bodies; for trimming off the edges of the wound to prevent bridging and too hasty healing, and for proper drainage. The case also shows that the sphincter can be cut through without causing incontinence if cut at right angles to the muscular fibers, as well as the ability to get along without locking up the bowels for a week, without the use of opiates, and without the use of rubber hose.

1. Spasm of the Stomach and Duodenum from a Roentgenologic Point of View.—Russell D. Carman

says that the favorite playground of spasm, whether of intrinsic or extrinsic origin, is the stomach. Three forms of spasm due to gastric ulcer may be distinguished: (1) The incisura or hour-glass stomach. The incisura is a spastic contraction of the circular muscle fibers in the plane of the ulcer, and shows as an indentation of the opposite curvature. Usually narrow, but of variable depth, persistent and permanent as to situation, it suggests at once the nature of the lesion and points toward its site. (2) Diffuse spastic distortion, to which gastric ulcer often gives rise, affecting a considerable extent of the pyloric segment. The stomach well outlined in its upper portion shades off into a poorly filled, vaguely outlined, antral area which may resemble the filling defect of a pyloric cancer. (3) Spasm of the pyloric sphincter. An ulcer situated in the pyloric segment is frequently accompanied by retention from a six-hour meal, as well as ulcers situated well away from the pylorus. This retention has been variously ascribed to impairment of peristalsis by the ulcer, to reflex pylorospasm, to gastric hypotonus, and to pyloric spasticity excited by hyperacidity. Cancer of the stomach aside from the organic filling may also produce more or less spastic distortion of the gastric contour. All the above spastic phenomena are intrinsic, that is, they originate from lesions of the stomach itself. Quite as frequent are the extrinsic spasms, which may be traced to a number of different sources. The differentiation of the types of spasm is best carried out by a process of exclusion and there are, according to the author, certain practical tests by which differentiation can be effected in most instances. Deformity of a gastric outline produced by an organic lesion is persistent, constant in situation, and unvarying in aspect. It cannot be made to disappear by giving an antispasmodic. Spasm resulting directly from an ulcer or cancer of the stomach is manifested usually in the segment involved, and especially in the area opposite the lesion. It is constant in situation. It is persistent and unvarying, though it is claimed that shallow erosions may cause intermittent spasm. If the spasm takes the form of an hour glass or incisura, its borders are clear cut, but if a large area is involved, it may show as an indefinite zone of incomplete filling. The lesion provoking the spasm may be seen as a niche, accessory pocket, or a neoplastic filling defect. The progress of the meal may or may not be retarded, depending on the extent and situation of the lesion rather than on the spasm. Spasm of any sort, whether intrinsic or extrinsic, disappears under general anesthesia; the practical test on which most roentgenologists rely for the exclusion of reflex spasm is the administration of belladonna or its alkaloid. In the duodenum a probable form of intrinsic spasm which has not hitherto been emphasized is that accompanying duodenal ulcer. Intrinsic spasm plays an important part in the roentgenological evidence of duodenal ulcers, and in the absence of spasm no deformity of the bulb will be seen in many instances. It appears that in the presence of an unchanging bulbar distortion one can safely assume that the spasm is due to an intrinsic cause.

2. Sarcoma of the Base of the Skull.—C. E. Royce reports a case and writes that he has found reports of only twenty instances of sarcoma of the bones of the base of the skull. The patient complained for nearly two years previous to his death of headaches, varying from a dull pain in the left temple to a very severe pain radiating to the right temple and sometimes to the occiput. He also complained of roaring in the ears, dizziness and diplopia and gradually lost the sight, first of the left eye and then of the right. While the man

looked decidedly ill and sallow there were few definite physical symptoms aside from those just mentioned. A decompression over the left temporal region revealed nothing but increased intracranial pressure, hernia cerebri forming at once. The only point of interest in the necropsy was the head. The under surface of the brain presented a globular mass much more dense than the brain substance about 9 cm. in diameter and intimately connected with the periosteum of the sphenoid bone between the two lesser wings. The description of this tumor very well illustrated the nature of these tumors. In general they are well encapsulated, and separated from the brain substance by pia-arachnoid, altering the brain substance by pressure changes only. The cranial nerves sometimes give the only evidence of the presence of such a growth, as in those growths involving the Gasserian ganglion. Frequently, however, there is extracranial evidence appearing in the nasopharynx, the hollow portions of the bones adjoining the nasal cavity, the ear, or in metastases, especially to the cervical lymph nodes.

3. Results from Blood Transfusion in the Treatment of Severe Posthemorrhagic Anemia and the Hemorrhagic Diseases.—Edward W. Peterson. (See MEDICAL RECORD, April 15, 1916.)

4. The Antiseptic Action of Ether in Peritoneal Infections.—John Saliba writes that he has used ether for over a year as a routine in all cases of peritoneal infection that came under his care at the Elizabeth City Hospital, N. C. He makes an instillation of one ounce of ether into the peritoneal cavity for a child above four years of age and three ounces for an adult, and employs proctolysis and Fowler's position in the after treatment. In all the cases in which this treatment was used there were no untoward after effects that could be attributed to an overdose of ether excepting in two instances out of a series of 248 cases, and these cases were of an exceedingly grave nature at the time of operation. The writer reports five cases of appendicitis in which he employed this measure.

1. Gunshot Wounds and Injuries of the Spinal Cord.—James Collier has made his observations on cases some time after the receipt of the injury. He makes no attempt to deal systematically with the subject, but brings up such items of his individual experience as he believes will excite interest and stimulate discussion. He classifies the lesions he has met as: (1) Direct lesions, or those caused by the passage of a missile across the spinal canal, whether it touch the cord or not. (2) Indirect lesions, those due to the indriving of bone, etc., into the spinal canal. (3) Secondary lesions, such as perithecal and intrathecal hemorrhage, medullary hemorrhage and thrombosis, meningitis and edema. (4) Remote lesions which may be found anywhere in the spinal cord, and chiefly near the surface; spots of necrosis, sieve like rarefaction, punctiform hemorrhage, edema, swelling of exons. Severe indirect injuries of the spinal cord may occur from the bursting of high explosive shells when the back is turned to-

wards the force of explosion without any external wound occurring, without any detectable lesion of the bones, and without even bruising of the soft tissues. The writer cites three such cases. In these three cases and in several others of which he has heard the lesion was in the lower dorsal region. He comments particularly upon intrathecal hemorrhage pointing out that blood effused into a free thecal space finds its way with the stream of cerebrospinal fluid into the lower part of the thecal space around the cauda equina and lumbo-sacral enlargement, and if massive in quantity may extend that space and may cause such matting and cicatrization as may completely destroy by pressure and evascularization the cauda equina, and if it extend high enough the lumbar enlargement as well. Smaller effusions by clotting and condensing adhesions may cause local signs of nerve root involvement. In a severe condition of this kind the physical signs may resemble exactly those of a complete lesion of the cauda equina or lumbo-sacral enlargement. In the less severe lesion of this kind the physical signs may be difficult of explanation unless the possibility of intrathecal hemorrhage and its results are kept in mind. A second remarkable condition referred to was that of total necrosis of the distal segment of the spinal cord which was found in one patient. The lesion was a total transverse lesion at the level of the third dorsal segment. Another important point which experiences in this war have brought out is that the influence of the higher nervous system upon the reflex action and muscle tone of the spinal cord is strictly homolateral so far as the cord is concerned. That is to say that a total unilateral lesion of the cord produces complete flaccidity with loss of knee and ankle jerks and reduction of superficial reflex upon the side of the lesion. The writer suggests certain points by means of which a distinction can be made between root lesions and central lesions, brings out certain points of interest in connection with disturbances of sensibility and cites a remarkable case of cervical shivering in whom the cervical laminæ were smashed in upon the cervical enlargement. Finally he gives a number of interesting prognostic indications.

2. The Dissociation of Cutaneous Sensations in Injuries to the Peripheral Nerves.—Donald E. Core during the last eighteen months has carried out a series of observations for the purpose of comparing the relationship to each other of the areas of anesthesia to different forms of cutaneous stimuli resulting from injuries to the peripheral nerves. The study of complete nerve injuries was carried out in postoperative cases in which the completeness of the division is certain. The author has found that it is not always easy to make quite sure that the lesion is or is not complete in those cases which are termed "severe" from the extent and intensity of the symptoms alone. The types of dissociation are sometimes mixed so that it is not easy to assign their true cause, other than to say that they are not due to complete division nor to pure compression. The statement may be made, however, that it is possible in the great majority of cases to diagnose the condition of the affected nerve from the dissociation of cutaneous sensations met with. In complete division the loss to brush is more extensive than to needle-point (cutaneous pain). In pure compression the loss to brush is less extensive than to needle-point. A dissociation characteristic of complete division associated with one of compression is occasionally met with. This leads to a lateral displacement of the two areas of sensory loss; it is met with when more than one nerve is injured, and when the nerves involved supply contiguous areas of the skin. It indicates the complete division of one of these and the compression of the other. When such a

dissociation is met with in the territory of one nerve it is possible that it is the result of partial division of the nerve with compression of the undivided fibers. In the course of this investigation several cases were seen that differed from the majority in that intense pain was a prominent symptom. The patient did not give any precise description of its whereabouts, further than that it was in the palm of the hand or sole of the foot. It was found that this condition was associated with incomplete injury of the nerve affected, the nerves most commonly affected in this way being the median and great sciatic.

4. Investigations of Strains of Tubercle Bacilli Derived from Sputum.—A. Stanley Griffith has been making these investigations for the Medical Research Committee. He has analyzed the results obtained from 212 cases of phthisis pulmonalis. Of the 212 strains, 205 were of the standard human type; four were of an atypical human type and three were of the standard bovine type. The bacteriological characteristics of the atypical strains are described. On the clinical side the cases have not presented any unusual features. These atypical strains resembled the human type in their pathogenic effect on rabbits and guinea pigs and in their mode of growth on serum and glycerine serum. Microscopically they exhibited very irregular morphology, there being many long, curved and beaded forms both in the sputum and in cultures. They differed from the standard human tubercle bacilli in the way they grew on agar, potato, and broth. On these media they were dysgonic and save from very minor differences on glycerine agar they have displayed characters which would entitle them to classification with bovine tubercle bacilli. The cultural features of three of the strains were practically identical. In making his cultures he had used the simple method which he has previously described of obtaining the cultures direct from sputum by means of antiformin. Further experience with this method has served to show that the use of high percentages of antiformin with short exposure possesses advantages over low percentages with long exposure.

1. The Toxicology of Salvarsan.—William Henry Wilcox and John Webster call attention to the fact that at the outbreak of the war it was found desirable that dioxidyamido-arsenobenzol should be manufactured in England. The English product was known as "kharsivan," and before being placed on the market was submitted to the writers for careful chemical and physical tests; these gave practically identical results with salvarsan. The toxic action of kharsivan was certainly not greater than that of salvarsan. The writers describe in detail the chemical and physiological tests that they have made and the preparation of salvarsan and neosalvarsan for intravenous and for cutaneous injection. After an injection of 0.6 gram of salvarsan they have found arsenic in the blood one hour after the injection, the amounts found in two cases being respectively $\frac{1}{2}$ and $\frac{1}{3}$ mg. in 100 c.c. of blood serum. The blood clot was found to be almost free of arsenic, this being found only in the blood serum. Salvarsan is

excreted mainly by the kidneys and bowel; it is present in the urine and feces for at least three weeks after an intravenous injection. In cases of death after the administration of salvarsan it is found in the abdominal viscera. A most interesting feature is that arsenic seems to be almost entirely absent from the brain and nervous system, so that symptoms of profound toxemia in cases of salvarsan poisoning are certainly not due to the action of the arsenic as such on the central nervous system. The writers investigated the influence of salvarsan on the milk of a lactating woman to whom the drug had been administered and found that arsenic was almost entirely absent from all the samples though the most delicate tests were employed. It thus appears that the benefits resulting to a syphilitic baby, who is suckling from an infected mother to whom salvarsan is given, cannot be due to the presence of salvarsan in the milk. The importance of a careful physical examination before the administration of salvarsan is emphasized and attention called to the contraindications, such as renal disease, in which the advisability of administering salvarsan depends upon the excretory efficiency of the kidney, disease of the circulatory system, serious bronchial conditions, and advanced degenerative conditions of the central nervous system. In discussing the treatment of salvarsan toxemia the authors emphasize the importance of prophylactic treatment. They advise an aperient the night before the remedy is administered and the avoidance of alcohol and tobacco for twenty-four hours before and after the administration. The patient should remain in bed on the day in which salvarsan is given and for twenty-four hours afterward. If there are slight symptoms the patient should be kept on a light diet and remain in bed until the temperature has become normal and all symptoms have cleared up. When serious symptoms, such as collapse, twitchings, stupor, or delirium occur, an intravenous injection of two or three pints of physiological saline solution should be given and repeated if necessary. Saline solution may also be given with advantage subcutaneously and by rectum. Where the blood pressure is not low venesection should be done. If the patient becomes comatose nourishment should be continued by stomach or nasal tube. In case of collapse strychnine may be given hypodermically every four hours in 1/40-grain doses, and oxygen, or oxygen passed through alcohol may be administered.

3. Amputations at Base Hospitals in France.—C. Gordon Watson refers to the fact that there has been considerable criticism of the flush amputation as performed at the base hospitals by surgeons at home. He states that, nevertheless, this method after a run of eighteen months is still the operation of choice in the class of cases for which it came into use, namely, severe sepsis threatening life. He shows the disadvantages of flap amputations under these conditions, and says that the advantage of flush amputations are: 1. Rapidity with minimum shock. 2. A plain open surface for dressing, which is favorable to the subsequent control of sepsis and which prevents pocketing. 3. Great diminution in the risk of secondary hemorrhage. 4. The operation provides the best mechanical relief of gas tension by dividing all the tissues at right angles to the muscle planes. 5. It allows a temporary amputation to be performed close to the site of injury, so that a permanent amputation can be performed later (when sepsis is under control) a little above the injured area. 6. In cases associated with fracture the proximal end of the bone can be, and should be, left intact (that is, not sawn through) and projecting beyond the plane of muscle section, thus minimizing the risks of osteomyelitis and also providing a useful medium (a) for the

application of pressure by means of dressing in case of hemorrhage (a practical point of great value), (b) for moving and fixing the limb, (c) for the application of extension to the skin. The secondary amputation should be done as soon as the sepsis is under control and the general condition of the patient is favorable to further amputation, and before extensive cicatrization has occurred. The details of the secondary amputation are important. If flaps are cut and muscle planes opened up, a "flare up" may be expected, but if the muscle attached to the bone is carefully separated from the periosteum by snipping with scissors until the amount of bone to be removed has been bared, and if the bone is divided without lacerating the granulation tissue, the operation can be done without any local or general reaction. The writer gives the details of the technique of the secondary operation, which experience has shown to contribute to its success.

6. A Note on Dysenteric Arthritis.—T. Gillman Moorhead finds that the occurrence of arthritis, single or multiple, as a complication or sequel of amebic dysentery has received very little attention at the hands of writers, though Phillips, Manson, and Osler have mentioned it. He says that in all cases of arthritis occurring in their troops a history of dysentery should be inquired for, and if such a history is obtained, a course of emetine should at once be ordered. He relates his experience with six recent cases in which emetine cleared up the arthritis most rapidly after other treatment had failed.

Berliner klinische Wochenschrift.

March 27, 1916.

Early Diagnosis of Progressive Paralysis.—Piotrowski refers to a published case of Nonne's in which beginning paresis was diagnosed solely by the reactions of the cerebrospinal fluid. The diagnosis was confirmed by autopsy. Clinically the picture was quite negative and before the biological tests the case had been regarded as neurasthenia. The mind was perfectly intact, and the end of the case in suicide was in accord with a depressive cast of temper. In Nonne's case the form reactions all fell out positively. Since reading this case the author has made the same diagnosis from a single reaction, a positive WaR in the spinal punctate. The patient was a soldier, aged 33, who denied not only venereal disease but exposure to infection as well (this doubtless refers only to his former life as a recent gonorrhea is mentioned). There was an old history of genitourinary disease—cystitis, orchitis, etc., and a record to the effect that he had been treated in 1915 for nephritis, gastric catarrh, neurasthenia and hypochondria. Upon examination his mind reacted correctly, the eyes and the reflexes were normal and there was negative WaR in the blood. His moroseness passed into ideas of persecution, but only at intervals. At a later period the WaR was obtained in the lumbar punctate. Did this find justify a diagnosis of commencing paresis? Lues cerebrospinalis could be excluded, likewise tabes, by the terms of the reaction alone. A vigorous treatment was instituted with HgKI and salvarsan, but even in the midst of this the picture of paralysis suddenly emerged in stormy fashion, an acute hallucinatory insanity having developed with evidences of dementia, while the general state became cachectic. There were, however, few phenomena which implicated the cranial nerves, the pupils remaining normal. Mania with anger affects was excluded by the diminished intelligence. Dementia præcox hardly came in question. The positive WaR in the spinal punctate spoke either for a lues or metalues,

and the former could be excluded through the failure of specific treatment. Hence metalues—save for its remote possibility of an unrelated psychosis—must in this case mean beginning paresis. The denial of venereal infection made when the mind was clear was at variance with some of the patient's mental content after he had become confused and self-accusatory.

Perforation of the Uterus with Prolapse of Intestines.—Heimann refers to the relative frequency of perforation of the uterus as a result of curettage for abortion. He relates the case of a woman aged 34, with history of three spontaneous births and a miscarriage. The puerperium had always been afebrile. When first seen she gave a history of three periods missed, with a profuse flowing during the past ten days and apparent escape of an ovum. The uterus was enlarged and the os admitted one finger. Remains of placental tissue could be palpated, and as these could not be detached with the finger an ovum forceps was used. In drawing forth the instrument a loop of intestine was found in its clutch. The patient was at once taken to the hospital. There was evidence of internal hemorrhage due to laceration of the mesentery. Median laparotomy revealed a perforation of the uterus at the left tubal angle, at which placental residues had been located. The torn away loop of intestine was resected after it had been drawn back into the abdominal cavity, and the tear in the mesentery sutured. The perforation in the uterus was closed with four catgut sutures. Despite the character of the intervention the patient made a good recovery.

Münchener medizinische Wochenschrift.

March 28, 1916.

Amyloid Degeneration as the Expression of an Infection with the Bacillus Capsulatus (Friedländer Group.)—Frank mentions Virchow's original discovery that amyloidosis follows upon chronic suppurations. Czerny apparently showed that sterile pus could produce this result in animal experiment, which seemed to exclude a bacterial origin. Krawkow, however, produced amyloidosis by means of cultures of pyogenic cocci, but only in rabbits; in dogs neither pyogenic cocci nor sterile (chemical) pus gave positive results. It was found later that bacteriotoxins and enzymes could be made to produce the lesions. The whole subject seemed to end in a *reductio ad absurdum*. The author therefore returned to studies of the clinical disease and in a man aged 60 he succeeded in cultivating a micro-organism from the blood. This subject, previously intact, had contracted a pneumonia which had gone to the stage of gray hepatization with plastic pleurisy and diffuse amyloidosis. In this case prolonged suppuration could be excluded. The sole causal factor which could be accused was the so-called pneumobacillus of Friedländer which had been responsible for the pneumonia and was also present in the circulating blood. The specimens found, however, did not completely correspond with the Friedländer, but clearly belonged to the same group of capsulate bacilli.

Blood Transfusion in War.—H. Fischer of New York, who has been serving at Oppeln, reviews the subject of transfusion with especial reference to recent work in the United States. The suture method of Carrel is naturally not adapted to military surgery without modifications, and even these are open to the criticism that the transfused blood cannot be measured. In all competitive procedures, the blood must become exposed to the air, so that certain chemicals which can delay coagulation must be used. The best known of these anticoagulants are herudin, sodium citrate, sodium oxalate, peptone and

glucose, and of this number sodium citrate has shown itself the choice. Credit for the introduction of this resource must be given to Hustin of Belgium although R. Lewisohn of New York not only made the same discovery independently but developed its possibilities as a result of much experimental investigation. His report appeared in July, 1915, and the author employed the technique in one case before leaving New York. As he finds nothing to suggest that Lewisohn's method has been essayed in Germany he asks his German colleagues to test it. To his New York case already mentioned the author is able to add a German case in the Military Reserve Hospital at Oppeln. The patient had not been injured in battle, but was suffering from an incoercible hemorrhage which followed extraction of a tooth. Much blood had been lost and the patient was in a serious condition. Five hundred c.c. of blood from a healthy donor were at once infused. The immediate results were rise of temperature to 40° C. and rigors. On the next day, however, he was feeling perfectly well, and was able to sit up in his bed. The benefit was permanent.

Deutsche medizinische Wochenschrift.

February 24, 1916.

Treatment of Acute Inflammations of the Air Passages in Nurslings.—Peiper discusses influenza in its most frequent manifestation of acute rhinitis. The symptoms are nearly the same as in the adult. By the second or third day the nose is occluded and the nursling is of course quite unused to mouth-breathing and as a result the respiration rate is much augmented. Asphyctic periods are experienced. Nursing becomes almost impossible, as it leads to dyspnea. Aside from this the child may refuse the breast or bottle. The younger the infant the worse the symptoms, and in the newly born acute rhinitis is a menacing condition. Active treatment is always indicated. If the nose is obstructed with crusts, the latter must be softened with olive oil, to which menthol should be added ($\frac{1}{2}$ per cent.). Weak antiseptic and astringent solutions must be introduced on pledgets or by means of a camel's hair brush; or ointments may be used. For antiseptics hydrogen peroxide or weak boric acid, for astringents silver salts. A little suprarenin should be added. While the nostrils are clear the child should be fed. If all other methods fail, pure suprarenin solution (1:5000) must be used to clear the nostrils. Purulent discharge from the nose, mixed with blood or not, suggest very strongly that nasal diphtheria is present. No chance should be taken here, as the mortality in nurslings is over 50 per cent. The local treatment is practically that of simple rhinitis—hydrogen peroxide, suprarenin. The condition may pursue a tedious course. Acute rhinitis may extend backward and produce a rhinopharyngitis which is usually accompanied by angina; or these affections may begin *de novo*. The presence of the deep-seated inflammation is usually made evident by swelling of the lateral chain of cervical lymphnodes, and later of the deep neutral nodes. The nose must not be sprayed or irrigated and the rhinopharynx must be reached from below through the mouth. Antiseptic and astringent powders may be insufflated *per os*. Packs for producing sweating are of much value in rhinopharyngitis. After a cool bath the child is wrapped in a wet bath towel, covered with flannel and hot water bottles applied. Retropharyngeal abscess may complicate influenza and is ushered in by fever. The symptoms are steadily aggravated day by day as the pus is gathering and the picture is absolutely characteristic, the head being held on one side and rigid. Liquids are regurgitated and choking spells are common. The

dyspnea is comparable with that of laryngeal stenosis. The diagnosis is usually possible with digital exploration and external palpation for lymphnodes. In doubtful cases the x-ray will solve the doubt. Erroneous diagnosis or unskillful treatment may lead to aspiration of escaping pus. The left index finger should be used as a guide for the knife, which must be properly protected save for the point. At the word of command, the instant the knife is withdrawn, the nurse bends the infant forward to prevent aspiration of pus. With sufficient opening relief is instantaneous.

Is Tetanus an Intoxication from Locally Elaborated Toxins?—Menzer asks this question and also "Does antitoxin act only antitoxically?" From its method of preparation bacteriolysins should also be produced. In the latter case bacterial endotoxins would be set free. In the present war tetanus there must be much mixture of infection, which does not occur in animal laboratory tetanus. Exceptionally one sees a generalized tetanus bacillemia, and this may be more common than is believed. Of thirty autopsies on subjects dead of tetanus, nineteen showed mixed infection of the wound, and in sixteen there were bronchopneumonic foci; meteorism was practically constant, and both phenomena are probably due to aspiration during the crises, although clinically the former were demonstrated in advance of the latter. Pulmonary infections often follow ordinary infected wounds. The author is inclined to attribute the lung complications of tetanus to this cause. It is possible that tetanus bacilli may be able in rare instances to cause metastases. To turn to the summation of the action of antitoxin, it has been noted that convulsions may be increased after an injection. The author attributes this behavior to the bacteriolytic action of the serum in setting free bacillary endotoxins. This should be especially noteworthy in tetanus bacillemia and metastases. In certain severe cases with probable hopeless outlook death seems to result more rapidly under antitoxin than under expectancy, especially the warm bath treatment which cannot avert death but seems to prolong life. Death in such cases may be due to a terminal sepsis. To sum up, war tetanus is often a sepsis, and at times perhaps a tetanus sepsis, so to speak. Antitoxin can liberate endotoxins if there is a tetanus bacillemia and aggravate the convulsions. In such cases it is better to use warm baths and isolation with a certain fixed amount of morphine.

Spinal Anesthesia.—L. L. Stanley has made observations on 280 cases of spinal anesthesia at the San Quentin prison, tropacocain being the agent employed. The series of cases includes operations for varicose veins, various operations on the legs, fistula in ano, hemorrhoids, operation on the scrotum, hernia, appendectomy, and gastroenterostomy. The writer describes in detail the method of procedure and, in commenting on the results, says: "In this series of 280 cases there has been no fatality. There has been comparatively little shock. Headache has occurred in only 8 per cent. of the cases. There has been no pneumonia following operations. There have been very few postoperative complications. There have been no permanent paralyses following the anesthetic. The period of convalescence has been shortened. With the relaxed muscles closing of the adominal muscles has been greatly facilitated. The blood pressure has fallen in most cases, but in the average case not to a dangerous degree. The height to which the anesthetic is effective is influenced by the length of time the patient is in the Trendelenburg position. The pulse rates is not influenced to any marked degree by tropacocain intraspinally." *Jour. of the Am. Med. Association.*

Book Reviews.

SURGICAL OPERATIONS WITH LOCAL ANESTHESIA. By ARTHUR E. HERTZLER, A.M., M.D., PH.D., F.A.C.S. Surgeon to the Halstead Hospital, Kan., the Swedish Hospital, Kansas City, Mo., and to the General Hospital, Kansas City, Mo. Second Edition. Price, \$3.00. New York: Surgery Publishing Co., 1916.

THE first edition of this work appeared in 1912 and comprised 205 pages and 104 illustrations. The present volume contains over 100 additional pages and 69 more cuts. This growth is due largely to suggestions from readers that the work be amplified from a manual for "occasional" operators, devoted to relatively minor intervention, to a volume covering the entire field of local anesthesia, and adapted to the needs of capital surgery. Hence automatically, so to speak, the book becomes a manual of operative surgery so far as the latter is practicable with local anesthesia, this term including the intravenous method. The special technique is given for each class of regional operations, save that sacral blocking receives a separate chapter. Anociassociation is not considered, doubtless because it involves the use of resources other than simple nerve blocking. The book may be warmly recommended for the steady operator, occasional operator, and undergraduate.

A MANUAL OF PATHOLOGY. By GUTHRIE MCCONNELL, M.D., Assistant Surgeon, Medical Reserve Corps, U.S.N.; formerly Professor of Pathology and Bacteriology in the Philadelphia Dental College and in the Medical Department, Temple University; Formerly Demonstrator of Pathology, Medicochirurgical College of Philadelphia; Formerly Assistant Demonstrator of Histology, University of Pennsylvania, etc. Illustrated. Third edition, thoroughly revised. Price, \$2.50. Philadelphia and London: W. B. Saunders Company, 1915.

THIS little manual has evidently proved useful, for it appears in a third edition, revised and brought up to date. The chapter on the blood is entirely new; other parts of the book have been rewritten; and, as a whole, the volume may be said to contain those points which are essential to the understanding of the subject of pathology.

MANUAL OF SURGERY. By ALEXIS THOMSON, F.R.C.S. Ed., Professor of Surgery, University of Edinburgh, Surgeon Edinburgh Royal Infirmary, and ALEXANDER MILES, F.R.C.S. Ed., Surgeon Edinburgh Royal Infirmary. Fifth Edition, Revised and Enlarged. Volume I, General Surgery. Pp. 801, with 289 illustrations. Volume II, Regional Surgery. Pp. 948, with 301 illustrations. Price per volume, \$3.50 net. Edinburgh, Glasgow and London: Henry Frowde and Hodder & Stoughton; New York: The Oxford Press, 1915.

IN this edition of Thomson and Miles' well known surgery we have a most satisfying treatise covering all branches of general surgery. There are three volumes in the set: Volume I being devoted to general surgery, Volume II to regional surgery, and Volume III (the last edition of which was reviewed in the *MEDICAL RECORD* May 23, 1914) covers operative surgery. In the first volume all subjects are treated which would naturally be included in works on the principles of surgery, such as inflammation, suppuration, and processes of repair; ulceration, gangrene, tuberculosis, syphilis, and tumors; fractures and dislocations; injuries in general and as affecting the various tissues and regions; and diseases affecting the various tissues such as bone, muscle, blood vessels, nerves, etc. In this volume we find numerous evidences that the revision has been most painstaking; for views are expressed and other details given that show a familiarity with the most recent literature. This is particularly manifest in the chapters on the blood vessels, the nerves, and certain chapters on diseases and injuries of bones and joints.

In the second volume the various lesions affecting different regions are taken up in detail, often with a preliminary summary of the essential points in the surgical anatomy and suggestions as to the conduction of the examination. The discussion of the different topics is generally all that could be desired, and in this volume, perhaps still more than in the first, the authors have shown themselves to be in touch with the later opinions and suggestions of authorities. For instance, we find

it emphasized that Paget's disease of the nipple and areola begins in the deeper structures rather than on the surface, as was long taught; and the sections on the spleen and pancreas and on gastric and duodenal ulcers show the influence of recent operative experience and reflect the latest views on etiology, symptoms, and treatment. The text devoted to the abdomen and the various intraperitoneal organs covers about 300 pages and is most valuable; for exhaustive discussion is accorded the more important subjects and considerable attention is paid to differential diagnosis and other topics of especial importance in the question of the moment. We note with satisfaction that in this volume we find an unusual number of references to the work of American surgeons.

BONE-GRAFT SURGERY. By FRED H. ALBEE, A.B., M.D., F.A.C.S. Professor of Orthopedic Surgery at the New York Post-Graduate Medical School and the University of Vermont; Visiting Orthopedic Surgeon to the New York Post-Graduate Hospital and Blythe-dale Hospital; Consulting Orthopedic Surgeon to the Mary Fletcher Hospital, Burlington, Vt., Sea View Hospital, N. Y., Muhlenburg Hospital, Plainfield, N. J.; German Hospital, Newark, N. J., and Waterbury Hospital, Waterbury, Conn.; Member of the American Orthopedic Association; Corresponding Member of the German Orthopedic Association, etc. Octavo of 417 pages with 332 illustrations, three of them in colors. Price, \$6.00 net, Philadelphia and London: W. B. Saunders Company, 1915.

It is perhaps hardly necessary to remind the reader that Albee's work has not only revolutionized the treatment of certain special types of fractures, but also many departments of bone surgery. While it is true that much experimental work had been done and that many of the cardinal principles involved had already been worked out, it remained for Albee to grasp the latent possibilities in bone transplantation and to work out a technique and apply the graft, not on the surface or in the medullary cavity, but as an inlay.

In this book we find a complete exposition of the principles involved in bone work of this sort and a complete description of the author's armamentarium and methods in handling the various lesions in which he has found the inlay bone-graft of service. Tables of contents should seldom find a place in the review of a book, but in this case the enumeration of the chapter headings seems the best way to briefly indicate the nature and scope of the work. There are eight chapters, as follows: The fundamental principles underlying the use of the bone-graft in surgery; author's electric motor operating outfit and technique of usage; the bone-graft in the treatment of Pott's disease and other lesions of the spine; the inlay bone-graft in the operative treatment of fractures; operative methods for remodeling or ankylosing the hip joint; the inlay bone-graft for fixation of tuberculous knee joints; infantile paralysis; osteoarthropathy (Charcot's disease); the wedge graft for habitual dislocation of the patella; the bone-graft in the treatment of diseases and deformities of the foot and leg, and miscellaneous surgical uses of the bone-graft. From this it will be seen that the author has covered the subject most completely.

FIRST AID IN EMERGENCIES. By ELDRIDGE L. ELIASON, A.B., M.D., Assistant Surgeon University of Pennsylvania Hospital; Assistant Surgeon to the Howard Hospital; Assistant Surgeon to the Philadelphia General Hospital; Assistant Surgeon American Stomach Hospital; Former Lecturer on "First Aid and Emergencies" in the University of Pennsylvania Medical School, etc.; 204 pages. Philadelphia and London: J. B. Lippincott Company, 1915.

THIS work, of pocket size and provided with a thumb index, is intended for firemen, the police, lifeguards, sailors, boy scouts, explorers, factory workers, and the laity in general. The conception and execution are alike excellent, although many will differ with the author in regard to some of his statements. Does anyone seriously believe to-day, that a man in uremic convulsions can usually be recognized by ammoniacal exhalations? Recent authorities have shown that in markedly convulsive uremia, nitrogen retention is much more likely to be absent than present. In true azotemia convulsions are never pronounced and are often absent. Writers of reference works should seek to exclude traditional errors and past-truths, although there is a strong temptation to give some criterion rather than confess ignorance.

Society Reports.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting Wednesday, March 1, 1916.

Dr. WILLIAM J. TAYLOR, VICE-PRESIDENT, IN THE CHAIR.

Hysterical Mutism, with Reports of Cases and Exhibition of a Patient.—Dr. G. HUDSON MAKUEN defined hysteria as essentially a disease of the mind—a psychical disease with many and varied psychophysical manifestations and symptoms, saying that it had been variously defined as “psychologic disaggregation,” “a psychologic immobilization,” a “psychologic forgetfulness,” a “psychologic lesion,” and a “disease of the personality.” The feeling of reproach which formerly attached to the diagnosis of hysteria had been superseded by the present knowledge that hysteria was an actual rather than a purely imaginary disease. No disease, the author thought, so strongly emphasized the close relationship of the mind and body. Freud’s psychoanalytic method now engaging the attention of the psychological neurological world and which consisted chiefly in an effort to ascertain the hidden causes of the various psychoneuroses by the use of so-called association tests and the analysis of dreams was mentioned. The differential diagnosis of hysteria and neurasthenia, always difficult, was made still more difficult by the frequently simultaneous occurrence in the same individual. Hysterical mutism was described as a form of mutism by no means common, bearing a close resemblance to the other manifestations of the disease, occasionally existing quite independently of all other hysterical symptoms, and differing from other forms of mutism in that it is of the profoundest character. As observed by Charcot, the mute is muter than mute. While Dr. Makuen had seen but two well defined cases of hysterical mutism, 71 cases had been collected by Marcel Natier of Paris more than twenty-five years ago. Dr. Makuen’s first case was reported before the American Laryngological Association in 1906 and was one of so-called traumatic hysteria in which the hysterical symptoms resisting all the known methods of relief yielded to an emotional excitement of an explosive nervous attack in the form of a nightmare or hysterical fit, during which he uttered several sentences with normal and phonatory and articulatory precision, following which his speech had remained normal for the several years he had been under observation. The second case and that of the patient exhibited was a girl of 13, who had always been more or less subjective minded and melancholy. Three years before she had had four convulsive seizures, preceded for several months by failing health and with some loss of power in the limbs, presumably the result of severe fright. The mutism was complete and the futility of attempting to cure her in her home environment being evident she was about to be placed in a hospital when she was taken by friends to a religious camp-meeting and induced to “pray back” her voice. The enthusiasm and excitement were said to have been intense and the girl was urged to pray long and loud. Apparently this was the process necessary to bring about a mobilization of the child’s psychical forces enabling her to speak with a laryngeal sound after many months of complete aphonia. While probably contended by those healing in this way that the cure was purely in answer to prayer, the author conceded that the exercise of faith was doubtless an important factor in the psychic change. A fuller history of the child’s early illness showed a positive Wassermann test obtained on two occasions. While this finding might change the etiological importance of the original convulsive seizures and hemiplegia the author thought it scarcely explained the mutism with its peculiar history and manner of cure. In both cases Dr. Makuen thought the final successful issue had probably been made possible by the psychophysical training leading up to it, and was convinced that his failure actually to cure his patients was due to his lack of ability to arouse in them the psychic representations necessary for the production and externalization of the symbols of speech. He believed that if physicians were better practised in the art of psychotherapy there would be fewer so-called miraculous cures reported outside the pale of the regular profession, and thought it probable that a more accurate knowledge of hysteria as a disease would give physicians a better understanding of the phenomena of the more serious psychoses.

Dr. J. HENDRIE LLOYD spoke of the necessity of dif-

ferentiating mutism, aphonia, aphasia, and dysarthria. He defined mutism as a condition in which speech was suspended, not abolished, in which the patient had not lost the power to speak, but simply the will—an affection entirely mental. In aphonia there was not the abolition of speech, but the abolition of voice. The manifestation of the affection was entirely in the larynx. Motor aphasia, he explained, was due to an organic brain affection, in which the patient had lost the memory or the power of making speech. The patient could still vocalize and might even be able to utter a few words, but his cortical speech centres were affected and he could not make words in his mind. Dysarthria also he described as due to a brain lesion, and as caused by a paralysis of the muscles of speech, the lips, the tongue, and the vocal cords; it was probably best seen in pseudobulbar palsy. Mutism was described as the symptom, as a rule, of a profound mental disorder. It was most commonly seen in the affections known as stuporous melancholia, or melancholia attonita. It might also be seen in the catatonic form of dementia precox. Cases had been recorded in which it had lasted for years to end in recovery. Dr. Lloyd had seen within a few days a case with a beginning second attack of atonic melancholia with mutism. In the previous attack the patient had remained mute for nearly a year and then recovered. While the mental state of such a patient was one of profound depression and negativism there was as a rule no dementia. The recovery of speech was sometimes sudden. Dr. Makuen’s case raised the question whether it was really a form of dementia precox. One of the nice questions confronting neuropathologists was the possible relationship of syphilis to dementia precox. That mutism, as defined by Dr. Lloyd, might be a symptom also of hysteria seemed to be established by the testimony of some competent observers. Dr. Lloyd was so convinced of the comparative rarity of pure mutism in hysteria, that in any given case of alleged hysterical mutism he should want to be fully assured that the more grave psychoses, such as stuporous melancholia and dementia precox, had been carefully excluded. The organic speech defects, such as aphasia and dysarthria, in his opinion, formed a class apart and could not be discussed in brief space. It was usually not difficult, however, to differentiate them from the so-called functional disorders, such as mutism and aphonia.

Dr. ALFRED GORDON said that apart from the mental affections, such as catatonic forms of dementia precox and stuporous insanity, where the mutism could be easily detected and formed one of the symptoms of the general picture of the disease, the condition presented no difficulty in recognition. Illustrative of the association of functional disturbance in the field of sensory disorders with organic disease of the nervous system, a case was cited of a woman of thirty-two with a strongly positive Wassermann reaction of the blood and spinal fluid, in whom there were optic neuritis and palsy of the third nerve with total hemianesthesia on the left side and concentric contraction of the visual field on this side. Under stress of a severe fright the woman became totally mute. This tended to confirm Dr. Gordon’s opinion that the hemianesthesia was functional in nature, in spite of the symptoms of organic involvement of the nervous system. Two weeks later the woman had a quarrel and immediately thereafter entirely recovered her speech. In Dr. Gordon’s judgment, mutism occurring under such circumstances was in 99 per cent. hysterical. In Dr. Makuen’s case he believed that parallel with the organic condition indicated by the Wassermann test and the presence of the Babinski sign there was a distinctly typical hysterical mutism.

Dr. CHARLES K. MILLS said that mutism as defined by Dr. Lloyd when present in a case of mental disease was due to a profound, delusional, depressive state, and that the existence of the delusional condition was usually recognizable by concurrent symptoms. If hysterical aphonia in a broad sense might be regarded as delusional, it was nevertheless distinctly different from the mutism of well defined mental disease and needed to be studied independently of the latter. In this case the aphonia or mutism was due to suggestion, it might be sometimes to autosuggestion, which, however, might have its origin in outside suggestion. In the hysterical case the suggestion acted especially upon the cerebral volitional mechanism rather than upon that logical mechanism the disorders of which produce the delusions or obsessions at the basis of insanity proper. Treatment should be instituted with these views in mind. Mutism of a delusional origin, if not self-limited,

at least seemed to be limited by influences beyond comprehension, and the question of treatment Dr. Mills regarded as difficult. Cases of true hysterical aphonia were open to more definite treatment, one based very largely upon the use of strong suggestion, which might, however, be accompanied by other methods. In his own practice Dr. Mills had frequently used a form of respiratory treatment, vocalizing associated with forced respiratory movements, which sometimes served to bring back speech, and had sometimes proved very efficacious in connection with other methods of suggestion. In the case of syphilitic hemiplegia, referred to by Dr. Gordon, there undoubtedly was not only a syphilemia, but in addition an hysterical or functional affection. With this in mind the explanation was not so difficult. The influences of the toxic agents upon the central nervous system were such as to reduce the cerebral powers of resistance and render the brain more susceptible to impressions from without and suggestions from within. Treatment in such a case should be directed to the relief of the blood state by the best possible modern methods and the use of strong suggestion.

Dr. JOHN H. W. RHEIN who had examined Dr. Makuen's case at his request had failed to find any evidence of hysteria; the examination had been negative, with the exception of the Babinski sign on the left side. In view of the fact that the Wassermann reaction was positive he felt justified in saying that the child probably had an organic lesion at the time she suffered from the hemiplegia. The symptoms referable to the mental condition and mutism he was inclined to explain as due to a specific psychosis plus syphilitic cerebral spinal involvement, or possibly, as suggested by Dr. Lloyd, a dementia precox. He did not believe the symptoms were entirely hysterical.

Dr. MAKUEN, closing the discussion, said he had hoped to have a fuller discussion of the differential diagnosis between hysterical mutism and motor aphasia. The only objective difference seemed to him to be that in the former the mutism was complete; in the latter, that the patient usually gave expression to more or less disconnected words and phrases. Contrary to Dr. Lloyd's observation that the patient had the power but not the will to speak, in the two cases studied by Dr. Makuen both patients desired very much to speak, both tried very hard to speak, but they seemed to have forgotten how; and, although they finally learned the articulatory movements of speech, they were unable to produce any vocal sounds. Dr. Makuen had concluded therefore that they had lost the necessary psychic representations for phonation. While, as stated by Dr. Rhein, the long illness in the case presented might be the result of the demonstrated specific infection, there could be no doubt concerning the hysterical character of the mutism. The changes in the color fields also, although not pathognomonic of hysteria, were at least suggestive of the condition. The mutism, however, could scarcely be anything other than hysterical. Supporting this, as stated in the paper, it was not unusual to have one or more hysterical symptoms in connection with organic disease.

A New Method of Injecting the Facial Nerve for the Relief of Facial Spasm.—Dr. GEORGE M. DORRANCE said that because of the rather confusing definitions found in the text-books of medicine, particularly those of a few years ago and because of the difference in treatment, he had taken the liberty of giving a brief differential diagnosis between facial spasm and tic, or so-called habit spasms. While alcoholic injections were ideal in facial spasm, they were entirely contraindicated in tics. True facial spasm was a reflex act occurring in a single muscle or group of muscles, and was thought to be due to some form of irritation in the muscles or the nerves of spinal or bulbar reflex arc. Tics, on the other hand, were voluntary contractions which had become a habit. The condition was a psychoneurosis and not a spasm. According to Patrick, "In spasm, the movement is an anatomical disorder; in tics a physiological one." Facial spasm at the onset might be confined to one part of a muscle. Later it involved the entire distribution of the facial nerve, and no more, and was practically always unilateral. Tics never involved only a part of a muscle and rarely involved all the facial muscles at any given time affecting associated groups of muscles and varying these from time to time. They were often bilateral. Facial spasm was painful and incapacitating; tics gave a sense of relief and caused no interference with function. Spasms were found in the mentally strong; tics in the neuropathic type. Another form of tic occurring after facial palsy was that in which the tic was syn-

chronous with the winking. This form, likewise, should never be injected. The reasons for devising a new method of injecting the facial nerve were that the older methods were inaccurate and dangerous. In the speaker's method it was impossible to hit the jugular vein, but it was possible to inject the nerve accurately at its foramen of exit from the skull. The needle (trocar and stylet style) which was 10 cm. long and 4 mm. thick, graded in centimeters, was inserted at the angle of the jaw (the skin having been painted with 5 per cent. tincture of iodine and anesthetized with 0.5 cm. novocain), and directed backward and upward until the point impinged upon the base of the mastoid. The handle of the needle was elevated and the point depressed, feeling the way carefully down and pushing the point backward and inward until the needle felt its way into the stylomastoid foramen. The styloid process prevented the needle from proceeding too far inward and obviated any possibility of hitting the jugular vein. If blood flowed upon removal of the stylet, one should not inject, as the point might have pierced a small vein. One should withdraw, clean the needle, and puncture again. If no bleeding occurred, a few drops of alcohol should be injected. Immediate facial paralysis occurred upon hitting the nerve. Two cc. more of alcohol should then be injected. The needle was removed and no dressing was required. Pain was relieved by hot compresses. The eye should be protected with goggles and washed out with boric acid solution at least twice a day. The method differed from the fifth nerve injection in the absence of trophic changes and corneal ulcers. The face should be massaged daily to prevent atrophy of muscles. The speaker had on several occasions injected one of the branches of the seventh nerve going to one or more muscles by sticking the branches anterior to the parotid. The results, however, here did not compare favorably with those of injection at the stylomastoid foramen. For injection at the stylomastoid foramen he used 2 cm. of 70 per cent. alcohol; for that of the branches, not over 50 per cent. alcohol. The spasm never recurred at the time of return of voluntary power, varying from a month to several years. In some cases there was no recurrence.

Dr. ALFRED GORDON, who in 1914 had presented before the college a paper with very similar title, concluded from his experimental work that a motor nerve treated with alcohol injected into the sheath or into the nerve itself suffered no damage to the nerve fibers and had found that there was complete restoration of the paralysis when the facial nerve was injected with alcohol. On the other hand, when the infraorbital was injected he had found marked trophic disturbance in the area of its distribution. This same observation was made regarding the sciatic nerve. A practical point gained from his experience regarding the point of injection was that the moment the facial nerve was touched there was flinching on the part of the patient. It was also to be noted that if the facial nerve is struck immediate and absolute paralysis will follow.

Dr. DORRANCE, in closing, explained his interest in the work because of failure in four or five instances in injecting the facial nerve. The paper, he said, contained nothing new, except the method of striking the nerve, which now made it possible to accomplish this without uncertainty. Because of the very greatly complicated condition of the whole subject Dr. Dorrance was disinclined to discuss it at the present time.

Some Facts and Fallacies Concerning Abdominal Adhesions and Bands.—Drs. GEORGE G. ROSS and J. BERNHARD MENCKE contributed this paper. The authors believed that much of the existing confusion concerning adhesions, bands, membrane, etc., might be obviated by the clearer grasp of certain fundamentals and an effort to distinguish between various groups and varieties of the structures instead of attempting to make one theory of etiology explain every case. All abdominal adhesions and bands they suggested might be grouped into the following classes: (1) Those adhesions and similar structures whose character and location made it evident that they were the result of peritonitis. (2) Those structures in which some doubt might exist concerning their being the result of peritonitis. The former class, they believed, gave more data upon which to form a conclusion; the latter formed the class about which discussion among surgeons was at the present centered. Membranes and adhesions not frankly the result of peritonitis might be again divided into (a) Structures whose character and location made it possible that they might be the result of fetal mal-

development; and (b) Similar membranes in localities in which this causation was not so plausible. The explanation of both these types which had been attempted upon numerous grounds was briefly outlined. The authors believed, since the existence of not infrequent antenatal peritonitis was proven, that adhesions found not to have been caused by a peritoneal inflammation after birth, were the result of a similar condition in the fetus; and that, whereas many of these adhesions were congenital, they were not developmental in origin. From such an origin, however, they excluded those instances in which there was but an accentuation or simple enlargement of a peritoneal membrane, fold or process normally present. From a consideration of the opinions of clinicians and experimenters it was shown that there was no agreement concerning these bands or membranes. Fallon even stated, it was said, that Jackson's membrane was always present and was a normal structure. With this view the authors were not at all in accord, and felt that there was every reason to believe that practically all of these structures were the result of peritoneal inflammation. Concerning adhesions frankly the result of one or more attacks of peritonitis after birth they believed the fact was frequently lost sight of that such adhesions were principally an effort of Nature to effect a cure or to limit infection. Progress in the diagnosis of abdominal adhesions was to be especially made by means of the x-ray. A less pleasing subject for contemplation was the present inability to deal effectually with such adhesions.

Dr. JOHN B. DEEVER, while believing that embryology played a rôle in the cause of adhesions, thought it played a much more conspicuous rôle with surgeons with little experience in dealing with peritonitis in all its stages; those operating upon many thousand cases were more impressed with the rôle played by inflammation. He had never been very much impressed by the rôle played by Jonnesco's membrane or Lane's kinks. Personally his results had been sufficiently satisfactory to warrant his continuing his present methods. He felt that men were governed by their experience.

Dr. ROSS, in closing, called attention to the fact that the word congenital, used in connection with the adhesions, was not offered in explanation; the adhesions were present at birth, while the ordinary conception of congenital was developmental. He did not believe the adhesions to be developmental, but inflammatory, although the inflammation occurred in the fetus. In dealing with adhesions he had followed all lines of procedure and all had been failures, and it was to him a cause of the greatest amount of chagrin to have these definite entities and not know how to handle them.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 21, 1916.

DR. NELLIS B. FOSTER IN THE CHAIR

A Case of Ochronosis Associated with Melanuria.—Dr. B. S. OPPENHEIMER reported this case. He said that the history of ochronosis was linked with several distinguished names. Fifty years ago Virchow described the first case and gave the name to the disease. Ochre meant pale yellow. It was not perfectly clear why Virchow selected this name since he himself described the cartilage and the cartilaginous structures as being black. The case he reported showed an aneurysm of the aorta and arthritis deformans. In 1902 Albrecht noted the occurrence of alcaptonuria with ochronosis; two years later Osler showed that the cases had clinical interest and could be diagnosed during life and should not be left entirely to the pathologist for study. He described the disease as it occurred in two brothers; one of them was for a time refused life insurance until it was discovered that he had not glycosuria but alcaptonuria; in fact, this was the first case of alcaptonuria recognized in the United States. The brother of this patient similarly was considered a diabetic in Paris, Carlsbad, Berlin, and London; but a short time subsequently Dr. Fitcher of Baltimore determined that this was also a case of alcaptonuria. After the association of ochronosis with alcaptonuria had been established Ludwic Pick, in 1906, first drew attention to another group of cases in which ochronosis was accompanied by carbolic acid poisoning. Eleven such cases of ochronosis due to the use of carbolic acid wet dressings had now been recorded. In addition, Pick was the first to

suggest the theory that the aromatic substances which were formed in the blood from the absorption of carbolic acid were converted into melanin by an enzyme "tyrosinase." In the cases of ochronosis with alcaptonuria, he believed that the homogentisic acid was the body that was attacked by the enzyme to form the pigment. Dr. Oppenheimer reported what was the fortieth case of ochronosis. The patient was a man forty years of age, occupation a presser. The family history was negative as far as the condition of ochronosis was concerned. There had been no consanguineous marriage such as had been recorded in previous case histories. Venereal history was denied. On being questioned about the peculiar bluish discoloration of the cartilage of both ears, he stated that it had existed previous to a frost bite. His urine had been reddish for the last three months and he had often noticed that his underwear was stained black. On further investigation it was learned that eight years previous he was supposed to have had sugar in his urine. His present illness dated back eighteen months, when bathing in the surf he experienced sharp, stabbing pains along the spinal column, radiating forward along the intercostal spaces to both hypochondriac regions. The pains grew more and more severe. He also had stiffness of all of his muscles of the back. He had a cough, never blood tinged until three weeks before admission, night sweats, loss of weight, and general weakness. He was treated for tuberculosis. Dr. Oppenheimer thought that the symptoms which were supposed to be due to tuberculosis were really the result of a chronic bacterial endocarditis, of which they found lesions at autopsy. When admitted to the Montefiore Home on November 8, 1915, he complained of lancinating pains along the spinal column, radiating along the intercostal spaces and to both sides of the abdomen. He had cough, occasional hemoptysis, obstinate constipation, and a general weakness. He weighed 104 pounds. Both ears showed a peculiar blue color. The sclera of both eyes also presented a faint bluish tint. In addition, there was a wedge-shaped bluish-black area of pigment on the sclera to the right of the cornea. Both axillæ were diffusely bluish-green in color. There was a pale, brownish diffuse pigmentation of the neck and temporal regions. The fingers and toes were clubbed. The lungs showed a few signs of suspicious tuberculosis. There was a loud systolic murmur. The arteries showed slight thickening. The liver was palpable 4 cm. below the free costal border and was very tender. The reflexes were all increased. The vertebral column was absolutely rigid and showed a general bow deformity. The spinal lumbar curve was obliterated. There was also a great deal of tenderness of this rigid spine, both in the thoracic and lumbar regions. The hip and shoulders appeared to be involved. The patient vomited persistently and ran an irregular sub-febrile temperature until the day of his death, when the temperature rose to 103° F. A half-hour after death the house officer noticed that the entire eyeball, exclusive of the cornea, had become a brownish-black color. On the day following it was noticed that the pigment in the axilla had become much darker than during life. The diagnosis was readily made on the greenish-blue color of the ears and axillæ, in addition to the black pigment in the urine that had been left standing. X-ray plates of the lesions were shown. Pathological specimens prepared by Dr. A. S. Kline were also presented. The essayist believed that the frequent association of chronic cardiovascular disease with ochronosis was very striking, especially in the alcaptonuria cases. This disease presented a well-defined picture, a disturbance in the intermediary metabolism, which resulted in ochronosis, in the deposit of pigment in the urine, possibly in cardiovascular changes, and finally in metabolic osteoarthritis and spondylitis.

Chemical Observations and Examinations.—Dr. N. W. JANNEY presented the results of chemical observations in this case. He stated that the urine was amber colored, of low specific gravity, turned black on standing. It did not contain albumin nor glucose, failed to rotate the plane of polarized light. Fermentation of the urine with yeast gave a negative result. Benedict's solution was reduced on heating, ammoniacal silver solution in the cold. With ferric chloride a green color was produced which immediately vanished. In the belief that alcaptonuria was present systematic efforts were made to isolate and identify homogentisic acid by the ester method of E. Schumm and by means of the lead salt. No homogentisic acid could be found. A colorless melanogen occurred in the fresh urine. On becoming alkaline

and standing exposed to the air the brown black melanin coloration developed. By a specially devised method, depending upon the insolubility of the melanin in 12.5 per cent. acetic acid, the pigment could be obtained from the urine, purified and analyzed. Similar preparations could likewise be obtained from the costal cartilages. The melanin was also present in various other organs and in the prostate in the form of concretions, one of which was analyzed. It was found to contain carbon, hydrogen, oxygen, nitrogen, sulphur, and iron. The analysis would be published later. Their results and the chemical behavior of the melanin classed it in the group of protein melanins, such as have been found in tumors. Alcaptonuria can be excluded in this case by the absence of homogentisic acid and the presence of a melanin pigment in large quantity which resembled the protein melanins.

In considering the pathogenesis of ochronosis the speaker said the known cases of ochronosis are divisible into three groups with regard to their origin, (a) ochronosis due to carbohic acid poisoning, (b) ochronosis due to alcaptonuria, (c) ochronosis cases in which both carbohic acid poisoning and alcaptonuria could be excluded. It seemed at first sight scarcely possible to find an explanation for the occurrence of the ochronosis syndrome in such divergent conditions. The work of Abderhalden and Guggenheim might, however, be applied to this problem. These authors showed that the ferment tyrosinase, which was present in various animal tissues, exerted a specific action on substances containing the oxyphenyl group, $C_6H_5O.H$. Melanin formation from the simpler phenol bodies, homogentisic acid, the amino-acid tyrosin and tyrosin containing polypeptids was essentially one and the same process, consisting very probably of oxidative syntheses involving oxyphenyl groups. It seemed then entirely reasonable to assume, as Pick has already done, for the carbohic-acid poisoning cases, that fermentative melanin formation taking place in the presence of excessive amounts of substances containing oxyphenyl groups was the underlying cause of ochronosis wherever met with. The carbohic-acid and alcaptonuria group of cases could be readily understood and explained on this basis. In the third group of cases (c), to which the writers' ochronosis patient belongs, the cause of the pigmentation was not so apparent. In these it was probable that as a result of disordered protein metabolism, the formation of melanin pigments related to protein took place from complex substances having the nature of protein or polypeptids containing the oxyphenyl group. The probable relationship of the melanin in this case to the protein melanins could be adduced in support of this view. In this way it was thought that a satisfactory explanation of the pathogenesis of ochronosis might be afforded by means of which all cases could be brought into correlation. The speaker stated that the full report of the chemical examinations, as well as a detailed development of the theoretical considerations growing out of this study would appear later.

Dr. GEORGE R. ELLIOTT said his attention had been called to the rigid spine in this patient at one of the hospitals in the city and he had also seen him at the Montefiore Home. The diagnosis of ochronosis had been overlooked until the patient entered the Montefiore Home. The careful study by Drs. Oppenheimer and Janney had added materially to the knowledge of the subject. The spinal rigidity in this case was interesting as not involving the cervical region. This he believed true of similar cases reported. Dr. Oppenheimer had referred to degeneration of the intervertebral cartilages and "lipping." The x-ray findings seemed to show considerable ankylosis of the lower three-fourths of the vertebral column, together with considerable new bone formation. This form of rigid spine clearly belonged to the so-called degenerative rather than to the true infective type of spinal rigidity. The primary lesion here was clearly intervertebral cartilage degeneration. All the other changes were added unto it. The so-called "lipping" and further new bone formation seen in the x-ray picture were the result of irritation, chiefly incident to the cartilage degeneration. In short a so-called osteoarthritis as contrasted with a true infectious ankylosis, as for example in the rhizomelic type where little or no new bone was thrown out, but where the small articulations were solidly glued together, so to speak, with no excess of new bone thrown about the edges of the articulations. There appear to be a number of different diseases giving rise to the type of rigid spine which this case illustrated, the so-called metabolic etiology where some chemical substance had played a part plus the irritation products

incident to the trauma produced through the intervertebral cartilage degeneration.

An Aspirating Bougie for the Esophagus and Stomach.—Dr. MAX EINHORN presented this instrument. He said that in the examination of patients with strictures of the esophagus they used the bougie. There was a certain disadvantage in the use of the olives that when they reached the place of obstruction they came away clear with nothing attached to them. Therefore it was desirable to learn what would be caught in the opening of a tube; if the latter were a stiffer instrument they would readily see if the parts touched contained decomposed material or not. Therefore he devised a so-called combined instrument: a bougie was provided with an opening to which an olive could be screwed on and the material aspirated; this instrument could be used either as a tube or as a bougie. The stilet could be placed in to facilitate its introduction, when removed, the syringe could be attached and the fluid contents aspirated. The insertion of the wire simply stiffened the tube a little.

Massive Hemorrhages from the Stomach Without Demonstrable Ulcer.—Dr. ALEXIS V. MOSCHCOWITZ read this paper. He said that early in 1916, within a period of less than one month, he had the opportunity of operating upon four patients upon whom the unequivocal diagnosis of a bleeding ulcer of the stomach had been made both by himself and by several very competent colleagues; and yet in none revealed the slightest tangible lesion of the stomach. In spite of the most unfavorable outlook in all these cases they all recovered. The fortunate outcome, however, while very gratifying, left him nevertheless with a sense of incompleteness of the study of the pathological data inasmuch as his observations were based only on the examination of the unopened stomach *in vivo*, and not on post-mortem material. The histories of the four cases he intended to report in full, but the time limit enabled him to report but the one he considered the most interesting.

A graduate nurse, 25 years of age, was admitted to the hospital on February 14, 1915. She had had typhoid fever nine years before. About three years ago, while in training school and on night duty, she suffered from a gnawing feeling in the epigastrium after a midnight meal, and this lasted for a few days. The test meals taken then were negative. She was considered to be a neurasthenic and she never was ill enough to be relieved of her duties. On February 14, at 2 P. M. she vomited about 30 ounces of blood and without any premonitory symptoms; at 4 P. M. a like amount of blood was vomited; at 9 P. M. 50 ounces of blood were vomited, and then the patient fainted. She was transferred to the hospital and treated with morphine, rest in bed, and ice-bag to the epigastrium. On the following day the hemoglobin was 47 per cent. In the evening she vomited 30 ounces of blood and again fainted. During the next three days there was a cessation of the vomiting, but there was a continuous melena, and, in consequence, the hemoglobin percentage dropped lower and lower. Operative interference was considered inadvisable on account of the patient's poor condition. On February 19 she was transfused by the citrate method by Dr. Lewisohn; this procedure raised the hemoglobin percentage from 35 to 55 per cent. In spite of this transfusion the condition became worse. She was so anemic that no accurate measurements of the hemoglobin percentage were obtainable with the Sahli instrument. Therefore operation was decided upon. At midnight on February 20, after a preliminary transfusion by Dr. Lewisohn, the stomach was exposed. All the viscera in the upper part of the abdomen were thoroughly explored, particular attention being paid to the stomach and duodenum. After carefully exploring the anterior wall of the stomach and finding nothing suspicious, the lesser peritoneal sac was entered through the gastrohepatic omentum and the entire posterior wall examined with the utmost care and absolutely nothing abnormal was found. In sheer despair Dr. Moschcowitz made a posterior retrocolic gastroenterostomy and excluded the pylorus. On the following day her condition was excellent. There was still some melena which could be readily accounted for by the bleeding which had occurred prior to the operation. On February 22 the condition of the patient was perfectly satisfactory; but at noon of that day the speaker was summoned to the hospital because the patient had gone into collapse and was in a moribund condition. An acute dilatation of the stomach was considered possible; therefore he passed a stomach tube and withdrew over a quart of bright red blood; this he followed by a lavage of the stomach with ice water until the

washings returned clear. From then the condition of the patient began to improve; the percentage of hemoglobin slowly increased and the patient was discharged from the hospital four weeks later, cured. The history and course of this case was typical of the "exulcerative simplex of Dieulafoy." The sudden profuse hematemesis without any preceding gastric symptoms was particularly suggestive. The post-operative course was also most interesting. The recurrence of an almost fatal hemorrhage thirty-six hours after operation was very interesting and would no doubt be regarded by many as proof of the failure of the operation. To his mind, however, such an argument was entirely erroneous. At best it might be argued that he selected in this case an indirect method to stop the hemorrhage. Had the condition of the patient been better he said he would have incised the stomach and searched for the bleeding point and with certainly a greater promise of success. Dr. Moschcowitz then gave a review of the literature on this subject.

Dr. MAX EINHORN said that he had been very much interested in the paper just read because he had paid considerable attention to this subject for some time and he had seen many patients with severe hemorrhages such as had been described and at operation nothing had been found to account for the condition. His cases, however, were only the exceptional ones where operation was required, but he had seen several of them. He reported the case of a lady who had been operated upon at the Mount Sinai Hospital one or two years ago. She had such severe hemorrhages that it was thought she should be operated upon. At operation nothing abnormal was found in the stomach. She made a good and complete recovery. But these cases did not explain to them that there was nothing present to account for these profuse, massive hemorrhages. Certain conditions should be borne in mind. One might be dealing with a hemorrhage due to a diapedesis from the gastric mucosa; there might again be an erosion in the stomach which led to an opening of a blood vessel. This was a condition described by Dieulafoy in which an artery was involved. And again there might be small ulcers present that were not discovered. Also there might be present ulcers which caused bleeding above or below the stomach; some might discharge blood into the esophagus. These were conditions which were not very frequent, but they might happen and should be borne in mind. In Dieulafoy's cases the symptoms of hemorrhage appeared in patients who were practically well. But the history of these cases did not separate those from gastric ulcer, cases in which there were no symptoms manifested before the hemorrhage. At operation they would find an ulcer anyway. Dr. Einhorn said he had been in Paris at the time when Dr. Dieulafoy spoke of a certain type of ulceration or erosion and brought out the point that in a great many instances they had to deal with some acute disease, such as pneumonia or appendicitis. Many of these cases were complicated by acute infectious diseases. They were accompanied with sudden and severe hemorrhages. What Dieulafoy had brought out tallied closely with the teachings of Rosenow to-day. In regard to the treatment Dieulafoy was of the opinion that all these cases should be operated upon, but Dr. Einhorn said he believed that many of these cases should not be operated upon in a hurry. If treated by rest and medical means there would follow a great percentage of cures, at least temporary cures. He believed that Dr. Moschcowitz would concur in his belief that in these massive hemorrhages four-fifths of the patients would recover if they were not interfered with. In closing Dr. Einhorn reported the instance of a lady who had these massive hemorrhages and severe pains. Because of the rise in temperature he was afraid of a perforation. However, operation was performed and nothing was found in the stomach to account for it. This patient died two days later, and what the real cause of her death was he did not know. No autopsy could be obtained.

Dr. RICHARD LEWISOHN said that he had been present at two operations performed by Dr. Moschcowitz when he had searched very carefully for the cause of the hemorrhage and could not find it. Hemorrhages might occur from small ulcerative processes. They all knew that at post-mortem examinations a very careful search of the organs of patients who had died from profuse hemorrhages of the stomach often failed to show the cause for the bleeding. There might be a small opening in one of the arteries in the arterial system in the stomach wall. Dr. Lewisohn referred to

one of the cases somewhat more in detail which had been reported by Dr. Moschcowitz. The patient was three years of age. On account of repeated profuse hemorrhages from the stomach transfusion was done four or five times, but the bleeding recurred time and time again; it happily stopped ultimately, so that the child was able to leave the hospital in apparently a normal condition. Since then examination showed that she had an enlarged spleen and he thought this was a possible cause of the hemorrhages from the stomach. The question as to what should be done in these cases was a difficult one to decide. Many of the patients made a good recovery and in a short time without surgical interference. As Kussmaul had stated, "these patients must be practically bled to death before they recover."

Dr. MOSCHCOWITZ closed the discussion. In answer to Dr. Lewisohn regarding the child who was two years and three months old and who was first admitted to the pediatric service of Dr. Koplik on April 24, 1914, with a profound anemia, a short systolic murmur at the apex, not transmitted, and a congenital dislocation of the left hip, etc., and who was discharged June 20 very much improved, but was readmitted on June 25, the physical examination revealed in addition to the previous findings and the anemia, a spleen which reached 1½ cm. below the free border of the ribs. He was quite in accord with the other remarks of Dr. Lewisohn, as Dr. Lewisohn described only a typical Dieulafoy's ulcer. Replying to Dr. Einhorn, he would say that all of the four reported cases were treated before the operation exactly by the method outlined by Dr. Einhorn. The treatment of gastric hemorrhages was not under discussion, but as the subject was mentioned, he would like to state that he was of the opinion that such treatment should be surgical; he saw no reason for the advice that gastric hemorrhages should be allowed to continue until the patient fainted from the loss of blood. As already stated, however, this was not under discussion, as it would be a topic sufficient unto itself.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

January 4, 1916.

ANATOMY.

1. Locate and explain the selective point for the withdrawal of cerebrospinal fluid.
2. Compare the general characteristics of the radius and ulna.
3. Define the different types of movable joint, giving illustrations.
4. Explain why "the clavicle is more frequently broken than is any other single bone in the body" (b) What influences the position of the outer fragment?
5. Describe formation and location of superficial and deep palmar arches.
6. Name branches and distribution of celiac axis.
7. Name and describe valves of the heart.
8. Describe the liver.
9. Give surface relations of the liver.
10. Name and describe the ligaments of the uterus.

PHYSIOLOGY.

1. Follow a molecule of sugar through the process of its digestion and tell what becomes of it in the body.
2. What is the physiological rôle of the adrenals? Name their secretion. What tissues depend most on this secretion?
3. What is the origin of the red-blood corpuscle, and what becomes of it?
4. Describe the physiological formation and uses of lymph.
5. Give a detailed description of the physiology of the liver.
6. Define secretion and excretion and give example of each.
7. Describe the physiology of the mammary glands.
8. What do you understand by cutaneous senses?
9. Give the functions of the cerebellum, the pons, and the medulla.
10. Give the nucleus of origin, the function, and distribution of the fifth cranial nerve (trigeminus).

CHEMISTRY.

1. What is meant by chemical incompatibility in medicine? Give example.
2. What chemical test will show the presence of alcohol?
3. Write the reaction which takes place when hydrogen peroxide comes in contact with pus or blood.
4. What is nitroglycerin? Write the formula.
5. What chemical test will detect albumin in urine? Explain the test.
6. What are the properties of bases?
7. What is a chemical antidote? Give two examples.
8. What is the difference between an oxidizing agent and a reducing agent?
9. What relation do amines or amides bear to alkalis?
10. Explain the formation of ammonia in urine.

TOXICOLOGY.

1. Give the possible sources, symptoms, and treatment of poisoning by phosphorus.
2. Name three indigenous poisonous plants. What are their symptoms?
3. Name two forms of fish poisoning.
4. Symptoms and treatment of snake venom.
5. Give the sources and symptoms of acute mercury poisoning.
6. Give the sources and symptoms of chronic mercury poisoning.
7. Sources, symptoms, and treatment of acute plumbism.
8. Sources, symptoms, and treatment of chronic plumbism.
9. Name two methods of rapidly emptying the stomach.
10. Differentiate between opium poisoning and three diseased states that resemble it.

PATHOLOGY.

1. Describe the pathology associated with cerebral apoplexy.
2. Describe injuries at the shoulder joint.
3. Describe pathology associated with pyloric stenosis.
4. Describe the pathology of pyelitis.
5. Describe the pathology of tumors of the bladder.
6. Define sapremia, septicemia, infarction, embolism, thrombosis.
7. Describe the pathology of gonorrheal arthritis.
8. Describe osteomyelitis of tibia.
9. Give the pathology of puerperal infection.
10. Give the pathology of carcinoma uteri.

ANSWERS.

ANATOMY.

1. Cerebrospinal fluid is withdrawn in the interspace between the third and fourth lumbar vertebrae. This interspace is wide, and is easily found, and the spinal cord terminates at the top of the second lumbar vertebra.
2. The *ulna* is the longer bone; it is larger at its upper extremity, it takes the chief part in the formation of the elbow joint. The *radius* takes a small part in the formation of the elbow joint; it is larger at its lower end, and it takes a large part in the formation of the wrist joint; the *radius* is also mainly responsible for the support of the hand.
3. *Types of movable joint.* (1) *Ginglymus*, a hinge-joint, which permits of considerable motion, but only in one plane, as the joint between the humerus and the ulna. (2) *Trochoid*, or pivot-joint, where the movement is limited to rotation, as the superior radio-ulnar articulation. (3) *Condyloid*, in which an ovoid head is received into an elliptical cavity, allowing of flexion, extension, abduction, adduction, and circumduction, as the wrist joint. (4) *Reciprocal reception*, or saddle-joint, in which the articular surfaces are concavo-convex, allowing of flexion, extension, abduction, adduction, and circumduction, as the carpo-metacarpal joint of the thumb. (5) *Enarthrodial*, a ball and socket joint, in which a globular head is received into a deep cup-like cavity, and allowing of flexion, extension, abduction, adduction, circumduction, and some axial rotation, as hip or shoulder joint. (6) *Arthrodial*, which permits of gliding movement, as the bones of the carpus on one another.
4. The clavicle is so liable to fracture, on account of its exposed position, and also because it is the only

bony connection between the upper limb and the trunk. In fracture of the clavicle, the *outer fragment* is displaced downward by the weight of the arm, forward by the action of the pectoral muscles, and inward because the clavicle normally keeps the shoulder away from the chest.

5. The *superficial palmar arch* is formed by the ulnar artery, and is completed by the ulnar artery anastomosing with a branch of the radial (superficial volar or princeps pollicis). It gives off the four digital branches. The surface marking is a line drawn transversely across the palm from a point where the web of the thumb joins the palm. The *deep palmar arch* is formed by the radial artery, and is completed by the radial artery anastomosing with a deep branch of the ulnar. Its branches are the palmar interosseous, perforating, and palmar recurrent arteries. The surface marking is a line drawn transversely across the palm, one-half inch nearer the wrist than the superficial arch.

6. The *branches of the celiac axis* are the gastric, hepatic and splenic. The *gastric* supplies the stomach, esophagus, lesser omentum and liver; the *hepatic* supplies the liver, stomach, pancreas, great omentum, duodenum, and gall-bladder; the *splenic* supplies the spleen, pancreas, stomach, and great omentum.

7. **VALVES OF THE HEART.** "The *mitral* and *tricuspid* valves are situated in the left and right ventricles respectively, at the auriculo-ventricular orifices, and prevent the passage of blood into the auricles during the ventricular systole. They consist of flaps or cusps, two in the mitral, and three in the tricuspid, connected by their bases to the auriculo-ventricular orifices; their free margins and lower surfaces give attachment to the chordæ tendineæ which connect them with the musculi papillares. They are formed of a duplicature of the lining membrane of the heart, strengthened by connective tissue. During the ventricular systole, the pressure of the blood in the ventricles presses their free edges, or rather their marginal surfaces, together, the musculi papillares regulating the tension of the chordæ and preventing the valves from becoming retroverted into the auricles.

"The *semilunar valves* guard the aortic and pulmonary openings. They consist of three semicircular folds attached by the convex margin to the wall of the artery at its junction with the ventricle, and are formed by a reduplication of the lining membrane strengthened by fibrous tissue. In the center of each free margin is a little nodule, the corpus Arantii, the three meeting in the centre when the valves are closed. On each side of the corpora Arantii is a thin semilunar marginal surface, where the fibrous tissue is absent, called the lunula; these surfaces come in contact when the valves close."—(Ashby's *Notes on Physiology*.)

The *Eustachian valve* is found in the right auricle, between the anterior margin of the postcava and the auriculo-ventricular orifice. It is semilunar in shape and is formed by a duplicature of the lining membrane of the auricle. The *coronary valve* is a semicircular fold of the lining of the membrane of the right auricle; it protects the orifice of the coronary sinus.

8. "The *liver* is the largest gland in the body, measuring in its transverse diameter from ten to twelve inches, and its anteroposterior six to seven, and its thickest part about three inches, and weighing about three to four pounds. It occupies the upper part of the abdominal cavity, and the right hypochondriac, epigastric, and a portion of the left hypochondriac regions. Its upper surface is convex and rests against the diaphragm and a small portion of the abdominal parietes in front. Its lower surface is in contact with the duodenum and stomach, the right kidney and suprarenal capsules, and the hepatic flexure of the colon. It is divided by the longitudinal fissure into the right and left lobes. The liver has five fissures, five lobes, five ligaments, five sets of vessels, and is inclosed in a fibrous coat, continuous at the transverse fissure with the capsule of Glisson. It is also invested by the peritoneum, except at the attachment of the coronary ligament." (Young's *Anatomy*.)

The *fissures* are: umbilical, of ductus venosus, of gall bladder, transverse, and for inferior vena cava.

The *lobes* are: right, left, caudate, quadrate, and spigelian.

The *ligaments* are: Falciform, 2 lateral, coronary, round and of ductus venosus.

The *vessels* are: Hepatic artery and veins, portal vein, and hepatic duct.

9. *Surface markings of the liver.* "Upper limit of right lobe—is along line from right fifth chondrosternal

articulation extending horizontally outward to a point about one inch below the right nipple, thence downward to the seventh rib at lateral aspect of chest. Upper limit of left lobe—along line from right fifth chondrosternal articulation extending across sternum slightly downward to a point about two inches to left of gladiolus, on a level with left sixth costal cartilage. Lower limit of right margin corresponds with line passing from behind forward about half inch below the lower margin of the right thorax to right ninth costal cartilage, thence obliquely across the subcostal angle to left eighth costal cartilage. Lower limit of left margin is represented by a curved line, with outward convexity, from left eighth costal cartilage to a point two inches to left of gladiolus and on a level with left sixth costal cartilage. Lower border of liver in middle line—about half way between xiphoid cartilage and umbilicus. Convex surface of liver on right side corresponds with seventh to eleventh ribs inclusive; and in front, with ensiform cartilage and sixth to ninth costal cartilages inclusive. Authorities differ considerably upon the relations of the liver to the thoracic wall." (Bickham's *Operative Surgery*).

10. The LIGAMENTS OF THE UTERUS are: (1) *Broad ligaments*, which extend outward on each side from the side of the uterus to the side of pelvis. (2) *Rectouterine ligaments*, which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments*, which extend from the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) *The ovarian ligaments*, which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) *The uterosacral ligaments*, which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroliac synchondrosis.

PHYSIOLOGY.

1. Sugar is taken up by the columnar epithelium covering the villi of the small intestine, and is carried by the blood stream of the portal vein to the liver; here it may be stored; it is carried by the blood around the body. The chemical changes which occur either in the blood or liver or other tissues are many: a molecule of dextrose gives rise to two molecules of glyceric aldehyde, each of these yields a molecule of lactic acid, the latter becomes pyruvic acid, which becomes acetaldehyde, which in turn becomes acetic acid, and this is oxidized to carbon dioxide and water, both of which are excreted.

2. The physiological role of the adrenals is the production of an internal secretion, called adrenalin or suprarenin, or epinephrin. This secretion causes constriction of arterioles, raises blood pressure, and stimulates muscle fibers which are supplied by the sympathetic system. There is supposed to be some connection between the adrenals and the thyroid and pituitary bodies.

3. In embryonic life the red blood cells are formed in the area vasculosa. Later on they are formed in the pulp of the spleen; in postnatal life they are formed in the red marrow of bone. They are broken down in the liver and spleen, and the hemoglobinaids in the formation of bile pigments and the pigment of the hair, skin, etc.

4. *Formation of lymph*: There are three main theories: (1) Ludwig's theory, or the filtration theory, coupled with osmotic changes between the lymph and blood; (2) Heidenhain's theory of lymphagogues; and (3) Starling's theory of the permeability of the capillary walls. The subject is covered up by E. A. Bainbridge as follows: "Lymph formation is not a secretory process, but is brought about by purely physical processes. The factors concerned are: (1) the capillary pressure, (2) the degree of permeability of the capillary walls, and (3) the metabolic activity of the tissues. There is no reason to suppose that in health the permeability of the capillaries alters, and therefore the formation of lymph is increased chiefly by variations in the first and third of these factors."

Function of lymph: (1) It conveys nutriment to all cells not directly reached by the blood; (2) in the intestines, it absorbs nutrient material (chiefly fat) and pours it into the blood stream for distribution; (3) it takes certain waste matters to the blood to be later eliminated by the lungs, kidneys, and skin.

5. "The liver plays an important part in the metabolism of all three classes of foodstuffs, especially in the

preliminary changes which they undergo after absorption. In the first place, it serves as a storehouse for glycogen, which it forms from the carbohydrate absorbed during digestion, and which it converts into dextrose and returns to the blood stream in order to keep constant the percentage of sugar in the blood. Secondly, it desaturates the fatty acids reaching it from the fat depots, and prepares them for the further metabolic changes which occur in the tissues. Thirdly, it removes the amino group from part of the amino-acids absorbed from the digestive tract, converting them into keto- or oxy-acids and transforming the ammonia thus set free, and also that reaching it from the portal vein, into urea." (Bainbridge and Menzies' *Essentials of Physiology*.) Other functions of the liver: Secretion of bile; conversion of hemoglobin into bile pigment; formation of uric acid, creatinin, and antithrombin, and production of heat.

6. *Secretion* is the process by which certain organs (glands and membranes) separate from the blood certain constituents which are further elaborated and serve some further office in the economy. *Example*, saliva.

Excretion is a similar process by which there are removed from the blood waste materials, and products of no further use to the body, and which if retained would be injurious. *Example*, urine.

7. "The mammary gland consists of a number of lobules embedded in fat and areolar tissue. Each lobule is composed of alveoli lined by columnar epithelium, resting on a basement membrane. The ducts open on to the nipple, and are lined by cubical epithelium; their walls are said to contain unstriated muscular fibers. During the secretion of milk the superficial part of the cells, which contain fat globules and secretory granules, disintegrates and is cast off to form part of the secretion; during the periods of rest the cell substance is reformed. The development of the mammary gland during pregnancy is brought about by the influence of hormones derived from the reproductive organs. In the earliest stage of pregnancy a hormone appears to be formed in the corpus luteum, and if a Graafian follicle is artificially ruptured in an animal the mammary glands develop for a short time apart from pregnancy. Later, another hormone is possibly formed by the fetus itself, since it has been shown that injection of an extract of fetal tissue into a virgin rabbit leads to growth of the mammary glands. That their development is due to chemical and not to nervous influence is further indicated by the fact that, even after the severance of all nerves to the mammary gland, it undergoes normal development during pregnancy." (Bainbridge and Menzies' *Essentials of Physiology*).

8. *The cutaneous senses* include the senses of touch, pressure, warmth and cold, which were all formerly summed up under the general term, "sense of touch."

9. *The functions of the cerebellum* are: Co-ordination of muscular movements, and maintenance of equilibrium.

The function of the pons is to provide a bridge along which impulses may travel to and from the cerebrum.

The functions of the medulla oblongata are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of coordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

10. **FIFTH PAIR OF CRANIAL NERVES.** *Origin*: Superficial, from side of pons Varolii; deep, from medulla, and floor of fourth ventricle. *Distribution and functions*: First, ophthalmic; sensory to anterior half of scalp, conjunctiva, and skin of upper eyelid, cornea, skin of nose, mucous membrane of nose, lacrymal gland. Second, superior maxillary; sensory to conjunctiva and skin of lower eyelid, nose, cheek, upper lip, palate, upper teeth, and alveolar processes. Third, inferior maxillary; sensory to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower lip, teeth and alveolar processes of lower jaw. It is also motor to the muscles of mastication (temporal, masseter, two pterygoids), mylohyoid and anterior belly of the digastric.

CHEMISTRY.

1. By *incompatibility* is understood the simultaneous administration or combination of substances not suitable for such combination. *Physiological incompatibility*

occurs when two remedies are thus administered which offset each other's physiological action, so that they are inert. *Chemical incompatibility* occurs when remedies which are mixed together undergo chemical decomposition or explosion.

The following prescription shows chemical incompatibility:

℞ Ammonii carbonatis 5j.
Syrupi tolutani,
Syrupi scillae aa 3iv.
Aque q. s. ad 5vj. M.

Sig. Take half an ounce every four hours.

In this prescription, the syrup of squill contains free acetic acid, and this acting on the ammonium carbonate produces effervescence and forms ammonium acetate. If the prescriber intended this, the prescription is not considered incompatible.

2. *Test for alcohol.* If alcohol is heated with a small quantity of solution of potassium dichromate, and acidulated with dilute sulphuric acid, the mixture acquires an emerald-green color, and the peculiar fruity odor of aldehyde is evolved.

3. In the presence of pus or blood hydrogen peroxide is decomposed into water and oxygen: $2\text{H}_2\text{O}_2 = 2\text{H}_2\text{O} + \text{O}_2$.

4. *Nitroglycerin* is, chemically, trinitroglycerol or glycerol trinitrate; it is also called glonoin. The formula is $\text{C}_3\text{H}_5(\text{NO}_3)_3$.

5. *The heat and nitric acid test for albumin in the urine:*

"The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered faintly acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3 .

"Albumin is soluble in alkaline liquids. The urine is therefore rendered acid, to prevent small quantities of albumin remaining in solution upon the application of heat, and thus escaping detection. Albumin is also slightly soluble in dilute HNO_3 , therefore acetic acid is used. It is also soluble in a large amount of acetic acid, therefore the addition of acetic acid should be limited to the amount necessary to produce an acid reaction. A urine rich in earthy phosphates deposits, on boiling, a precipitate closely resembling that of coagulated albumin, therefore HNO_3 is added after heating. It dissolves the phosphates, but does not affect the albumin. Nitric acid cannot be used alone as a test for albumin, because, if the urine contain an excess of urates, these are decomposed upon the addition of acid, and the almost insoluble uric acid is precipitated, and might easily be mistaken for albumin."—(Witthaus' *Essentials of Chemistry*.)

6. *Properties of bases:* They have an alkaline taste, and a soapy feel; when acted upon by an acid they form a salt and water; in strong solutions they are corrosive.

7. *Chemical antidotes* act as such by uniting chemically with the poison and thus converting it into a harmless or insoluble compound. *Examples:* Salt with silver nitrate; magnesium sulphate with lead.

8. An *oxidizing agent* is a substance which is able to give up oxygen to other substances.

A *reducing agent* is a substance which is capable of removing oxygen from a compound.

9. The liquid, volatile alkaloids are amines; the solid alkaloids are amides.

10. *Ammonia in the urine.* "Ammonia is produced in the body as the result of protein catabolism, and most of it is converted into urea. Some, however, is used to neutralize the acids which circulate in the blood, and so the body is protected against "acidification." The excess of ammonia salts so produced appears in the urine, so that, to a certain extent, the amount of ammonia in the urine is an index of the amount of acid in the circulation."—(Lyle's *Physiology*).

TOXICOLOGY.

1. *Poisoning by Phosphorus.* *Sources:* Acute, from ingestion of poisonous doses of phosphorus, or match heads or rat poison; and chronic, affecting those who are employed in the manufacture of matches. *Symptoms of acute phosphorus poisoning:* "Eruption of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours, pain in the throat, a

sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies."—(From Witthaus' *Essentials of Chemistry and Toxicology*.) *Treatment:* By an emetic or the stomach tube remove from the stomach all of the poison which has not been absorbed; then give old French oil of turpentine or potassium permanganate; the food must be free from fats and oils.

2. *Three indigenous poisonous plants:* Aconite, tobacco and stramonium.

Symptoms of poisoning by aconite usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

Symptoms of poisoning by tobacco: Weakness, nausea, vomiting, giddiness, cold and clammy skin, rapid pulse, dyspnea, and extreme depression.

Symptoms of poisoning by stramonium: Dryness of the throat, thirst, difficulty of deglutition and spasms upon swallowing liquids, face at first pale, afterwards highly reddened, pulse extremely rapid, eyes prominent, brilliant, with widely-dilated pupils, complete paralysis of accommodation, disturbances of vision, attacks of giddiness and vertigo, with severe headache, followed by delirium, occasionally silent or muttering, but usually violent, noisy, and destructive, accompanied by the most fantastic delusions and hallucinations. Usually the urine is retained, and the body temperature is above the normal. The delirium gradually subsides, and the second stage, that of coma, is established, with slow, stertorous respiration, and gradually failing pulse, until death occurs from respiratory or cardiac paralysis, or sometimes in an attack of syncope during apparent amelioration.

3. *Two forms of fish poisoning:* Poisoning by a species of tetradon, and by mussels.

4. *Symptoms of snake venom:* Intense shock, severe pain in part bitten, area of pain rapidly increases, local partial paralysis, intense swelling of the injured part which later becomes livid and gangrenous, fainting, vomiting, small frequent and irregular pulse, hemorrhages, bloody stools and urine, lethargy, difficult respiration, convulsions and death.

Treatment: Thoroughly suck or cup the wound; cauterize or excise the part; subcutaneous injection of potassium permanganate; iodine locally; antivenene; coffee; stimulants; electricity; keep the patient warm and quiet; transfusion of blood, or intravenous injection or normal salt solution.—(From Brundage's *Toxicology*.)

5. *ACUTE MERCURIAL POISONING.* *Source:* Ingestion of calomel, corrosive sublimate, or other mercurial preparations; external application of mercurial ointment. *Symptoms:* A burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; bloody stools, also salivation may occur.

6. *CHRONIC MERCURIAL POISONING.* *Source:* Certain occupations in which mercury is used (such as silvering of mirrors). *Symptoms:* Teeth tender and becoming carious, ulcerations of mouth, anemia, tremor or palsy, slow pulse, an eczematous eruption.

7 and 8. The most common sources of lead poisoning are the following: "The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead.

The symptoms of acute lead poisoning are: "Metallic taste; dryness of the throat; thirst; severe colicky ab-

dominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions; and tetanic spasms."

APOPLECTIC COMA.	UREMIC COMA	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pin-point size.
Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia with convulsions on one side.			

The treatment of acute lead poisoning consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesium is also useful. It should be preceded by an emetic, or by the use of the stomach tube."—(Witthaus' *Essentials of Chemistry*.)

Chronic lead poisoning: "The early symptoms are often very obscure. Various symptoms of indigestion are first noticed with progressive emaciation and mental depression, with anemia and a peculiar whiteness of the skin probably due to contraction of the peripheral capillaries. Sometimes a blanching of the fundus of the eye or amaurosis due to a similar contraction of the capillaries is an early symptom. Then a twisting, grinding pain around the umbilicus comes on and gradually becomes more severe. It may be relieved by pressure. The abdomen is hard and restricted. As a rule the bowels are obstinately constipated, but occasionally there may be scanty, hard, clay colored, painful evacuations. The urine is diminished or suppressed, the skin sallow, cold, and clammy, the breath fetid, mouth and throat dry, and a blue line on the edge of the gums next the teeth, most noticeable next to the incisors, which are discolored and brown. This blue line may be developed as early as three days after ingestion of the poison. The gums are tender and bleed easily. The pulse is generally decreased in frequency. As the case progresses, or after repeated attacks, paralysis begins to appear, affecting chiefly the extensor muscles of the forearm, though not limited to them, sometimes extending to the interossei, and generally affecting first those muscles which are most imperfectly supplied with blood. The paralysis is symmetrical, generally affecting the corresponding muscles in both arms, and is often preceded by numbness of the fingers and hands. The affected muscles become more or less atrophied, leading to general debility ("lead palsy"). The nervous system becomes affected, and headache, vertigo, amblyopia, amaurosis, delirium (sometimes furious) and epileptoid convulsions precede death. Albuminuria is frequently, and jaundice occasionally, present. In many cases severe pain in the joints is one of the most prominent symptoms, probably due in some manner to interference with the functions of the kidneys.

Treatment: "For the removal of lead from the tissues with which it has entered into a more or less stable combination potassium (or sodium) iodide in doses of 10 grains three times a day has long been recognized as one of the best. It is but just to say that its efficacy has recently been called in question by some of our best clinicians. Warm sulphur baths have been found useful. Atropine or morphine and atropine may be given hypodermically for relief of the colic. Cocaine hypodermically has also been successfully used to relieve both the pain and constipation. Calomel and gamboge, castor oil, or olive oil, may be given to overcome the constipation. Belladonna or hyoscyamus may be added with advantage to either of the cathartics. Alum sometimes acts well as a cathartic in these cases. As a prophylactic measure tea as a drink and a dose of sulphur occasionally, both act by precipitating lead from solution."—(Riley's *Toxicology*.)

9. *Two methods of rapidly emptying the stomach:* (1) The use of the stomach tube; (2) hypodermic injection of apomorphine hydrochloride, gr. 1/10.

10. The following table (from Eisendrath's "Surgical Diagnosis") gives the diagnosis:

PATHOLOGY.

1. In *cerebral apoplexy* "the internal capsule is almost always involved. The pons is quite frequently the seat of hemorrhage, and occasionally the cerebellum, but very rarely the medulla. The size of the involved area depends upon the amount of blood extravasated and upon the density of the tissue. It is more diffused in the white than in the gray matter. The effects of the hemorrhage may be primary or secondary. Primary effects are tearing and compression of the brain-substance. If the patient does not immediately die, softening occurs. As a result of the staining by the retained hemoglobin the area is known as red softening.

Shortly after the blood escapes it undergoes coagulation, forming a cerebral hematoma. This acts as a foreign body and sets up an inflammatory reaction, with more or less hyperplasia of the surrounding neuroglia. The fluid portion finally becomes absorbed, the corpuscles broken down, and the pigment liberated, which stains the walls of the cavity. Occasionally a cyst filled with a clear fluid may form. If all fluids are absorbed, the walls of the cavity may come in contact and a scar result.

Other primary effects are distant ones in the form of paralysis, both motor and sensory, and generally on the side of the body opposite to the seat of the hemorrhage. Although there may be a considerable return of the lost faculties, yet in a majority of cases permanent damage is done. This is due to the secondary effects—the *secondary degenerations*. These are systemic, and follow the directions of the nerve impulses. The commonest degeneration is one of the pyramidal tracts. The optic tract and fibers from the temporo-sphenoidal area may also be involved. In the brain there is finally loss of nerve-cells, without, however, destruction of the neuroglial fibers."—(From McConnell's *Pathology*.)

2. The commonest injury of the shoulder joint is dislocation. When this occurs there may be rupture of ligaments, muscle fibers, nerves and vessels; the joint and neighboring tissues are infiltrated with blood; if the dislocation is reduced promptly, the blood is absorbed and repair is brought about by proliferation of connective tissue.

If the dislocation is not reduced within a certain time, the tissues that are pressed upon by the bones may atrophy; the articular end becomes covered with connective tissue derived from the lacerated capsule, the cartilage becomes fibrillated, and new bone may be formed; these various changes may be followed by ankylosis or may result in periostitis.

3. *Pathology of congenital pyloric stenosis:* "The essential lesion is the thickening of the pyloric ring from hyperplasia of the circular muscular fibers. The pyloric canal assumes a funnel shaped or a cylindrical form, hard and incompressible. On section its walls are thick and dense. The pyloric orifice may be so contracted that only the passage of a fine probe is possible. The duodenal end of the pylorus projects into the

duodenum, and suggests the appearance of the cervix uteri projecting into the vagina. The mucous membrane of the pyloric canal usually shows one large, single, longitudinal reduplication with many smaller parallel folds. This longitudinal reduplication or projection of the mucous membrane still further increases the stenosis. The muscular hyperplasia fades gradually away on the stomach side of the pylorus, but terminates rather sharply at the pyloric ring, although it is possible for muscular hypertrophy to extend outward a short distance into the duodenum. The longitudinal fibers are but little affected, although in a few instances the muscular layer shares to a small degree in the hyperplastic process. The stomach itself is usually dilated. Its wall in the pyloric half shows evident muscular hypertrophy, which fades away toward the fundus so that the wall of this latter portion of the stomach is of normal thickness, or may even be thin."—(Lockwood's *Diseases of the Stomach*.)

4. *Pathology of pyelitis*.—"A diffuse inflammation spreads upward from the pelvis of the kidney along the straight tubules. It may lead merely to formation of fibro-cellular tissue, or there may form small abscesses, cylindrical in the medullary, more spherical in the cortical portion, which show as streaks and points of pus when the gland is cut. Taken alone the latter are indistinguishable from the minute abscesses of pyemia. Sometimes a large collection of pus, even 3 or 4 pints, forms in the pelvis of the kidney. Such a collection distends the pelvis and the capsule of the kidney, dilates the calyces, and flattens the renal tissue against the circumference, while coincident nephritis reduces it to fibrous tissue. Septa remain to mark the divisions between the calyces, and the whole organ forms a large loculated abscess. In the abscess cavity stones are often found. Bacterial decomposition of the urea sometimes renders the urine alkaline, and then phosphatic concretions will form on the wall of the renal pelvis, or on the stones."—(From Bain's *Medical Practice*.)

5. *Tumors of the bladder*.—"Polypoid thickenings of the mucosa are quite frequently found in chronic inflammations of the bladder. *Fibromata* generally appear as small villous outgrowths, covered by epithelium; they are very vascular and may give rise to such considerable hemorrhage that grave or fatal anemia ensues. Occasionally bits of the papillary growths may break off and be passed through the urethra or they may be large enough to cause obstruction. These tumors are benign, but there is a possibility of their becoming malignant. True connective-tissue tumors, particularly sarcoma, are rare. *Carcinoma* in the form of a squamous epithelioma is an infrequent primary tumor. It occurs as a cauliflower mass that frequently undergoes ulceration. The neighboring organs are generally involved by contiguity. Secondary *carcinoma* may follow malignant disease of the sexual organs, of the rectum, or of the prostate by direct extension. The bladder is very rarely the seat of a metastatic growth. Cysts are very infrequently found."—From McConnell's *Pathology*.)

6. *Sapremia* is the condition due to the absorption of putrescent substances, but not of the microorganisms which cause them.

Septicemia is the presence in the blood of microorganisms (usually pyogenic) but without the development of metastatic abscesses.

Infarction is the plugging up of an end artery and so causing an area of degeneration.

Embolism is the obstructing of a blood vessel by the lodgment of a foreign body.

Thrombosis is the coagulation of blood within the vessels during life.

7. *Gonorrhea arthritis*.—"One or several joints may be involved, generally the former, the knee, ankle, and wrist being most frequently affected. The inflammation may be acute or chronic, and varies in extent as well as in degree. Although the synovial membrane alone may be involved, the ligaments and periarticular structures are very apt to be thickened and infiltrated. Except in the mildest cases, the pain is severe and there is fever. Suppuration may occur, and ankylosis is very prone to follow even the milder cases."—(Stewart's *Surgery*.)

8. *OSTEOMYELITIS OF TIBIA*. *Pathological Changes*: "The area of the medulla affected becomes hyperemic; exudation occurs in the cancellous spaces, Haversian canals, and under the periosteum. Pus soon forms in these three situations. If the disease begins in the superficial part of the bone, the pus may only be sub

periosteal, the deeper part of the bone escaping, though large areas of the superficial portion may die from the combined action of (1) stripping up of the periosteum by the pus, (2) strangulation of the vessels in the bone by the pressure of the exudation, and (3) the toxic action of the bacterial products. . . . When the disease begins in the deeper layers of the bone, the pus may reach the periosteum, or extend along the medullary cavity, so that the veins become filled with septic thrombus, which may be disintegrated and carried off as septic emboli (pyemia). There is profound toxemia, and necrosis of the whole diaphysis may occur. . . . If the infection is mild, a chronic abscess may be formed in the cancellous tissue. The usual course of an acute case, if a patient survives, is that there is some necrosis of the shaft of the bone. The abscess bursts externally, and there are numerous openings in the skin leading through openings (cloacæ) in the periosteum and involucrum down to the sequestrum. The sequestrum becomes loose in six weeks to six months."—(From *Aids to Surgery*.)

9. *Pathology of puerperal infection*.—"As a result of injury to the uterus or vagina during or after delivery and the action of bacteria which may gain access to the tissues in this vulnerable state, the puerperal uterus is liable to become the seat of a series of severe and often destructive inflammatory and necrotic changes. These may be confined to the uterus; they may induce serious alterations in surrounding parts; they may lead to an involvement of the peritoneum or to septicemia or pyemia and its accompanying lesions in the most distant parts of the body. In some cases a more or less extensive gangrenous inflammation of the mucous membrane and the underlying parts may lead to the casting off of larger and smaller shreds of necrotic tissue and the formation of deep and spreading ulcers, which may be accompanied by severe parametritis and fatal peritonitis.

In other cases the inflammation is membranous and may affect the vagina, leading to necrosis, gangrene, ulceration or peritonitis. In connection with either of the above forms of inflammation, or without them, there may be thrombosis of the uterine sinuses, purulent inflammation of the veins, suppuration and abscess in the uterine wall, suppurative inflammation of the ovaries and tubes, and, owing to the generalization of the infectious material, metastatic abscesses in the lungs, spleen, kidneys, etc. Or acute pleurisy, ulcerative endocarditis, erysipelas, purulent inflammation of the joints, hyperplastic swelling of the spleen and lymph-nodes, thrombosis or thrombo-phlebitis of the saphenous veins, etc., may follow. In some cases which rapidly pass to a fatal termination the local lesions may be but slightly marked and general alterations characteristic of pyemia, such as metastatic abscesses, etc., be entirely wanting. Death is, in such cases, apparently, due to toxemia or septicemia."—(Delafield and Prudden's *Pathology*.)

10. *Pathology of carcinoma of the uterus*.—"Cancer of the body of the uterus occurs in less than 2 per cent. of all cases. It is more frequent in nulliparæ than carcinoma cervicis, and tends to occur rather later in life than cancer of the cervix. The disease begins superficially or deeply in the mucosa. Epithelioma, malignant adenoma, adenocarcinoma, and pure carcinoma are found, the latter being of the scirrhous or medullary type. In the malignant adenoma there is an atypical proliferation of the glands; they become folded up irregularly; the intervening connective tissue may be very scant, and the gland spaces may touch at points. They are lined with a single layer of columnar epithelium.

In the adenocarcinoma, parts may show the structure of the malignant adenoma, and parts that of the ordinary cancer where the loculi are filled with epithelial cells. These growths form swellings in the wall. When near the cavity, the mucosa may ulcerate over them. Gradually the uterus becomes excavated. Adhesions may form with adjacent structures, and secondary deposits develop in the peritoneum, ovaries, tubes, vagina, etc. The epithelioma may grow diffusely through the whole cavity, or as an isolated fungoid growth, which may become polypoidal. Metastatic nodules may form in different parts of the uterine wall. These tumors are covered with layers of polyhedral cells; very rarely pavement epithelium is found like that in ordinary epithelioma. The mucosa of the body gets thinned."—(Webster's *Diseases of Women*.)

(To be concluded.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	W. H. Sanders, Montgomery	Montgomery... July 11
Arizona*	J. W. Thomas, Phoenix	Phoenix... July 4
Arkansas	T. J. Stout, Brinkley	Brinkley... May 9
California	C. B. Pinkham, Sacramento	Sacramento... June 27

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Therapeutic Hints.

Myocarditis.—In the stage of insufficiency, J. M. Anders recommends the observance of absolute rest and in suitable cases the administration of the following:

R Strychninæ, gr. 1/5.

Sparteini sulphatis, gr. ij.

Caffeinæ citratis, gr. xvi.

M. et div. in pil. No. VIII.—*Penn. Med. Journal.*

Grippal Colds.—Dr. Beverley Robinson recommends the following as a safe and efficient remedy in the treatment of influenza and grippal colds:

R Caffeinæ, gr. v.

Ammonii salicylatis, 3i.

M. et div. in capsulas No. XX. Sig.: Two of these capsules should be taken by an adult, every two hours, for four or five doses, and then every three or four hours. If the capsules cause slight nausea, which is rare, this may be relieved by drinking a little vichy with each dose.—*N. Y. Med. Jour.*

Hemoptysis.—

R Pulveris ipecacuanhæ et opii, gr. xx.

Aluminis, gr. lx.

Sacchari, gr. xxx.

M. et div. in chart No. VI. Sig.: One powder every 4 to 6 hours to a child of one to two years.

Dutch Buttermilk.—Let one quart of milk stand in a warm place till it is thick. Put it in the butter churn and churn for 20 minutes. Put in a saucepan 1 heaping tablespoon flour, and 1 heaping tablespoon granulated sugar. Mix them well, then add slowly the contents of the churn. Put the saucepan on a good fire and stir till the milk boils. Then take it off. Put in a bottle as much as baby will take. For young baby dilute with water, but as soon as able leave water out. Feed as warm as possible.—Edward A. Keller.

Herpes Genitalis.—Queyrat recommends the following:

R Mentholi, gr. x.

Guaiacolis, gr. x.

Zinci oxidi, dr. 1½.

Unguenti aquæ rosæ, oz. 2.

M. et div. fiat unguentum.—*Paris Médical.*

Acid Dyspepsia in Infants.—

R Pulveris ipecacuanhæ, gr. i.

Pulveris rhei, gr. iv.

Sodii bicarbonatis, gr. xxiv.

M. et div. in chart No. XXIV. Sig.: One powder every four to six hours to a child of one to two years.

Myalgia.—

R Tincturæ aconiti

Tincturæ iodi, āā 5ij.

Tincturæ opii, 5iv.

Linimenti chloroformis, 5iij.

M. Sig.: For external use.

Seasickness.—

R Hyoscyaminæ

Strychninæ, āā gr. ss.

Extracti gentianæ, gr. xx.

M. et div. in pil. No. XI. Sig.: One pill every 10 minutes for 1 hour, then every 20 minutes.

Facial Erysipelas.—Nobécourt claims to have obtained excellent results in the treatment of this condition by the continued application of a 5 per cent. solution of methylene blue. The solution is applied by a camel's-hair brush or a cotton swab to the diseased surface and for an inch beyond on the surrounding healthy tissue. The application is renewed twice daily, morning and night.—*Journal de Médecine.*

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

VITAL FUNCTION TESTING METHODS AND THEIR INTERPRETATION. By WILFRED M. BARTON, M.D. Published by Richard G. Badges, Boston. 255 pages. Price, \$1.50.

ENDEMIC DISEASES OF THE SOUTHERN STATES. By WILLIAM H. PLATTNER, M.D., and LLOYD THOMPSON, M.D. Published by W. B. Saunders Company, Philadelphia & London; 546 pages; with 117 illustrations. Price, \$5.00 (cloth); \$6.50 (Half Morocco).

A TREATISE ON MEDICAL PRACTICE. By OTTO JUETTNER, A.M., Sc.M., Ph.D., M.D. Published by A. L. Chaterton Company, New York; 519 pages. Price, \$5.00.

YEAR BOOK OF PHARMACY. Published by J. & A. Churchill, London. 512 pages.

CHRONIC TRIGONITIS.

By H. W. E. WALTHER, M.D.,

NEW ORLEANS

CLINICAL ASSISTANT IN GENITOURINARY AND VENEREAL DISEASES,
TULANE UNIVERSITY OF LOUISIANA, SCHOOL OF MEDICINE;
ATTENDING UROLOGIST, PRESBYTERIAN HOSPITAL, VISIT-
ING GENITOURINARY SURGEON, CHARITY HOSPITAL.

A REVIEW of the more recent text-books on genito-urinary surgery will show that the subject of inflammation of the trigone of the urinary bladder has been totally ignored. J. W. Thompson Walker¹ has recently called attention to the fact that in the majority of cases of cystitis the inflammation does not affect the whole surface of the bladder mucous membrane, but involves most frequently the base (trigone) while the rest of the bladder escapes. Follen Cabot,² in his monograph on disorders of the bladder, contends that this subject has never received the attention it deserves. The European writers have contributed the most valuable descriptions we have concerning this disease.

Of the synonyms under which chronic trigonitis has been described might be mentioned cystitis colli vesicæ, cystitis papillomatosa, "irritable bladder," cystitis colli proliferans edematosa and cystitis colli proliferans s. vegetativa.

Knorr,³ in 1900, was the first to accurately describe chronic trigonitis. In his first paper he reported thirty cases and the description of the symptomatology and pathology of this disorder as given by him are so complete as to leave little for others to describe. The second contribution of Knorr⁴ to this subject appeared five years later, in which he reiterated and further confirmed his opinions as laid down in his earlier writings. Zuckerandl,⁵ Winter,⁶ Heymann,^{7,8} Gorodistsch,⁹ and Zechmeister and Matzenauer¹⁰ have been among the most prominent German writers to contribute to the subject. Stoeckel,¹¹ in his monograph on cystoscopy, gives a very accurate picture of the disease.

Of our own writers, Garceau¹² has perhaps given us the best and most complete description of chronic trigonitis to be found in American literature. Pilcher¹³ in his excellent work on cystoscopy gives a very graphic description of chronic trigonitis, and closes his remarks on the subject by stating that "many cases of chronic cystitis resolve themselves into chronic trigonitis." Farniss¹⁴ has recently stated that about 30 per cent. of the cases seen in the gynecological department under his care complain of some disturbance of urination, either alone or in association with diseases of the genital organs, and of these fully 90 per cent. have cystitis colli or trigonitis. Cary¹⁵ and Sommer¹⁶ have also added to the valuable literature on this subject. Cary states that "one of the most frequent causes of bladder irritability in women is

chronic, local cystitis involving the trigone," and on the same subject Sommer says "there is a large class of sufferers in whom the affection (chronic trigonitis) is limited to the bladder neck and adjacent trigone."

Anatomy.—The floor of the urinary bladder is divided, arbitrarily, into two main parts, viz., the anterior and posterior segments, the anterior half being known as the trigonum and the posterior half being known as the bas-fond or fundus. Only the anterior or trigonal portion will be considered here.

The boundaries of the trigone are formed by the two ureteric ostia and the internal vesical sphincter. The base line of the trigone (2 to 2.5 cm. in length) being a slightly elevated ridge extending from one ureteral orifice to the other is known as the ligamentum interuretericum, the muscle band of Bell or the bar of Mercier. It is this bar which furnishes such material aid to the beginner in cystoscopy in finding the orifices of the ureters. The lateral boundaries (1.8 to 2.5 cm. in length), leading up to the apex of the triangle, are formed by lines from the ureteral orifices to the internal vesical sphincter.

Fenwick describes this triangular area in the bladder as smooth and of a dull red appearance, very sharply marked off by this color from the yellow, sandlike shore of the adjoining posterosuperior and lateral walls. It is to be recognized by its well-defined area, its slight elevation from the rest of the vesical mucosa and its characteristic color. The area of the trigone may present slight differences in the male and female. The prostate gland in the male causes a fairly even prominence, although this may be absent, while in the female there is a prominence due to the cervix, with rather deep lateral recesses to either side.

Pathology.—The bladder changes in chronic trigonitis are confined chiefly to the trigonum vesicæ, although it is rare to find the internal vesical sphincter and posterior urethra totally free from involvement in the process. In the beginning nothing more than an intense redness of this part of the bladder may be noted. At times it may be difficult to differentiate this stage of true inflammation from simple hyperemia of the trigone. The intense redness is seen to extend at times beyond the confines of the trigone proper, and may be seen in spots or splotches adjoining the trigonal border. Engorgement of the capillary vessels is early noticed. Later, as the process advances, besides the deep scarlet color, the mucosa becomes swollen from edema and rises up here and there quite sharply from the remaining surface and takes on a spongy, woolly or cumulus appearance. Later the mucous membrane is thrown up into stiff folds or ridges, with occasional shreds of muco-pus or desquamated epithelium adhering to it. Bierhoff,¹⁷

in particular, has drawn attention to this particular inflammatory thickening of the epithelium which rise above the trigonal surface and appear cystoscopically as miniature polypi or villi. At times it is impossible to differentiate between this pseudopolypoid growth and true papillomata of the bladder. Bierhoff has seen cases where these polypi cover the entire surface of the trigone. Ulcers are not commonly seen, as is shown by the report of Knorr, who, in thirty cases of chronic trigonitis, found but one case with an ulcer. Occasionally varices, erosions, and petechiæ are observed, and when seen probably account for the hematuria in some of the cases of trigonitis. These spots will bleed with the slightest instrumentation.

Marked changes of the vesical sphincter accompany the trigonal inflammation, of which loss of contour, swelling and blanching are the most noticeable. Excrescences may be seen about the sphincter as above described on the trigone, and at times reach large dimensions. Garceau speaks of one of his cases, where a polyp grew just outside of the sphincter in the urethra, which gave rise to much pain during micturition and was the cause of long-continued partial incontinence. Legueu²¹ speaks of vesicles or tiny cysts of the trigone and urethral orifice often seen to accompany this condition. Zachmeister and Matzenauer affirm that intense injection of the posterior urethra constantly accompanies chronic trigonitis.

Microscopically Garceau has found the inflammatory changes to be subepithelial in character. In a case of his, small massed collections of lymphocytes forming an area similar to lymphoid tissue, and a few lymphocytes in the stratified epithelium were found. In addition, pathogenic organisms were always found.

Etiology.—The cause of this disease has been divided by most writers into two classes, viz., (a) those in which there has been a primary infection, and (b) those in which the infection has, secondarily, become engrafted upon a simple hyperemia of the trigone due to the engorgement of these parts accompanying some pelvic disorder. The commonest cause of primary infections is, undoubtedly, uncleanly and rough catheterization or other instrumentation of the bladder. Trigonitis is much more prevalent among women than among men. Of the infections caused secondarily to some other condition, Peyer, Winter, and Guterbock classify the etiological factors under three groups, namely: (1) urethral, (2) vesical, and (3) perivesical.

1. Urethral. Urethritis, fissure of urethra, condylomata, urethral caruncle, malignant tumors, periurethral processes.

2. Vesical. Cystitis, hyperemia, varices, tumors, foreign bodies, ulcerations, vesical atrophy, trauma.

3. Perivesical. In the female: uterine tumors, pregnancy, malpositions of uterus, new growths of the cervix uteri, exudates, parametritis, perimetritis, metritis, salpingitis, ovaritis, hematocele, pelvic abscess, pelvic peritonitis, cellulitis, extra-uterine pregnancy, vulvitis, colpitis and intestinal changes.

In the male inflammations or new growths of the prostate, seminal vesicles, vas deferens, testis or epididymis, and intestinal or pelvic gland changes. These latter (perivesical) causes usually bring the infection to the vesical trigone through the hematogenous or lymphogenous routes.

The bacteriology of chronic trigonitis varies dur-

ing the course of the disease. In some cases very little if any organisms are ever seen upon microscopical examination of centrifugalized specimens of the urine. Bierhoff²² has reported fifty-seven such cases observed by him in the Berlin General Polyclinic, in which the urines were repeatedly found bacteria-free, in whom he found epithelium, pus and blood cells—often in excess—and upon cystoscopy found only the trigone of the bladder the seat of any demonstrable inflammation. In none of these cases did he find a tuberculous bladder. Byford²³ calls attention to hyperacidity, the result of faulty metabolism, as the probable causative factor for the persistence of trigonal inflammations of this type, and makes a plea for medical (dietary) treatment of these cases in conjunction with the local treatment. Kelly²⁴ has also found hyperacidity a factor in trigonitis.

However, when bacteria are present one will at times encounter a mixed infection at one examination and at another time the urine of the same case shows a pure culture. There is a tendency for one bacterium to predominate, while the other organisms will be noted in very small numbers. The colon bacillus is the most frequent offender. Staphylococci, streptococci, gonococci, proteus, pneumococci, bacillus pyocyaneus, typhoid bacillus, and pseudodiphtheria have been among the other organisms noted.

Symptomatology.—Chronic trigonitis is always ushered in with a marked diurnal frequency of urination. At the start this frequency may be painless, but as time elapses the patient will complain of pain during the act of micturition, and this symptom is accompanied by urgency and tenesmus. At this later stage the frequency becomes nocturnal as well as diurnal, and pain over the suprapubic region and the urethra may be complained of. In rare instances one will see a case with no pain whatever, and the only symptom which brings them seeking relief is the frequent urgent desire to void urine. Hematuria is often marked to the degree of being noticeable to the eye—at times frankly blood red in color. Cloudy urine, due to the bacterial, pus, blood and epithelial content is also commonly observed, although clear urine (to the eye) is seen at times in these cases, and here it requires the assistance of the centrifuge and microscope to make the diagnosis. Seventeen out of the thirty cases found by Knorr had clear urines. Garceau has pointed out that the absence of pus or other cellular elements in the urine has thrown many off the track in the diagnosis, and these cases are then erroneously considered neuroses. Chronic trigonitis does not commonly cause febrile reactions or constitutional symptoms unless the true causative factor be a constitutional disorder.

My experience with cases of chronic trigonitis has convinced me of the fact that the symptom which gives the patient the most trouble is the marked, uncontrollable frequency and urgency of urination, which will always be present at the height of the inflammation. This affection will be so distressing at times as to force patients to void urine every fifteen minutes, day and night. When this stage is reached they will be found reluctant at the thought of, or even refuse outright to leave their homes for even short walks, for fear that the frequency and urgency, which now borders almost upon incontinence, may overtake them while out and cause embarrassment. Mere existence

itself becomes burdensome to these unfortunate individuals. Very despondently they come to consult the urologist, and when any hope is held out to them, when relief or even cure is emanant of attainment, expressions of eternal gratefulness from these sufferers form no little share of our reward.

Diagnosis.—The cystoscope alone can make the diagnosis of chronic trigonitis with accuracy. This instrument will demonstrate the presence of any local change, their seriousness, and the extent of their pathological characteristics. In studying these cases thoroughly, both the bladder and the posterior urethra must be included in the examination. For this particular class of cases I generally employ the Acmi model (convex, close vision) sheath with the large examining lens system of the Brown-Buerger combination cystoscope as made by Wappler. My plan has been to make these instrumental examinations as painless as possible, and so, usually a half hour before cystoscopy, I have a quarter grain of morphia administered hypodermically, and at the same time, after having preliminarily washed out the bladder well with warm boracic acid solution, I instill several ounces of a 0.5 per cent. solution of alypin into the viscus and allow same to remain for from fifteen to thirty minutes, as advocated by Braun. A few minims of adrenalin to each ounce of the alypin solution usually enhances its anesthetic value, will not cause excessive blanching, and acts as a retarder to the mucosa so that the alypin is but slowly absorbed. I have used alypin freely in cystoscopic work without any dangerous sequelæ.

In making an orientation of the bladder successful the viscus should be fairly well distended so that the folds of the mucosa are all smoothed out, so as to avoid falsely interpreting as abnormal something that might be perfectly normal. One should also bear in mind the fact that should the bladder be over-distended with fluid the mucosa may appear artificially anemic, and, when compared with the trigone, which is often more deeply injected than the rest of the bladder, the examiner may be misled by considering a normal trigone to bet the seat of a chronic trigonitis.

However, when the disease is present, the entire trigone is found to be the seat of a well-marked inflammation. The mucous membranes, from the ligamentum interuretericum to the sphincter internus, appears of a deep red color, while the surface presents a metaplastic process of the epithelial cells, grayish white to grayish red in spots, cumulus in appearance, the result of the diminished power of reflection of the inflamed membrane. The rest of the bladder is normal. Some writers describe the mucosa of the trigone as taking on a satiny appearance, and Viertel¹² states that this appearance was due to the beginning formation of papillæ. This same writer has also called attention to the fact that the trigone, in these inflammations, is frequently the seat of a large number of small cysts, varying in size from a poppy seed to that of a millet seed. These cysts often extend from the apex of the trigone through the sphincter into the urethra.

Bierhoff¹³ has noted the diffuse hypertrophy of the papillæ at the trigone in some cases. "The surface of the inflamed mucosa," he says, "presented a satiny, roughened appearance; on closer examination, I believed, I was able to discover papilla-like excrescences. To decide the question I

employed the ureter cystoscope, passing a ureteral catheter into the bladder, and laid it directly upon the inflamed area, into which it sank, revealing in most beautiful distinctness the rosy, satiny, non-transparent, hypertrophied individual papillæ standing out clearly in contrast to the brown color of the catheter." I personally have never seen either the small cyst formations spoken of by Viertel or the diffuse hypertrophy of the papillæ as observed by Bierhoff. The cases observed by me have shown the trigone and bladder neck dark red in color, with the mucosa in this area thrown up in thick folds, due to the metaplasia of the epithelium, and here and there tiny pseudopolypoid-like formations. The ureteral ostia were included in the inflamed area in one of my cases, almost totally obscuring the ureters from view. The balance of the bladder mucosa was normal in all my cases, except that one showed marked trabeculation in the bas-fond, but not accompanied by any inflammatory condition in that area. In one of my cases colliculitis was present.

Therefore, in routine urological examinations, where the cause of a bacteriuria, a pyuria, a hematuria, or a combination of these symptoms is being sought for—should the ureteral catheters rule out the kidneys and ureters, and a careful examination of secretions microscopically rule out the seminal vesicles, prostate and urethra, and where the typical red, inflamed trigone and vesical neck present themselves in the cystoscopic picture with the rest of the bladder perfectly normal—trigonitis should be considered the cause of the symptoms presented.

Trigonitis must be differentiated from the psychoses, such as: (a) hysteria with vesical symptoms; (b) "stammering bladder" or the "bégaiement urinaire" of the French writers, and (c) essential incontinence. At times such differentiation is fraught with many difficulties, and it will often require much patience on the part of the examiner to come to the correct conclusions. A study of the individual, noting his peculiarity in one way or another; a careful study of the history of the case; a complete examination of the reflexes, and a thorough examination, chemically and microscopically, of the urine should help one to reach a decision.

Treatment.—Chronic trigonitis is undoubtedly one of the most distressing ailments that the physician is called upon to treat. In regard to the prophylaxis of this disease it might be said that the ingestion of irritating drugs or foods, excessive indulgence in alcoholics, too violent an exercise which ends in near exhaustion, exposure to cold or wet, and the prolonged voluntary retention of urine should be conditions to be avoided. Any perivesical or pelvic disease should be remedied so as to avoid future trouble.

Absolute rest in bed is essential to the favorable management of the severe forms of this disorder. Nourishing, nonirritating liquids and light foods should be given. Alcoholic beverages are forbidden. Forced water drinking is usually contraindicated. Warm baths to keep the skin active are an adjunct.

The bowels should be kept active with the cathartic waters such as Carabaña, Hunyadi Janos, or Apenta. To alleviate the pain in the bladder and vesical sphincter, a mixture of a dram of tincture of hyoscyamus and a dram of potassium acetate well diluted in water is given every four hours. A suppository containing ten grains of anesthesin

placed in the rectum at bedtime will often give these patients a comfortable night. Hot sitz-baths morning and night, followed by a hot water bag to pubic region also gives much relief at times. When these and similar remedies fail, morphine sulphate in quarter-grain doses must be given.

Urinary antiseptics internally have their place here, and I believe urotropin, in 15-grain doses repeated every three hours, to be superior to all others. The alkalis must obviously be dispensed with while giving the urotropin. Should the urine fail to show a strongly positive acid reaction to litmus, acid sodium phosphate or sodium benzoate in 20 to 30-grain doses should be given at the same time, but not with the urotropin.

As regards the local treatment, it seems to be conceded by all the writers on this subject that irrigations do little if any good. A warm irrigation, combining in solution a 1/10,000 silver nitrate with a 1/8,000 potassium permanganate can be tried. With 1 per cent. boric acid solutions distention of the bladder can be practised, using hydrostatic pressure. Cary uses a two-way catheter of Dickinson for this irrigation.

It is with the instillations and topical applications of silver nitrate, however, where results have been most gratifying. By first producing anesthesia locally in the bladder with alypin, novocain, or eucain, instillations of thirty to sixty minims of silver nitrate in strengths of from 0.25 to 2 per cent, can be employed twice weekly. Through the Kelly cystoscope applications can be made directly to the trigone by using a 5 per cent. silver solution on a cotton swab; the pure lunar caustic stick is also used in this way. Cysts on the trigone should be punctured; diffuse hypertrophy of the papillae in this area, when tending toward chronicity should be curetted. These two last-mentioned procedures can be performed through an operative cystoscope in the male and through a Kelly tube in the female.

Should all of the above-mentioned procedures fail, it may be found necessary, as a last resort, to do suprapubic cystotomy, thoroughly remove the pathologic process on the trigone by curettage or otherwise apply the necessary treatment through the surgical incision and then drain the bladder, for a time, through the suprapubic wound, with a Pezzer or Pilcher catheter.

THE ROLE OF THE WISH IN THE MANIFESTATIONS OF THE EPILEPTIC TYPE OF NERVOUS CONSTITUTION.

A RATIONAL INTERPRETATION AND TREATMENT FOR THE EPILEPTIC SANE.

BY RUSSELL G. MACROBERT, M.D.,

NEW YORK.

ASSISTANT PHYSICIAN IN OUTDOOR DEPARTMENT, NEUROLOGICAL INSTITUTE.

A TEXT book has for years classified epilepsy as one of the "diseases of the nervous system without known nervous anatomical basis." There it stands, by the side of its sister disease hysteria. The mystery of hysteria has been exploded, and now perhaps no disease exists which permits of such exact and rational treatment; but epilepsy remains a mystery, and is generally regarded as one of the most serious afflictions that can befall the human race. It has been for years the predominating mystery of human ailments. Its explanation has seemed dependent upon the explanation of human existence, so profound were the depths to which the human being seemed plunged by its manifestations, and so profound the amnesia with which he returned. The disease epilepsy has long been classed as a psychoneurosis, but perhaps something of the ancient atmosphere and superstition which styled it the sacred disease persisted about it and served as a protection from the rational explanation due. Mechanistic conceptions have been unhesitatingly applied to other human affections, but something seems to have restrained us from tackling the mental side of epilepsy with our mental mechanisms, for although it is unhesitatingly styled a psychoneurosis, a physical or chemical causation is diligently sought.

Many gross bodily reactions, though showing both physical and chemical change, can be demonstrated as resulting from the dominance and sway of a nonconscious mental motive. In fact, all organic reactions have a purpose. Purpose is back of every physical, as well as every mental act. The logical purpose in every bodily change is not possible of demonstration. The change is an attempted adjustment of existing conditions, but is in relation to organic laws we do not always understand. Psychic change can be more readily demonstrated to have a purpose in view, because the purpose is in definite relation to some known laws and to the character or constitution of the psyche. There should not be doubt, however, that a purpose is behind every unit of life, every system of units, and every combination of systems. In sudden anemia of the brain, as in a faint or cardiac syncope, loss of consciousness is automatically induced, the horizontal position results, and the anemia of the brain

is overcome by the return flow of gravity—a striking example of a nonconscious purpose. The loss of consciousness of the epileptic has not this mechanical cause; has no explainable pathological change in the brain as its cause. Its admitted cause is “psychoneurotic,” and being so the evidence is with him who says that the cause is mental and has a mental significance.

The mental significance of acts arising in the nonconscious is often obscure. The loss of consciousness of the epileptic is in accord with a nonconscious purpose, and has a nonconscious mental significance. It is a purposeful effort of the driving forces, whose direction is almost altogether nonconscious. If some irritant substance enter the intestine, nonconscious processes proceed to deal with it, and they expel it without consulting conscious systems as to the degree of increased peristalsis required. The reason for the action remains entirely nonconscious. If some irritant arise in connection with the psychical processes, it is dealt with also by the nonconscious systems, or psyche, and according to the character and constitution of the psyche. Differences in the character or constitution of the psyche will result in different ways of dealing with difficulties. One type will encounter a difficulty with added force, another will choose a different path around the difficulty, and another will retreat or withdraw from the situation. Differences in physical constitutions are apparent by the difference in the size of the skeleton, the character of the fleshy covering, and in the vigor of the various vital functions; differences in mental constitutions are apparent by the difference in the character and quality of thoughts, opinions, and methods of dealing with the situations confronted. A mental constitution is recognizable in this way by its manifestations, and has no physical representation that is patent.

The epileptic type of nervous constitution² exists on the basis of this classification of an individual, by a set of manifestations. It indicates a class of individual that deals with difficult situations in a characteristic manner. The convulsions and sudden loss of consciousness indicate certain peculiarities of mental make-up. The epileptic is acting according to the nonconscious direction of his specific mental make-up, and is accomplishing some desire, or attempting to do so, by his manifestations. This desire is wholly nonconscious; and the manifestations, which are its gratification, are wholly nonconscious in significance. A proper understanding of the epileptic is obtained only by clearing up the confused relation between the physical and psychical sides of the problem. I beg, then, for a consideration of the epileptic under three heads, his constitution, irritations, and manifestations.

the morbid phenomena. This implies a normal condition of the neuron up to the point that lies within the possibility of present means of investigation. The changes that occur in the nerve cell beyond this point have to do with the highest nerve processes, such as thought and association. The reactions of the hysteric register no change up to this point; no lesion responsible for a hysterical paralysis can be demonstrated in the muscle or up the nerve tract to the brain cells. No change can be here discovered by the pathologist, who is obliged to say that the normal stimulus to the muscle is interfered with by the mind or the section of the cells through which mental function operates. Another action of the mind can so operate as to banish absolutely what was to all appearances a complete paralysis and accomplish it instantly. If a change in the cellular structure does occur with these mental processes, which cause an hysterical paralysis, it is of such a nature that it can be instantly neutralized.

In the picture I wish to draw of the epileptic type of nervous constitution, I shall allot to the functional nerve change producing the epileptic manifestations, a 1 per cent. physical basis, and a 99 per cent. psychical basis. My division is purely arbitrary, and the 1 per cent. is cautiously granted for two purposes: to allow for the possible neural change that at some future time may be demonstrated, occurring in the cell accompanying mental function, and to give a basis for all the psychical elements such as instincts and emotional tendencies which are the determinants of mental function, for want of some more definite basis for them to rest upon. The latter are recognizable only by their manifestations but it is in the brain cell that we lose the thread in tracing an instinct or an emotion. As fire is frequently recognized by its smoke only, so is the existence of instincts and emotions recognized only by their outward or objective manifestations. They are obviously present, and obviously heritable, but their secrets are tied up in the mystery of the brain cell or—beyond. I make, then, the two divisions in the epileptic constitution: the psychical—to do with conscious mental actions, instincts, emotions, and all the vast nonconscious mental life; and the physical—consisting of brain cell constituents, that are the residing place of characteristic determinants of psychical function. Of this physical portion, no part lies within the possibility of present day demonstration methods. Of the psychical portion of the epileptic constitution, many characteristics have been widely observed and their peculiarities noted. His conscious mental life is replete with evidence, in many instances, sufficient to group the epileptic with his epileptic fellows. His mentality is characterized, for the most part, by a

CHART: THE FOUR PRINCIPAL FACTORS IN THE INTERPRETATION OF THE EPILEPTIC.

The Epileptic Type of Nervous Constitution.—*Functional* is a term applied to nervous diseases in which no known anatomical change underlies

feebleness, unreasonableness, lack of insight, and irritability. Some show waywardness, vicious impulses, and lack of will power. There are many

epileptics, however, whose conscious mental life is normal and even vigorous, and these are mostly the ones that are all about us, whom we know not of, and represent a class which is as great as that whose psychical degeneration, symptoms, or circumstances, demand their custody and statistical enumeration. The conscious mental life of the epileptic, indicates, we may say, only 5 per cent. of his characteristic features, as against 95 per cent. indicated by the nonconscious mental life; the division again being necessarily arbitrary, and used only as a basis of approximate illustration.

The very foundations of the epileptic character are in the peculiar constitution of his nonconscious mental life. Any personality has a nonconscious basis. Actions, reputations, and character depend upon the constituents of our nonconscious mentality and its functioning. Actions are reflexes, and their character is the result of the co-ordinating and regulating influences of nonconscious processes. The nonconscious determines involuntary action, mental and physical. The nature of our nonconscious is determined by the character of the equipment and tendencies, with which we are supplied by heredity, to deal with our experiences. The manner of dealing with the situations by which we are confronted is determined for us, therefore, to a great extent by heredity. A disfigurement of this inherited equipment, such as is caused by dwarfed instincts and misshapen emotional tendencies, will certainly influence and color the manifestations that arise from our nonconscious mental life.

Deformed instinct endowment will transfigure and cripple our reactions to reality. Nonconscious activity has a character which is commensurate with the ability, and in accordance with the construction, of the nonconscious mentality, but works always to conserve the organism, and its manifestations are logical to the nonconscious purpose, though to all else, in most instances, void of significance. The significance of the manifestation to the nonconscious purpose will be found to be in the nature of an adjustment, or an attempt at adjustment, to some irritating condition, physical or psychical, interpreted through sensations coming to the brain. A deformed nonconscious mentality, presupposes a weak or deformed manner of dealing with the situation in hand. The epileptic nonconscious is a medley of deformed instincts and emotions, and the result of their play on the organism which they control. The epileptic may be, in some way, physically deformed, but he is frequently well within the normal range. He is, however, without exception nonconsciously feeble-minded, and family trees and other statistics show him actually more closely related to the feeble-minded than to any other class of individual. His constitution is solely the product of heredity, so the equipment for his specific reactions is present at birth. His psyche is infantile in type, and its reactions of a primitive order. The epileptic reactions appear in some cases in early infancy, and as their significance to the organism is present at that time, we may expect, when we come to consider them, to find them of a very elemental nature.

The infantile behavior as a reaction to various situations, with which the nonconscious is confronted for solution, persists through life because the deformed instincts and primitive motives persist, and are the very basis of the epileptic constitution. I consider the cause of the epileptic reactions to be a controlling mental mechanism that is infantile and deformed, and void of the mature logic

of perfect instinct equipment. The reactions present no adult or mature logic, and as infantile are on the principle of a pain and pleasure motive of elemental nature. Picture the epileptic, therefore, possessing a very primitive mental or adjusting mechanism, reacting in accordance with its direction, when his nonconscious is embarrassed by irritating or difficult situations. His psychical equipment, in this way, produces the reactions by which an individual is readily classified as possessing the epileptic type of nervous constitution. A great variety of stimuli may act as inciting factors, but without this specific constitution the specific reactions could not occur. The nature of the irritation bears no relation to the end result. The reactions are merely the epileptic's way of responding to a difficulty or embarrassment occasioned by irritation of almost any nature.

Heredity produces the epileptic constitution. All evidence confirms that fact. The manner of this heritage is not altogether clear. In a previous paper¹ I brought out what seemed to me the immense culpability of a defective mother instinct as an influencing factor in the prenatal development of the epileptic type of nervous constitution. Of other predisposing hereditary elements varying percentages must be allotted to such factors in the forebears as insanity and feeble-mindedness, hysteria, alcoholism, epilepsy and emotional instability as exemplified by uncontrollable temper. There are possibly others, unknown but equally important.

As the physical nature of the epileptic's trouble is perhaps still a matter of strong opinion in certain of my readers, and they are trying to reconcile what is being said with their experience of physical factors in epilepsy, I will enter at once on the role of the various irritations which have been noted as apparent stimuli to this type of nervous system and incitors of its specific reactions.

The Irritations or Stimuli That Excite the Manifestations.—If we regard the epileptic constitution, then, as a feeble or infantile nonconscious mental life, which results from the inheritance of a deformed instinct and emotional equipment, we see immediately, the position—as stimuli—of the great variety of physical and psychical troubles, which at different times have been considered the cause of epilepsy, and the possible secret of the whole problem.

These stimuli, acting upon the epileptic constitution, may be either of a physical or of a psychical nature. Of the physical, perhaps among the most important are those arising from the gastrointestinal tract: disturbances of the bowel such as constipation, intoxication, chronic inflammation, or anomalies of its structure, exercise great influence on the prevailing moods of mental life. This is a matter of common observation and need not detain us. Glandular dystrophies and irregularities in the balance of the internal secretions play a part for discord in nonconscious mental activities. A brain tumor or other pathological condition of brain tissue or its envelopes may act as the irritating influence. Perhaps these and all other derangements from the physicochemical plane are in all no more than 10 per cent. of the irritations which excite this peculiar nervous organization to its specific reactions. The other 90 per cent. are psychical—when the stimulus appears to originate in the highest brain cells, or the cells concerned with thought and association.

These psychical stimuli fall readily into three

groups: 1. Prolonged nerve strain, such as mental overwork and worry. 2. Acute nerve strain, such as fright, which is common. 3. Ideogenous, which are strictly nonconscious and nonapparent stimuli, that may arise from situations in dreams, or nonconscious mental adjustment processes. Those of the former two groups have often been noted. The latter group, however, is probably much the largest, and hence the reason why in epilepsy "exciting causes are not present in the majority of cases," to quote from the recent edition of Dana's text-book.⁴ It is partly because of the previous inaccessibility of the stimuli of this group that past treatment of epilepsy has been so futile. Lucky was the epileptic who presented very evident physical disturbance as the inciting factor of his attacks; its removal or alleviation was usually responsible for the cure in the few cases in which epileptics were cured.

This great inaccessibility of the large percentage of the excitants of epileptic attacks is sufficient reason for an attempt to solve the problem from another direction. A thorough investigation into the nature of the specific reactions has resulted. The realization that the reactions are always the same, no matter what the character of the stimuli, opens the first door to the treatment of the epileptic. They are but the bad habits of a certain personality. They are resorted to whenever the irritation is sufficiently provoking. To the epileptic the source of irritation does not matter. He has a habit that will serve him in any instance. He can withdraw from the difficulty he cannot face. Once his manifestations are seen definitely as originating from the nonconscious mental life the solution is another door nearer to us. The significance of any mental accident is found in the answer to the questions, "What is the task which the patient does not wish to fulfil? From which necessary difficulties of life does the patient try to withdraw himself?" as put by Jung of Zurich.⁵ In the case of the epileptic the fact that the manifestations are the result of a nonconscious desire to withdraw from some irritation, physical or psychical, is a light in our path. They are the disguised fulfilment of a nonconscious desire, and serve in some way that seems particularly beneficial to the infantile motive behind, to relieve him of his irritations. The steps in the interpretation of the manifestations let us consider in turn.

The Specific Manifestations of the Epileptic.—The typical manifestations of the epileptic character are sudden loss of consciousness, convulsions, and amnesia.

The loss of consciousness ought to be regarded without controversy as manifestly a psychic demonstration. In the first instance consciousness is a condition of awareness of mental processes. Loss of consciousness is the deprivation of this awareness. There is no tenable theory for the loss of consciousness of epileptic seizures that will connect it with any physical lesion supposedly responsible for it. The loss of consciousness can be explained in only one way. It is essentially a manifestation of the biological mental activities. It occurs with a purpose, and plays a part in the dominating idea expressed in the epileptic seizure. Consciousness is not compatible with the situation adopted by the nonconscious motive, and so is summarily dismissed. In an hysterical manifestation the organism lives again through a situation of the past. In the epileptic manifestation a situation of the past is also

enacted, but, unlike the hysteric, is marked by a profound loss of consciousness; so we should expect the situation represented by the epileptic seizure to be a situation in his past life where consciousness did not exist.

The fit of the adult may be an exact counterpart of the fit of infancy, but the significance of the situation relates to a still earlier date. The fit represents an attempt of the epileptic to realize himself again *in utero*, which gives him a feeling of security and protection, by the reversion to a previous stage in his development where irritations were unknown.

The convulsions of the epileptic have all the outward appearance of a very thorough physical demonstration. They do not so readily appear of a psychic nature as does a disturbance of consciousness. There is no ailment that shows with anything like the rapidity of an epileptic attack such a complete involvement of the body in every plane of activity—sensorimotor, physicochemical, and psychical. The rapidity and certainty of the involvement is indicative of a very powerful motive behind. The movements, often described as "a clotted mass of movements," represent no conceivable purpose that can be connected with a physical derangement. This very irregularity of movement, when viewed in the light of the psychic purpose, is full of significance. The seizure represents a stage of intrauterine existence. This is a time when coordination over muscular movements is not developed, coordination only commencing in a small way some time after birth, and being not very far advanced for several years. The incoordinated movements of the fit supply a muscular realization of the former state. The epileptic feels the situation represented, in every cell and system of his body. The aimless movements of the child *in utero* are performed, because the organism is, for the time being, dominated by the idea of its return to that state. The situation is represented with all the vigor of which the organism is capable, which is quite characteristic in this respect of all mental accidents. The whole situation bears a close resemblance and relation to sleep walking, or the enacting of a situation that is being dreamt. Some people in their sleep laugh, cry out, walk, struggle, or by other muscular movements enact the experience of the nonconscious mental activity of their dreams. The epileptic acts out his dream, as it were, more thoroughly. He is transferred to his situation with a vigor and thoroughness that are characteristic of and only possible to a powerful mental motive. The epileptic seizure has never been comprehended through the ages because it was never conceived that the organism could be so forcibly thrown back to a former situation by a trick of the mind. The revelation that in an hysterical manifestation the organism usually reverts to a past situation makes this now understandable. It is only one step farther to see that the epileptic manifestation represents a situation that is previous to birth and has the accompanying loss of consciousness of that time. The text-books have been recently warning that the distinction between epileptic and hysterical fits was by no means the easy matter that it was formerly considered, and that the old cut and dried rules of distinction would have to go. Cabot⁶ in 1912 said there was no way in which they might positively be distinguished, in certain instances, and Dana says that "epileptic seizures of characteristic type may be caused by psychic states." This only helps us to see that in the mechanism the two are closely related. Both epileptics and hysterics are

controlled by a nonconscious mental motive and both revert to the past. The situation represented by the epileptic seizure is of a time previous to birth, that of the hysterical seizure any time from birth on. The real distinction in certain difficult cases rests exactly on the point as to whether there was a profound and certain loss of consciousness. Men who did not consider that the psyche had this important role in epileptics must frequently have been astonished by the close relation of the hysteric to the epileptic seizures in certain instances.

The *amnesia* that follows the profound epileptic seizure is in comparison to the depth to which the nonconscious purpose realizes its endeavor. Conscious memory of the situation experienced never occurs. It is not possible to get the epileptic to recall where he has been or to relate the happenings in his spell. He cannot interpret what he has felt. A nonconscious mental system has broken through and acted out something that the conscious governing faculties would not approve. If the action of the nonconscious motive were understood by consciousness it would not be allowed to perform. It is imperative that the action should be void of significance to the conscious controlling systems, so all vestige of memory is peremptorily dismissed. A nonconscious mental system is for the time being in control, and the whole performance is according to its wishes. The epileptic is unable to return from the depths to which he descended in his fit, and bring any recollection of the experience with him. There is, however, little doubt that there is a physical memory of the situation, for a feeling of well being persists for days at least after the fit, but this is not translatable into terms the epileptic consciousness can understand. This secret nonconscious purpose has been proven by an analysis of epileptic deliria and by the interpretation of dreams, and demonstrated to be a striving on his part to return to intrauterine life.

Ferenczi⁸ in 1913 drew up the analogy between attacks of temper in children and the epileptic fit. He spoke of how some children when thwarted will cry out, stamp, or roll about in a rage, and show violent reactions of anger, which are quite ineffectual to make any change whatever in conditions. The whole situation represents an absolute inability to accept or adjust. The child persists in a determined attitude that the irritating situation is not so because it just should not be so. There is an effort to force circumstances to be different by a supreme effort of thinking them different. This often finally results in the child stiffening out, losing the breath, and becoming blue—the whole performance being not unlike an epileptic fit, but passing for the not uncommon "bad fit of temper." He also calls attention to the resemblance of the movements in an epileptic fit to the normal incoordinate movements of the infant when gleeful or angry. He suggests that the epileptic fit represents regression to the infantile period of fulfillment of wishes by means of incoordinate movements.

Clark⁹ in 1915, working on this basis, presented the theory that the fit of the epileptic represents strivings on his part to return to intrauterine life. He recited analyses which seem to argue this point convincingly. This flight to the mother life has for some time been observed in various psychoses. The delirium of an epileptic as analyzed by MacCurdy showed the epileptic living again his intrauterine existence. That the fit represents to the organism a return to the womb is beginning to be

pretty generally believed by those interested in epilepsy, and this view is already insinuating itself into the text books¹⁰ on neurology. Clark's explanation for this striving is on the basis of its being a psychosexual attachment of the epileptic to a parent. This fixation he considers to be of a homosexual nature because he finds that it is usually on the parent of the same sex as the epileptic.

I regard the motive and significance of the fit in a different way, considering the withdrawal of the epileptic to the intrauterine life as a reaction to difficulty, and the assumption of a situation known to the organism as one where the difficulties he is facing did not exist, the whole effort expressing a *complete renunciation of adaptivity to reality*. The significance to the epileptic of this return to the womb is of greatest importance, in view of the treatment I propose for the epileptic, so let us consider it at further length.

The Significance of Epileptic Manifestations.—A psychical mechanism is indisputably responsible for the epileptic manifestations, and nothing results from a psychical mechanism that is not fraught with meaning. The meaning in psychical accidents, such as those of the hysteric, is usually deeply disguised or symbolic, and has to a great extent the mechanism of a dream. It is found representing in a strange, often weird manner, the fulfilment of a wish. Numerous illustrations of this are in print, where manifestations of a mortifying character proved on interpretation to be wish fulfilling. When the wish was revealed and demonstrated and the whole incident clearly seen by the patient, the manifestation was dissipated—verifying the correctness of the interpretation. The reactions of the epileptic are of this nature, differing but slightly from those of the hysteric—the epileptic being transferred to a situation that existed previous to his birth; and the hysteric to one of any time from birth on. The nature of the hysteric mind is not of such a profoundly infantile type as that of the epileptic in its nonconscious activities, and is differently constituted. The reactions of the hysteric are from a higher psychobiological level. Both illustrate the dominance of the organism by a mental idea. The idea of the epileptic is a desire to consider himself free from his irritation—not born. The reaction occurs when the organism has been subject to a grievous strain, either of mental or of physical source, and the fit gives relief in some way. Almost every writer on the subject has noticed that the epileptic appears to feel better after a fit. It gives relief from the irritation and seems, as Stoddard says, "to clear the air."¹¹ The organism lives again for the time being, with every atom of its structure, its free and irresponsible prenatal existence, which must obviously represent to it a flight from its difficulties. Not being able to adapt itself to the difficulties that beset it, the infantile nonconscious overpowers consciousness with a feeling of freedom from them, and dominates the body with this idea. It reverts to a situation in the past, where such difficulties were not encountered and where there was no conflict, as all responsibility was assumed by the mother. It is a situation that is agreeable and proves eminently satisfactory as a temporary recreation and relief. The irritability of the epileptic before the fit is an indication of the trouble that is going on. The frailty of the infantile mind soon gives way and goes down before the force of the impulsive idea that may almost threaten life itself to accomplish its purpose.

Some conscious control of the impulse is frequently seen. I recall an epileptic who was brought to the Institute for observation. He had been having attacks every eight or ten days, with fair regularity, for a considerable time previously. They would occur usually at night. For half a day beforehand he would have an aura of numbness in the right hand. Special effort was made to witness an attack, and the patient, who was a boy of only twelve, soon became quite alarmed at the apparent seriousness of his trouble. He became so nervous and fearful lest one should occur that he stayed awake, or attempted to do so, on the nights when the aura had been experienced. If he dropped off to sleep he would awaken in alarm, fearful at having allowed himself to do so. He exercised such anxious restraint during his eight weeks in the hospital that he did not have one attack. He was allowed to go about as usual, playing, even roller skating, and no precautions were taken during his stay to diminish his liability to attacks. He had none until this anxiety and fear had subsided, a long time after he left the hospital, when they recommenced and continued as before. It serves to illustrate a very strong influence on the part of conscious systems to control the situation.

My study has, in various ways, served to convince me that consciousness would be able, in suitable cases, to exercise a prohibiting control, if properly directed and armed with an intelligent understanding of the mechanism—much as in the manner by which the hysteric has been relieved of serious mental accidents, such as blindness and convulsions. It is a consideration of the epileptic as presented here that leads me to suggest what appears to be, in the light of our recent successful treatment of the other psychoneuroses, a rational treatment of the epileptic sane.

The Treatment.—I propose to deal, in this paper, with the treatment of such epileptics only as have a fair degree of intelligence, believing that at the outset of such a radical treatment it is best to confine ourselves strictly to the more favorable cases, until large experience with the method reveals to us a manner in which to proceed that may be broader in its scope.

Between the attacks there is as a rule nothing about this class of epileptic that is particularly objectionable. The fit and the loss of consciousness are the only troublesome features, but his present position is a pitiful one. There is no treatment for him that is successful in staying the disease. The rare case recovers spontaneously; the remainder continue. There is a tendency also to psychic degeneration. Peterson draws a picture that makes part of the mechanism of this psychic degeneration plain and shows all too truly the present situation of the victims of this affection: "A study of the psychology of epileptics in general gives us a sort of composite picture, to which all of these patients conform more or less closely. The mental attitude of the epileptic is due to a variety of circumstances. In the first place, he has a consciousness of the dreadful nature of his malady. He is in a state of expectant attention as regards the sudden blackness and prostration which are to strike him unawares at any time, in any place, like the lightning from a clear sky. He can never share the social pleasures of his fellows. The schools are not open to such as he. When he becomes old enough to work he finds that no one wishes to employ him. Every avenue of education, every trade and calling, every road to mental progress, is barred. He is a social outcast, an object of com-

miseration, a burden to his friends, perhaps a family blemish to be kept concealed. The doctor is called in, and, taking as a rule a hopeless view of the case, abandons him to the mercy of the bromides which further his mental, physical, and moral degradation. In this way the epileptic character is evolved."¹² Certainly such a situation exists that no apology seems needed for introducing a treatment that springs from a new viewpoint.

A systematic study of the epileptic is the first step. Every possible source of local irritation should be investigated. Any slight physical or physiological fault may be an irritant, and should be corrected. Toxic conditions should be sought for and remedied. There should be a very thorough physical examination and a searching neurological one, which latter should include an investigation of the mental processes, their difficulties, and problems. Help should be rendered from the side of the *irritation* if any possible indication presents itself, and the patient put in the very best physical and hygienic condition possible.

The *constitution* of the epileptic should be strengthened in every possible way. This means education. All possible should be done to improve him mentally. He should be educated as well and as thoroughly as his circumstances permit. He should be taught self control, patience, perseverance, and tolerance. His education should include physiology and psychology and as thorough an understanding of his human machine as possible. He should be taught an interest in the world about him. Some regular absorbing occupation is to be strongly recommended. Too much cannot be said along these lines. These are points particularly helpful to all epileptics, and it is from this side chiefly that the colony treatment has been so beneficial. Too much praise cannot be given to the efforts of the epileptic colonies.

The specific treatment directed to the *manifestations* hinges on the patient understanding the meaning of his fit according to the exposition given here. It is best undertaken by one skilled in the analysis of psychological situations. The rationale of the treatment is based on the fact that the epileptic fit is the result of a mental situation, is a mental fact, and as such has a motive and meaning which are possible of discovery and adjustment. Being a mental fact, it is capable of being influenced and controlled by conscious reasoning faculties. There is required for its control a complete understanding of the situation by the patient. He must see clearly the mechanism of his condition as the fulfilment of a nonconscious desire. Its relation to the hysterical mechanism can be brought out, and illustrations used. The manifestations of hysteria are every day being shown to be the result of a distinct wish on the part of the individual. The wish discovered and demonstrated to the hysteric, the manifestation is dissipated and does not reappear. When it is perceived in its true light, for exactly what it means, it cannot act again, for it serves its purpose no longer. Consciously it is not wanted, and consciously it is recognized and under control. There are many examples of this published. Ames' cases of hysterical blindness are striking examples of wish fulfilment; and what is almost a parallel with the epileptic—the case published by Ames and me of "Psychogenic Convulsions the Result of a Wish."¹⁴ The wish in these cases was discovered by psychoanalysis and the accidents of the hysterical completely banished by its revelation.

The plan of treatment is analytical and educational. It should take place in a succession of interviews with the epileptic, perhaps over a long period of time. By conversation the mental grasp of the epileptic can be determined and the explanations put in terms of his understanding. A thorough conception should be obtained of his knowledge of mental processes. His psychology may be very crude, but he will have ideas of some nature about his conscious and unconscious mind, and these ideas can form a basis for some explanation of the workings of his trouble. His understanding of the mind can be gradually supplemented by explanations and examples. He will realize in his own way how, for example, a disordered gastrointestinal tract causes certain vivid dreams, or gives them color, and, gradually, how physical processes influence his unconscious thoughts and make him irritable. He may be made to recall how on certain occasions he awakened in terror from a horrible dream, and even perhaps sprang out of bed. By having him recall and tell about these things, material for examples and illustrations will gradually pile up. He will soon come to understand thoroughly in a personal way how his unconscious mind, or whatever he sees fit to call it, influences his conscious actions and behavior. He can be shown how a certain amount of mental activity, of the nature of dreams or adjusting processes, is continually going on below the level of consciousness. He will supply the illustrations most of the time himself, and it is well to allow him to do so. He will see how no experience is ever lost, how incidents of years before may suddenly flash into consciousness. He will learn how these experiences are used in his dreams and nonconscious mental life. The wish psychology must be elaborated for him, and he must be led to see and to comprehend thoroughly, leading the way mostly himself by his questions and personal recollections, the influence of unconscious desire in all involuntary actions. The rôle of the wish in the hysteric he should comprehend. He should be given numerous examples showing the manifestations of hysteria as bearing always a distinct relation to the question "What does the patient wish to avoid?" and how the wish once recognized by consciousness is controlled and the hysterical manifestations dissipated. If difficulties of the epileptic nonconscious have become apparent they can be used as definite illustrations, to exhibit the mechanism of his own actions. He must be shown how his nonconscious mentality has not met its problems "like a man," as it were; how it has been irritated by certain difficulties, and has met these difficulties by literally saying "I wish I had never been born," so forcibly that the body had been suddenly dominated by the wish, and transferred as nearly as possible to the situation when he was not born. He should be made to see that his nonconscious has obtained a certain amount of relief in this way, and that he has fallen into a bad habit of thus giving vent to his temper or pent-up irritability. All questions should be met and full explanations repeatedly made in the manner that he will best appreciate. He should be told that his trouble is not of such a serious nature as was formerly believed before its mechanism was understood; how its treatment now just hinges on his ability to thoroughly understand the situation; that as he gradually realizes the whole situation it will be woven into the tissue of the personal controlling consciousness and can be banished, as all psychic occurrences can when thoroughly understood.

This is the treatment that I propose for the intelligent epileptic. I offer it as a basis to work upon. To those with experience in the analysis and treatment of psychic disorders, its use, I believe, will be productive of good results from the outset. However, upon the thoroughness with which it is pursued will rest much of its success—success to be measured solely by the disappearance of the epileptic manifestations. Upon the skill of the therapist will doubtless depend the quality and thoroughness of the treatment, but the whole procedure does not appear to me to be beyond the power of any neurologist or physician, with experience in the analysis and treatment of psychological situations; and to the efforts of such it is certainly best confined for the present. This treatment is offered with confident hope that it will be found successful, and will serve as the basis for the development of a treatment which will be applicable to a larger class of epileptics than that to which at present we must limit ourselves—the epileptic with a fair degree of intelligence. However, I would like to recall that the case published by Dr. Ames and me, of "Psychogenic Convulsions the Result of a Wish," was a patient who, although eighteen years of age, was far below that mentally, and was shown by the Binet-Simon test to have the intelligence only of the average child of twelve. She was, of course, of the hysteric, not of the epileptic, type, and the situation represented by her fit was one of only four or five years previously, and not so profound and remote in her mental life as that situation represented by the epileptic fit. The mechanism will appear, however, to those studying it as practically the same, and the same fortunate result should be expected.

Summary.—From the viewpoint taken in this paper, the epileptic manifestations themselves are seen to be definite psychical accidents, of much the same nature as the accidents of the hysteric; in fact, differing but little in the main features and mechanism, excepting in the point that the epileptic enacts a situation of a time previous to birth, and therefore accompanied by the profound and certain loss of consciousness of that time, whereas the hysteric enacts a situation, in his accidents, that may refer to any time from his birth on, so that they are unaccompanied by the profound loss of consciousness. The treatment is therefore of a nature somewhat similar to that which has recently been so successful in hysterical cases—the complete education of the epileptic to the point of understanding the whole mechanism and purpose of his fits. This of course must limit us in our treatment to those epileptics only who have preserved a fair degree of intelligence.

WHAT LIFE INSURANCE COMPANIES CAN DO TO ASSIST IN THE CONTROL OF CANCER.*

By HENRY WIREMAN COOK, M.D.

MINNEAPOLIS, MINN.

VICE-PRESIDENT AND MEDICAL DIRECTOR, NORTHWESTERN NATIONAL LIFE INSURANCE COMPANY.

No more notable or inspiring phase has occurred throughout the development of life insurance than the recent interest taken by insurance companies in efforts along the line of social service. And yet it is really a natural development of this great and varied industry. Originating in the previous century largely as a gambling pastime in England, life insurance has passed through a truly remarkable adjustment. After being established on a solid mathematical basis which is without parallel in any business, life insurance succumbed to and later overcame the abuses which came not unnaturally with the rapid amassing of such huge sums of money, and is finally being conducted on the highest possible plane of business and professional ethics.

This business development has utilized and even stimulated the development of at least three learned professions—medicine, mathematics, and law. Now, as a final crowning achievement, life insurance goes a step beyond the strict business side—even the strictly scientific side of the industry—and takes its rightful place as a broadly humanitarian activity, with its social as well as financial obligations.

Anyone who has seen the exhibits of some of the insurance companies at the different world's fairs and other suitable places of public gathering during the past ten or twelve years—particularly the wonderful Prudential and Metropolitan exhibits at San Francisco and San Diego—could not but be deeply impressed by the large amount of good that these pioneer companies are accomplishing, and also by the great potential power for social service which lies within the grasp of the life insurance companies of this country to-day.

And there is available more than potential power; there is an active desire and even eagerness on the part of insurance officials to co-operate with various social agencies in any legitimate way compatible with business requirements. But while a great deal has already been accomplished, particularly in the field of the prevention of tuberculosis, a vastly increased amount of work can and will be done along similar lines.

There are two directions particularly in which insurance companies can offer invaluable aid in the control of cancer. The first is in the collection of

*Read at the midwinter meeting of the Medical Section of the American Life Convention at Birmingham, Ala., March, 1916.

authoritative statistics on the subject; the second is publicity and education. I shall confine my remarks entirely to suggestions in regard to the latter, as the machinery for the former has been laid out and is already in motion under Mr. Hoffman's able leadership as chairman of the Committee on Statistics of the American Society for the Control of Cancer and the Conference Committee of the American Society for the Control of Cancer for the Statistical Investigation of Cancer, which includes Mr. Hoffman, Mr. Hunter of the New York Life, Dr. Symonds of the Mutual Life, Mr. Dublin of the Metropolitan, Dr. Jaquith of the Prudential, and Dr. Wells of the Equitable.

The Equitable, the Metropolitan, and the Prudential have been particularly notable in one direction—that is, in keeping their policyholders instructed in questions of health through the medium of their excellent policyholders' publications. The company with which I am associated, the Northwestern National, has issued similar tracts and literature to its policyholders for over ten years, and many other companies are using the same means. In fact, the remarkable institution known as the Life Extension Institute, with its varied activities, is an outgrowth of insurance life salvage work, Mr. Rittenhouse, the president, having previously conducted the conservation department of the Equitable, and Dr. Fisk, the medical adviser, having made similar notable contributions while with the Provident Savings and the Postal Life.

The publicity which lies within the grasp of insurance companies, practically without expense, through the medium of their routine communications to policyholders (premium notices and receipts, policyholders' publications), through agency meetings and agency bulletins, is immense, and is rapidly becoming one of the most formidable weapons in the fight in behalf of improved health conditions and a generally increased life expectancy. And the very nature of the business of life insurance—and this campaign should include health and accident as well as life companies—makes it peculiarly fitting that through the routine channels of the business, health propaganda should find their way to the public.

There is an additional force to any formal communication if it is associated with something of more personal interest. A premium notice accompanied by a little pamphlet on some question of health preservation holds the recipient's attention more effectively than would merely the formal notice, so that such an inclosure should be an immediate help to the company and not a burden. Policyholders appreciate the personal interest on the part of the company in things which this effort suggests, and it makes them feel that their company is well up in the public health movement, which is a large issue to-day, demanding and receiving a widespread interest.

Only a part of the benefits of life insurance is included in the financial statement showing the millions of dollars paid annually to policyholders and beneficiaries. The constructive and conservative influence of the principles upon which life insurance is founded—that is to say, thrift, protection of family, and business obligations—has had, undoubtedly, a most profound impression on society, and now this influence is being expanded along definite lines of social service, a development which adds materially to the humanitarian benefactions of the business.

There are fifty million life insurance policies in force in the United States, and there are several hundred thousand agents. Every policyholder should be the recipient at intervals of information which will make him better able to give intelligent care to his health and the health of his family, and which will give him a basis for exerting a proper influence on health questions in his community. A very large share of the neglect and opposition on the part of the laity in matters of public health is due to ignorance.

One practical result of such an educational campaign is increased company and general public expectancy, and therefore increased mortality savings.

A man who is selling life insurance should know the theory and the elements of the practice of health and life conservation. Such knowledge not only renders him a more useful citizen but also undoubtedly tends to make him a better salesman. The subject of life insurance can sometimes be opened and interest gained through the subject of health conservation.

In succession each of the newer developments of medical sciences can be given immediate publicity and made operative with a saving of time, which means a saving of lives, through such life insurance service. Take, for one example, the Allen treatment for diabetes. We have called this treatment to the attention of our policyholders; and if the results of the treatment are as favorable as now appears probable we will save a considerable sum in mortality payments, besides adding many useful years to the lives of those of our policyholders or of our policyholders' friends who are passing sugar in the urine. That the medical profession cannot be entrusted with the prompt application of such advances in their own science is shown by the numerous statements we have received from policyholders that their family physician never hear of the Allen treatment—and it has been over two years since the first reports came from the Rockefeller Institute. In some cases these physicians had a large practice in big cities.

Publicity is the secret of advance in the control of cancer. A very large proportion of American physicians are not yet thoroughly aware of the salient points in this control, and, as a matter of fact, a layman and insurance official has perhaps done as much as any physician in this field. I speak of the well-known work of Frederick L. Hoffman. Many other influential laymen are deeply interested and active in this campaign, and many are associated with some of our leading physicians and surgeons in directing the activities of the American Society for the Control of Cancer.

Very valuable campaign material has been collected by this society, as well as by the Metropolitan and the Prudential life insurance companies, and is embraced in several pamphlets which ought to be on file in every insurance office for reference. The pamphlet of which Mr. Dublin of the Metropolitan has sent me 100 copies for use at this meeting has been distributed by that company to its policyholders for several years.

This cancer symposium presented to-day, and so forcibly led by Mr. Hoffman's treatise, will bring the subject of cancer control to the attention of all insurance officials and, through insurance publications, to many insurance agents.

But merely bringing the subject to mind for temporary consideration without having stimulated definite action will lose to the discussion its greatest value. Can we not translate the sentiment now

created into specific action? If every insurance office where the subject of cancer control has been brought to mind would do something about it, instead of letting the idea recede into what Grover Cleveland called "innocuous desuetude," a considerable forward step would have been taken.

There can be no doubt in any of our minds as to the force in behalf of an enlightened public which rests in the hands of insurance companies; and we must also realize that publicity, and publicity again and again, is necessary to bring about a real advance in the control of cancer. This education must be brought direct to the people. It cannot be left entirely to the medical profession. A doctor may know all about the radical cure of precancerous conditions, or he may not; but if his patient hides her knowledge of the lump until it ulcerates, the doctor's knowledge has lost any value to her.

The men and the women of this country must be made to understand:

1. That cancer is a disease that one person in eight over forty dies of.
2. That cancer is recognizable in an early, or precancerous, stage.
3. That ignorance of the early signs is very dangerous and often fatal.
4. That cancer recognized early and given prompt radical treatment at competent hands is curable in a large proportion of cases.
5. That quack, patent, non-surgical treatment of cancer is responsible for the loss of many lives annually.
6. That ignorance of the early signs and of the necessity for prompt action is a large element in the present mortality from cancer.

These represent the cardinal points, elaborated and emphasized in the tracts, papers, lectures, newspaper articles, etc., which are opening the way for a systematic effort in cancer control similar to the one which has accomplished such large results during the past two decades in the control of the white plague.

In order to put the matter into as concrete shape as possible I have prepared a small folder which will fit into the ordinary premium notice and premium receipt envelope, and which contains a short collection of some of the facts requiring publicity which the Society for the Control of Cancer has indorsed.

I would greatly appreciate the privilege of putting the matter before you in the form of a resolution, as I feel that the formal indorsement of this meeting will carry a great weight in determining action and therefore in accomplishing results. I would therefore like to move, Mr. Chairman, if such action is within my rights, that the Medical Section of the American Life Convention heartily indorse the present movement toward the control of cancer, and that we recommend that during the current year 1916, each company holding membership in the American Life Convention prepare and distribute to its policyholders and agents, in some suitable form, authoritative advice in regard to this disease, its frequency, its treatment, and general control.

The companies that will co-operate in this way will perform a double service—a service to the public and their policyholders in the saving of many useful lives among the latter; and also a service to the companies, in that it will cause a certain increased saving in mortality. If adopted, this concerted action should mark a most valuable forward step in the control of cancer.

RADIUM AND SYMPTOMATIC BLOOD PRESSURE.*

BY DOUGLAS C. MORIARTY, M.D.,

SARATOGA SPRINGS, N. Y.

I HAVE two thoughts which I wish to present for your discussion to-day:—high blood pressure and its significance, and the use of radium for its relief.

The more I see of patients who have a symptomatic blood pressure, the more I am convinced that we do not give them the careful attention they require. These people are invariably moody and nervous, and the knowledge that their blood pressure is high is a constant menace to their health, as they live continuously in a state of apprehension. They are happy if the pressure is down 5 mm. to-day, and morose if it happens to be up 5 mm. to-morrow; notwithstanding the fact that this deviation from day to day is not more than the actual error of manipulation. They are usually uninformed as to the cause of the symptom, and apparently it has never been taken into consideration whether their individual index is a normal one for them or not.

So I believe that our patients should be taught the cause and significance of an increased blood pressure. This would allay the natural perturbation that is felt when they are informed of the presence of this symptom. As a rule, much of the nervousness and apprehension would not have occurred, or will disappear, when their condition is explained and they understand that a high blood pressure is only a *symptom*, and not a disease, *per se*. They should know that their increased pressure is probably a normal index for their pathological state; that its presence is essential if nature is to keep a balance in the performance of her functions; and that, while it is a symptom of a morbid condition, it is necessary, and one that will be present until the exciting cause is controlled. The best illustration we have of this statement is the number of people who go about perfectly happy, with a constant high blood pressure, until they discover that their pressure is high.

I do not intend to minimize the importance of this symptom, nor to suggest that it is not an anxious one. But I must deprecate the unfortunate influence which this knowledge seems to have upon our patients when they are simply told that their blood pressure is increased, without some explanation.

Consequently, when we are estimating the blood pressure of a patient and find that it is relatively high, we should go more into detail; tell him that it is the exciting cause and the pathological condition which are of importance and not the registered measure. He should be told that it is an index to either a functional or an organic derangement; that if the trouble is organic, the increased pressure is necessary, and is nature's method of balance; while if the trouble is functional, an effort will be made to control it by removing or correcting the exciting cause; and that this knowledge must be had, and this conclusion reached, in every individual case that carries an increased blood pressure, and that it is the only criterion.

It is a common observation that both physicians and patients are inclined to the continuous use of drugs to relieve high blood pressure. This is not good practice and should be avoided except to relieve some temporary condition.

*Read before the Saratoga County Medical Society May 3, 1916.

It is well to lay particular stress upon the fact that patients often have a high index which is a normal one for the existing condition; that it is essential to their well-being and must not be interfered with. On the other hand, when we do meet high blood pressure which is a true hypertension, the welfare of the patient will be enhanced when it is controlled. In other words, no patient should be judged by comparison with any other patient, but only after a study of his individual case. In this way only will a safe working conclusion be reached.

So I urge that we explain to our patients that their increased blood pressure is an indication of a more or less complex condition, which may have been developing over a period of years; that it may be functional and involve the toxins of the alimentary tract; or it may be organic, involving the kidneys, heart, and blood-vessels. Explain that such a condition frequently occurs in a hard-working person who has an exacting business, which has been carried on under constant nervous strain, without periods of rest. Such an individual has, perhaps, been in the habit of eating quickly and irregularly, often being over-fed with rich, highly-seasoned, nitrogenous food. When to this are added tea, coffee, tobacco, and alcoholic stimulants, the individual, while still young in years, is old in fact. Thus, as Bishop states, "that which in early life was a case of indigestion, after many years of such living, has developed into a nephritis with a high blood pressure." Perhaps the condition may not have progressed so far as this; or it may have gone still farther, and degenerative changes may have occurred in the heart, kidneys, and blood-vessels. In the latter case, if compensation gives out, we will probably have a secondary low blood pressure which is of serious omen.

I shall not attempt to describe the early, progressive, or late symptoms of arteriosclerosis, as I simply wish to call attention, at this time, to the baneful effect upon the patient's mental condition, of symptomatic blood pressure, when the reason for the presence of this symptom is not fully understood. The successful management of such a case is possible, I believe, only when the patient thoroughly understands its significance.

I have been treating patients with symptomatic blood pressure for years with our mineral waters, particularly those who have come to Saratoga for their health, and with uniformly good results. It has, of course, been necessary to correct the exciting cause, so far as possible, by a carefully regulated régime and not by the use of drugs. I have learned to value the Saratoga mineral waters as a therapeutic agent very highly. I am not unmindful of the benefit of a regulated life, such as is followed when one is taking a cure. I fully appreciate the "few-protein" diet of Bishop and the vegetable protein diet of Kellogg; and I recognize the importance of clearing the intestinal tract and increasing elimination by the use of salines and the alkalies, as well as the advantages of the omission of tea, coffee, alcohol, and tobacco, and the benefit to be derived from the use of mineral-water baths. Yet I imagine I see an effect beyond all these when one uses our Saratoga mineral waters therapeutically. I have also noted that they had a remote effect, *i.e.* a general betterment which was noticeable months after taking a course of treatment at the Springs. It has always seemed to me that the improvement I noted in my patients when using these waters could not be entirely accounted for by their chemical

analyses, and that their action was unusual; and I have for many years expressed myself to that effect. I now believe this remarkable action to be due to their radium content.

It has been my experience that the blood pressure of a patient taking the cure will drop from 20 to 60 mm. of Hg. in a period of from four to six weeks, almost without fail. Of course, I exclude in this statement those in whom advanced cardiovascular or renal degeneration exists. All etiological conclusions concerning symptomatic blood pressure point to perverted metabolism as the primary cause, regardless of the terminal pathological symptom. Physiologically we are taught that radium stimulates the individual normal cell to increased action,

FIG. 1—View of emanatorium.

or corrects a perverted cell action by its influence on the enzymes. It also affects the nervous system and produces dilation of the blood-vessels.

Clinically we know, beyond possibility of contradiction, that it increases very promptly the red blood cells, increases elimination from the kidney, in the quantity of both the water and the solid content of the urine; it also acts as a stimulant to peristalsis, thus being a mild cathartic and increasing in this way elimination from the alimentary tract; and it invariably produces a sensation of general well-being. Possibly small quantities of radium act as synergists, or perhaps the reverse is the case. In any event, mineral waters containing radium salts, or those that are radioactive, have their therapeutic possibilities materially increased.

The objection has been made that a few Mache units of radium contained in a liter of our water could not act as I believe it does. It is, however, a recognized fact that radium possesses an almost incomprehensible catalytic power, even in infinitesimal doses; larger doses do undoubtedly possess added therapeutic possibilities.

After studying the reports of the physicians of the European spas and those from the London Radium Institute, I learned that they generally believed larger doses of radium emanation to be essential to the best therapeutic results; and that while their waters contain radium in larger quantities than our Saratoga mineral waters, yet they had found it helpful to fortify the action of the waters by the further use of radium element. I was impressed with their results, and decided to adopt their methods—this plan of treatment, therefore, I put into effect early in the spring of 1915.

I experienced quite some difficulty in adjusting my equipment for activating water and for inhalation purposes. I have, however, finally succeeded in arranging a very satisfactory outfit which answers my purpose admirably. I have for your consideration some photographs of the apparatus which I trust will prove of interest. The features of more particular importance to which I desire to draw your attention are the following:

1. The subceiling effect, which reduces the cubic air space without the sensation of stuffiness.
2. The electric fans, which keep the air in motion, thereby making the treatment more agreeable.
3. The separate compartments within the emanatorium, together with an improved arrangement for distributing the emanation, make it possible to vary the quantity administered.
4. The provision which makes it possible to freshen the air in the emanatorium by the introduction of oxygen.
5. The arrangement for the removal of CO_2 from the atmosphere.
6. The apparatus for activating water is arranged so that there is very little lost space—therefore we have a high percentage of efficiency.

The entire outfit, although composed of several units, is so constructed that all or any part of the emanation can be thrown into either of the treatment rooms; this also applies to the apparatus which activates the waters.

During the past year I have treated fifty-six cases in which there was an increased blood pressure with radium emanation in addition to our mineral waters plus a regulated régime. These cases may be said to be too few to warrant the formation of an opinion concerning the possibilities of radium, particularly as over half of these patients were under observation only from four to eight weeks; nevertheless I do believe that my experience has taught me that radium possesses valuable therapeutic properties. It will be interesting for you to know that in varying degrees there was in every one of the cases a lowering of blood pressure index and an increased red blood count. I desire to bring to your attention a few brief case histories that may serve to illustrate the above conclusions. My findings as a whole show that radium emanation lowers symptomatic high blood pressure, and I might add that even in cases showing advanced structural changes in the kidney, heart, and blood-vessels I have found it helpful.

CASE I.—Mrs. F.; extremely nervous temperament;

has always lived well; has a cocktail before dinner, and often a highball or wine with dinner. Has suffered with colonic stasis and its concomitant toxemia for several years; is anemic, sallow, and has a red blood count of 4,000,000, the blood pressure varying from 150 to 160 mm. She was ordered to drink radioactive water daily

FIG. 2. Apparatus for activating water. A, motor-driven air pump; C, D, wash bottles; E, radium solution; F, G, protective bottles; J, activated water jar; L, cork for filling.

containing 15,000 m.u. in divided doses. At the end of a month her complexion cleared up; red blood count increased to 4,600,000, with a reduction of the blood pressure to 140 m. and a general sense of well-being.

CASE II.—Miss M., housewife, complained of severe neuralgic pains, malaise, loss of appetite, disturbed sleep, and torpid bowel; distressed breathing on going upstairs. Blood pressure 230; urine negative on repeated examinations, except that the specific gravity varied from 1004 to 1010. Red blood count 3,400,000. She was given 50 micrograms radium element intravenously, followed by a second injection three weeks later of 25 micrograms, with 1 liter (100,000 m.u.) of activated water daily. At the end of four weeks her blood pressure was 180, with a red blood count of 5,400,000, and there was a feeling of general betterment. At the end of eight months her blood pressure is 165; she has had no remedies other than periods of taking the activated water.

CASE III.—Mr. B., age 76, merchant in active life. Complained of shortness of breath and precordial pain on slight exertion; no other symptoms. Blood pressure

230. Urine showed fine granular casts, no albumin; specific gravity 1004-1006. This patient was given 25,000 m.u. of activated water daily in four divided doses. After a distressing reaction it was discontinued, and tried again after forty-eight hours with 15,000 m.u. daily. This was also found to be too large a quantity, and finally 6000 m.u. per day were tolerated, which were later increased gradually until 30,000 were given in twenty-four hours. This resulted in a lowering of the blood pressure to 185, with a decided relief from the symptoms that had appeared on exertion.

CASE IV.—Mr. S., age 74, master carpenter, was seen in consultation. Patient had intense dyspnea on the slightest exertion, was unable to lie prone, had constant cough, with mild edema of the lungs. Both legs were edematous nearly to the trunk; he had a ruptured compensation and a secondary low blood pressure of 105. The urine was loaded with albumin; small and large granular casts were present. He was given 50 micrograms of radium element intravenously, with 25 micrograms one week later; also 1 liter (100,000 m.u.) of activated water daily. In forty-eight hours his dyspnea was relieved and he was able to lie prone; edema of the legs entirely cleared up and he was decidedly more comfortable for a period of two weeks, when he suddenly died.

CASE V.—Mr. D., age 56, in active life; has suffered from glycosuria for three years past. This condition is absolutely controlled by a regulated diet and life, except that he has a constant blood pressure of 158 to 165. This patient was given 40,000 m.u. of radium emanation in activated water daily, which caused a distressing reaction. Eventually he could tolerate activated water containing 20,000 m.u. daily, and continued to take that amount for two months, with the result that his blood pressure was reduced to 120 mm. and remained under 130 for a year.

CASE VI.—Mrs. K., housewife, 60 years old, an active, high-strung, nervous woman. Complained of continuously painful muscles, and that she was not up to her regular duties—headache, malaise, loss of appetite, and disturbed sleep. Bowels regular. Blood pressure 190. Urine negative. I gave her $\frac{1}{2}$ liter of radioactive water (50,000 m.u.) daily. After a period of four weeks blood pressure was 175 and she stated she had not felt so well in years.

CASE VII.—Mr. S., janitor, age 60; hard-working, closely confined man. Is anemic and sallow, has digestive disturbance, and is not able to continue his duties. Blood pressure 185; hemoglobin 65; red blood count 4,800,000. Was given daily a liter of radioactive water.

FIG. 3.—Section through emanatorium, showing scheme for forcing radium emanations into the emanatorium and apparatus for removing CO_2 from the atmosphere. A, motor-driven air pump; B, oxygen tank; C, D, wash bottles; E, radium solution; F, G, protective bottles; H, receptacle for emanations; K, lime-water for removal of CO_2 from the air in the emanatorium.

containing 100,000 m.u., for six weeks with a complete restoration of his well-being. Blood pressure 170; hemoglobin 80; red blood count 5,600,000.

I am aware that the indications for the use of radium emanation could not be determined from these few cases. This is so for two reasons: first, the small number of cases, and second, there is such a paucity of knowledge concerning the proper dosage.

I inaugurate a course of treatment with either radioactive waters, radium emanation by inhalation, or an intravenous injection of radium in the form of a soluble salt. The radioactive waters are given in doses ranging from 25,000 to 100,000 Mache units of emanation per day, in divided doses after meals and at bedtime.

Radium emanation by inhalation is given daily in the emanatorium for a period of two hours—this daily treatment is further fortified by prescribing a varying amount of radioactive water taken at the beginning of the sitting and at the end of the treatment. The ordinary emanation content of my emanatorium shows 250 Mache units of emanation per liter of air.

Radium element in the form of the soluble salts is given intravenously in selected cases either at the commencement of the treatment or after the response to the radioactive waters or the radium emanation by inhalation has not been sufficiently effective. As a rule, I follow the first injection with a second in two weeks, and vary the quantity from 10 to 15 micrograms of radium chloride. Administration of radium intravenously is always followed up with a course of waters and inhalation.

I would sound a note of warning, or at least urge precaution, in the use of large doses of radium emanation at the commencement of the treatment of any patient, as I have many times observed a special reaction from radioactive waters, such as severe headache, malaise, digestive disturbances, and a rise in temperature. When this supervenes the treatment should be discontinued for a day or two, after which the course can be resumed with about one-fourth of the original dosage and gradually increased until the desired result is secured. In this manner of procedure almost any amount of radium emanation can be administered.

There are other clinical points of importance which should be considered, but the time at my disposal will not permit their discussion.

311 BROADWAY

The Vacuum Cleaner as an Insect Catcher.—A writer in the *Scientific American Supplement* suggests that a house can be rid of night-flying insects by lighting an electric lamp in a room, and then as the insects gather they are trapped by holding the nozzle of a vacuum cleaner over them.

THE DIVIDING LINE BETWEEN MEDICAL CHARITY AND MEDICAL BUSINESS.*

By E. A. CODMAN, M.D.,

BOSTON, MASS.

THESE are days in which we hear much of the inherent "rights" of the individual. I suppose that "charity" and "business" are individual "rights," but I doubt if there is any individual right to confuse them as we do in medical practice—in fact, as the public forces us to confuse them. The public demands "humbug" from the doctor and from the politician. Success in either profession is almost unattainable without some of it. Must it be so eternally or can we hope to gradually eliminate it at least from our profession? One of our pet humbugs is to confuse charity and business.

It is difficult to define "charity"—particularly in its semi-medical usages. The work which we do at the charitable hospitals without direct financial recompense—is that charity?

From six definitions of Webster's as to the meaning of the word "charity" I have selected two: First, "Whatever is bestowed gratuitously on the poor for their relief." Second, "That disposition of heart which inclines men to think favorably of their fellow-men and to do them good."

Now, which of these definitions best fits our hospital work? The first is a clear enough definition—"whatever is bestowed gratuitously, etc." It may be a worn-out and worthless shoe that does not fit and gives no relief. It may be a useless operation which we do with good intent, but which results in lifelong suffering. Nevertheless, these are things "bestowed gratuitously on the poor for their relief." Business would bluntly say, "Relief given to the poor, as a part of the business." It would not ask any credit without delivering the goods—i. e. the relief. But this cold business statement lacks the sentiment of sacred intention which accompanies the worthless shoe or the maiming operation!

Now what of the other definition? "That disposition of heart which inclines men to think favorably of their fellowmen and to do them good." There is nothing here which speaks of the poor; in fact, this definition applies alike to rich and poor and it insists that good be done as well. Not an old shoe but a good one. Not a useless operation but one which does good! And there is nothing incompatible in this with good honest business, which Webster says is: "any particular occupation or employment for a livelihood." Good business merely assumes that you do so well that your fellowmen will think favorably of you and do you good also.

The burden of the argument which follows is against the kind of medical charity which combines business and Webster's first definition, and in favor of the kind of business which uses the kind of charity implied in the second definition. The public has had enough of the "whatever is bestowed gratuitously" kind of charity and needs the "do them good" kind, even if it comes hand in hand with honest business. Inefficiency and dishonesty in either charity or business should be equally abhorrent to our profession, and honest business will give efficient charity its full play and help us to have "that disposition of heart which inclines men to think favorably of their fellowmen and to do them good." This is difficult under present hospital con-

*Read before the Harvard Medical Society of New York on January 22, 1916.

ditions. Pretence and humbug perhaps even more than "commercialism" tend to make us think unfavorably of our fellowmen. Our present system of conducting "charitable" hospitals is full of pretence and humbug. If we frankly acknowledge the business part of it, there is still plenty of chance for honest "charity." The ideals of the medical profession can be better maintained by conducting business with "charity" than by pretending that our "charity" is not business.

A GEOMETRICAL DEMONSTRATION OF THE PROPOSITION THAT CHARITY SHOULD BE ELIMINATED FROM MEDICAL BUSINESS WHICH SHOULD, NEVERTHELESS, BE CONDUCTED WITH CHARITY.

PRESENT USAGE

FIG. 1

Fig. 1. Let the hexagon include all cases which are under the care of the medical profession whether these cases are rich or poor, curable or incurable, efficiently or inefficiently treated by quacks or scientists, regular or irregular practitioners. You know the absurdities under present usage. The rich and fashionable are paying ridiculous fees. Sometimes to osteopaths or other irregulars for great relief or serious damage; and sometimes to our best surgeons, gynecologists, and practitioners for simple and occasionally useless or inadequate operations or courses of treatment. We see simple cases which any well-trained young doctor could care for, taking the time and energy of some great teacher; we see the most difficult cases being operated on by the young and inexperienced interne who will never be a good surgeon; we see many an ambitious young surgeon relatively idle during his best years between the interne and the staff appointment. We see well-to-do cases in the charitable hospitals and the most pitiable cases of respectable poverty paying their last dollar for inefficient treatment from some too busy man with a "reputation." Perhaps worst of all we see the nonproductive "practical" surgeon who uses the hospitals for what they are worth to him without paying back to medical science by teaching and research the debt which he owes her for his opportunities. Contrast his golden harvest with that of the truth-seeking pathologist whose services are so invaluable and yet so grossly underpaid.

Fig. 2. This hexagon represents the ideal which we all seek and the community would be glad to grant us. Even when all cases become curable it will require educated labor to cure them. The community has always been willing to pay enough money; the trouble has been to distribute it evenly.

The money now spent by the State, by the municipalities, by endowed institutions, etc., taken with that now *earned* by the medical profession or squandered on quacks or on the "successful" members of our profession, would be ample to take care of the

THE IDEAL

FIG. 2

health of the community if the organization of our work was thorough. But we have not yet begun to subdivide our work on any rational basis. Let us do it now as far as we can into charity and business, curable and incurable, rich and poor.

CHARITY

BUSINESS

FIG. 3.

Fig. 3. Let the hexagon still include all cases and let us divide them into those appropriate for medical charity and those appropriate for medical business. Obviously the dividing line cannot be a sharp one. A case which would be an expense to a busy surgeon would mean a few dollars more to some recent graduate. It is the relative wealth of the patient and the doctor which determines the question in most cases. Nevertheless, some cases are surely subjects for good business and others are surely objects of charity. We can, therefore, draw a dividing line if we do not make that dividing line definite. The important question is as to which side of the middle to draw it. Depending on this decision it will, though indefinite, become a variable increasing toward its limit. Everything in the world can be subdivided and each subdivision can in turn be subdivided. The question is then, does the line progress toward the business side or toward

the charity side? Is it desirable to have medical business or medical charity take care of the mass of the people?

CHARITY

BUSINESS

FIG. 4.

Fig. 4. I think you will all agree that our American democratic ideals would answer that any decent self-respecting body of people would want to pay justly for goods delivered. We should all be glad to see charity in its usual meaning approach its minimum limit. We should be glad to see justly paid medical business take care of so many cases *successfully*, that the endowed institutions could use part of their funds for salaries for the men who are able and willing to study how to relieve the few remaining incurables. The more that abstract medical science (= endowed teaching and research institutions) turns over to applied clinical science (= the practitioner and self-supporting private institutions) the more educated, honest laborers (= careful practitioners and salaried specialists in institutions) will be needed.

INCURABLE

CURABLE

FIG. 5.

Fig. 5. Again the hexagon includes all cases. All cases can be divided into curable and incurable if the dividing line be indefinite. Some pathological conditions are always curable; some always (hitherto) incurable, but the majority are now one and now the other with the infinite variations of circumstance and personality. But surely we can say that

the object of our highest professional ideals is to conquer the hitherto incurable diseases and to teach the rising generation of students how to efficiently apply our knowledge. Perhaps this dividing line may still be on the *curable* side, but its direction of progression is toward the *incurable*, as in Fig. 6.

INCURABLE

CURABLE

FIG. 6.

Fig. 6. This illustrates the variable "curable cases" increasing toward its limit and the variable "incurable cases" diminishing toward its limit.

POOR

RICH

FIG. 7.

Fig. 7. Again the hexagon represents all cases, but this time there is the same indefinite line to separate the rich and the poor. The equitable distribution of wealth is the aim of political and economic science. Whether this is to be brought about by monarchy or democracy, socialism or feminism, war or the single tax is not less one of the problems of our profession than of the rest of mankind. At least, we may agree that this variable should approach the limit of the total exclusion of poverty from our hexagon.

Fig. 8. If it were not for envy and jealousy there would be no logical objections to the rich becoming richer, provided the poor did also. This diagram merely argues that the proper direction for progress is to make the poor richer not the rich poorer. Everything which we know is a variable approaching a limit. The polygon itself by the addition of

an infinite number of sides tends to become a circle. The outer circle is our "ideal"—the mathematical conception of a circle; the inner circle is the "practical" and contains what little we do know. When we work in unison with the expansion of the inner

which are those that are both poor and incurable and hence objects of charity. Therefore it is desirable to increase the province of the business triangle by cutting off areas from the other triangles. We want to keep business from inefficient meddling with the incurable rich so that the money which the rich are glad to pay to individuals or to bequeath to institutions will be used for the incurable poor and the salaries of those invaluable men who are conquering the incurable diseases. We want to oblige business to relieve charity of the curable poor so that charitable funds can be concentrated on the study and care of the incurable poor.

FIG. 8.

circle toward the outer circle, we stand for truth and are happy. When we distort truth for our own end, for our institution or for our country, we sing out of tune with the universe and sooner or later are unhappy.

FIG. 9.

Fig. 9. In this figure all our original hexagons (Figs. 3, 5, and 7) are superimposed. Which triangle thus formed is the most desirable? Starting with business and going to the right. (1) Those in the business half that are both rich and curable. (2) Those in the business half that are rich and tending toward the incurable. (3) Those that are in the charity half but are rich and incurable. (4) Those that are in the charity half that are both poor and incurable. (5) Those that are in the charity half but are poor and curable. (6) The curable poor cases in the business half. Obviously the two most appropriate triangles are the first, in which are those cases that are both rich and curable and are, therefore, rightly cared for by medical business, and the fourth in

FIG. 10.

Fig. 10. If, in Fig. 9 we were correct in thinking that the business triangle should expand by absorption of the others, and in Figs. 3-8 we were correct in estimating the direction in which the variables were increasing, then by superimposing the second set of diagrams (Figs. 4, 6, and 8) we should find the two in unison and the business triangle become a smaller hexagon increasing toward its limit inside of a larger one. This we do actually find to be the case and from it we see that the smaller hexagon—honest medical business or applied clinical science—treating only curable cases—constantly taking on more poor for the sake of treating more rich—relieving charity of the curable, etc., etc., is the ideal we were seeking in Fig. 2. *Quod erat demonstrandum.*

Like other geometrical propositions this problem has its corollary. For the future development of medical science we must acknowledge applied clinical science or medical business as a legitimate child and educate it to be honest as well as learned. My philosophy would add other sides to the hexagon, justice versus injustice, truth versus falsehood, and so on until a many sided polygon is formed and show you that a circle growing within a circle is the symbol of human progress.

Practically, what can the modern physician do toward the realization of these ideals? Such radical changes do not come suddenly; it is by helping a little in one direction and then in another that we push good things along.

You know my answer—help on the End Result System. It is the part of our medical science to determine which are curable cases suitable for business (= applied clinical science) and which are relatively incurable cases suitable for special study

and record by experts in scientific institutions.

Let each hospital and each individual in each hospital put off on the "man higher up" every case in which he seriously doubts his own ability to effect a cure. And *vice versa* let each of us who are the "men higher up" refuse to care for the simple curable cases which our juniors can treat as well as we can. Most of our best men do this now, but let us make it the fashion, so that those who do not do it will be unpopular.

When this applies to individuals it will begin to apply to hospitals. Why should the small poorly equipped, poorly financed non-teaching hospitals be allowed to experiment with unusual and difficult cases? Let us encourage the small hospitals to send their bad cases to the great teaching hospitals—let us even put some penalty on such small hospitals unless they show good results—and honor them if they do. And let us encourage private hospitals which advertise to treat only those cases which they are qualified to treat and thus render themselves subject to litigation if negligent or unscrupulous. Even if appendices, like teeth, can be pulled for a dollar, there will be plenty of expert work left for the medical profession.

The more that any science can turn over to "applied science" or business, the greater service it is to the world and the more does the world value it. Let us make for the truth-seeking, scientific clinician a place comparable to that of the great electrical and engineering experts to whom even "big business" has to turn. Let the "charitable" people of the world through the endowed institutions pay such men salaries large enough so that they in turn can be "charitable" if they want to, without pretending that their business is "charity."

Let us encourage those of our colleagues who use charity for business to get out of charity into honest business—provided they use *applied science* and deliver the goods as the bridge builders, electricians, and chemists do now.

In other words, let us legitimize the "no cure; no pay" idea which for centuries has been the bugbear of "the men higher up" in the profession. The "leaders" of the medical profession even to-day, perhaps fear that if they once admit that which is logically obvious, *i.e.* the end result system and its corollaries—that their own incomes might materially decrease. This is a ridiculous fear for the best men will still be the best men, and all will be better men if we discard an ignominious old bugbear which shielded medical science in its infancy like a protective tariff.

Nowadays the medical profession is safe in acknowledging the obvious right which any man has to treat patients *successfully only*, because in order to do this a team of trained and honest men backed by a responsible financial support is necessary to set up a successful "No Cure No Pay Institute." Such an institute will have to pay for mistakes and accidents as the railways do.

The real question is: Have we yet attained a sufficient fund of applied clinical science to be able to allow such an institution to pay a profit?

227 BEACON STREET

Pain at Root of Neck and Cardiac Irregularity.—Dr. D. Owen Williams has noted this condition in a woman aged 59. There was marked local pulsation with coupled beats corresponding to the heart sounds. Under appropriate cardiac treatment the pain passed away within four days, the heart sounds becoming normal.—*British Medical Journal*.

THE PRACTICABILITY OF RATINGS IN APPOINTMENT AND PROMOTION OF MEMBERS OF THE VISITING STAFF.*

By ROBERT L. DICKINSON, M.D., F.A.C.S.

BROOKLIN, N. Y.

CAN the municipality select surgeons for its hospitals without some clear and full schedule of the qualifications that make for fitness?

Are qualities various, and institutional needs various, and is some classification feasible?

Can boards of trustees of semi-private hospitals name staff members on mere reputation and opinion and decide between rival candidates on such a basis?

Can the American College of Surgeons grant diplomas without plotting the factors that make up the merit that can claim membership?

Shall the College, in a nation-wide study of hospitals (or even the Pennsylvania Bureau of Medical Education and Licensure, in their list) endorse institutions that, in appointment and promotion, lack any real study or detailed knowledge of the *quality* of the work of the members of their staff.

And is it not fair to say that no city, nor trustee, nor college receives reports showing how this dele-

gated power over life and death is used, while any government office makes records of the quality of the work of the personnel, and any well managed factory knows how to do it?

I dare to present a scheme for such records in hospitals. These err, of purpose, on the side of overfulness. They are submitted with two prefatory statements; first, that it is the firm belief of their compiler that while an analysis like this is desirable the general impression concerning a professional man in the minds of his colleagues is, as a rule, a correct and fair valuation. Second, that the labor and expense of obtaining and maintaining a record must not exceed its value in increasing the efficiency of the workers.

There are but two thinkable attitudes toward marking and comparing the qualifications and efficiency of professional men. Either one may contend that it is not feasible to lay a yard stick to

*Part of paper presented before Harvard Medical Society, New York, January 22, 1916.

common sense or set a gauge on judgment; or else, one may divide the hospital work to be done by the physicians and surgeons into its component parts and study results, and then seek to analyze the characters and traits needed to effect these results. The old point of view that regarded medicine as something mystic and intuitive we need not discuss here. You know, as the public does not, that there is no hospital governing board, which, when a vacancy occurs or the day for annual appointment comes round, can ask for the equivalent of a baseball fielding average or race track record, or government office rating as applied to visiting surgeon, house surgeon, or nurse. A consensus of opinion made up of general impressions and personal preference or prejudice decides. No record of effectiveness and personal characteristics exists. Seniority, friendship, and many unavowable undermotives actuate a choice or a promotion. The time has surely come for us to catch up with the Civil Service, with the army and the navy, and with many corporations.

From all available sources I have asked for counsel, and from this experience and advice plans were worked out to meet the need of more accurate measurement of men in our profession when the demand came to six of us, in this way. The Advisory Committee of the new Greenpoint Hospital was urged by the Commissioners of the Department of Public Charities of New York City to labor to make it the best possible under the circumstances, and to select its personnel for fitness only. When we began to define fitness it was found to be no simple matter.

Then when the Deputy Commissioner asked us to present a detailed annual report concerning the character of the work done by each member of the Professional Staff the committee did not know where to turn for a plan of rating such work and a method of charting it. Yet we saw that his claim was reasonable in asking for nominations based on demonstrable performances and characteristics, and that work must certainly permit of analysis. "The report," said Mr. Wright, "if possible, should contain more than statistics as to the number of appendectomies or pneumonias, *i.e.* it should show by collateral information the general result of these operations. We should know not only whether or not we are doing needed work, but also whether or not our work is producing as speedy and good results as possible."

I believe we would all welcome some not too complex scheme of record of performance, "provided that the trouble and expense of obtaining and maintaining such efficiency ratings did not exceed the value of the record in increasing the effectiveness of the service." Happily, most happily, our best authority on the subject, Griefenhagen, assures us that the Civil Service experience and departmental work has shown that of the several methods of marking employees a "system which is 50 per cent. accurate will probably have about 90 per cent. of the practical value of a system that is absolutely accurate."

"The processes involved in the preparation and keeping of efficiency records have many desirable effects in indirectly increasing the efficiency of the service. The process of standardization, and the determination of the superior officer who shall furnish the data upon which markings are to be based, invariably bring the internal organization of each department to light, make it necessary to define

clearly the responsibility of each superior officer, establish definitely the lines of authority, eliminate conflicts, indicate defects in the scheme of organization and often make the remedy obvious. *A record of conduct and attitude of employees must indicate conformity with regulations and this naturally necessitates the preparation of such regulations, which in itself is a desirable thing.*"

The speaker showed slides covering the charts of the organization of the personnel of a newly rebuilt semi-private hospital of 280 beds, with its seventy professional appointments (including out-door services), and also of the new municipal hospital of 250 beds, together with the charts clearly defining power and functions and activities of the different boards and groups and individuals. The lines of authority and responsibility in all of these were the result of the study of the particular institutions. Only one sample of the eight charts is here given.

REPORT ON CANDIDATE FOR HOSPITAL (OR DISPENSARY) POSITION

Name	Age	Address	Date
Education; school, college year and degree (specializing at college in any matters bearing on this appointment); medical college, year and degree (any special work bearing on this appointment). Post-graduate courses, American or foreign; time in each; name of teachers; degrees or certificates. Training for special work.			
A—Experience; hospital, residence; duration, service covered (medicine, surgery, obstetrics, specialties); special hospital, if any, and names of heads of services under whom duty was actually performed.			
Training in technical or manual dexterity.			
Training in laboratory methods.			
Training in teaching—didactic, clinical.			
Training in writing, publications, editorial work (stenography, typewriting, charting, drawing).			
Training in research.			
Training in executive work.			
Dispensary Service —Name of institution.			
Duration of service.			
Name of chief of service.			
Size of service.			
Variety in service.			
Hospital Visiting Service —Name of institution.			
Duration of service.			
Name of chief of service.			
Size of service.			
Variety in service.			
How many months on duty each year as assistant or in charge of service?			
Medical Societies; past and present memberships, with years of membership, together with average attendance and average frequency of taking part in program and discussion; in committee work; in official positions. American and foreign conventions and congresses attended.			
Visits to Clinics; habit of seeing other men at work. Dates of visits to clinics other than in New York City.			
Related Interests; social service and municipal work, such as Health Department, Red Cross, health propaganda, etc.			
Other Interests.			
B—Quality of Previous Professional Work (thoroughness, rate of work, effectiveness).			
1—Preliminary examinations, habit of consultations.			
2—After-care, examinations for discharge, instructions to follow on.			
3—Histories, personal inspection, personal notes, reviews.			
4—Laboratory work, supervision, personal work.			
5—Training of subordinates; hospital staff, dispensary staff, nurses.			
6—Record of end-results and habits of following up cases.			
Diagnostic Skill.			

Technical Skill in treatment and operation.
Judgment.

C—*Personality*; integrity; disinterestedness; obedience to rules, team-play; kindness, cheerfulness; enthusiasm, and ability to inspire these.

D—*Progressiveness* (see medical societies and clinical travel, ante). Original work; new methods, operations, instruments, and plans of organization devised or participated in.

E—*Executive Ability*; initiative; organizing power control; continued attention to and interest in administrative detail after organizing; follow-up.

F—*Teaching*; staff, dispensary, students; nurses; in public clinics.

Summary:

Signature of examiner making special detailed report.

Signatures of Board endorsing this report in case of nomination.

Note—Examiner will initial statements which he can verify of his own personal knowledge or from personal inspection (*e.g.*, histories, operative skill).

A FORM OF ANNUAL REPORT ON THE EFFICIENCY OF EACH MEMBER OF THE PROFESSIONAL STAFF.

Name	Position held	Date
------	---------------	------

Average number of beds in his charge

(Salary Residence in hospital, yes, no

Year of appointment)

A—*Quantity of Work*; months on duty; total visits required; total visits made; total hours given to hospital (or dispensary); vacation; illness, absences, excused, unexcused.

Estimated committee service (work done for institution other than strictly professional).

B—*Quality of Work* (thoroughness, rate of work, effectiveness in each of the following factors):

1—Preliminary examinations; habit of holding consultations.

2—After-care, examinations for discharge, instructions to follow on.

3—Histories, personal inspection, personal notes, reviews, studies on end-results.

4—Laboratory work, supervision, personal work.

5—Training of hospital staff, dispensary staff, nurses.

6—End-results (Codman method): The end-result cards easily grouped for each individual, record successes and errors, the errors scored as

(a)—Lack of technical skill.

(b)—Lack of judgment.

(c)—Lack of care or equipment.

(d)—Lack of diagnostic skill.

Failures grouped also by

(a)—Patient's enfeebled condition.

(b)—Patient's unconquerable disease.

(c)—Patient's refusal of treatment.

(d)—Surgical or medical calamities.

Methods; comments on full histories by Chief review by Consultant or Efficiency Committee; choice by Staff of certain operations as tests (*e.g.*, suppurative in clean laparotomies).

C—*Personality*; integrity; disinterestedness, obedience to rules; team-play; kindness, cheerfulness, and ability to inspire these.

D—*Progressiveness*; study of literature; travel to other clinics; membership and attendance at medical societies; originality; researches; publications.

E—*Executive Ability*; initiative; originality; organizing power; control; continued attention and interest in administrative detail after organizing.

F—*Teaching*; staff, dispensary, students, nurses; at public clinics.

G—*Inspections*; number by Trustees, Consultants, Hospital Inspector.

Certain defects to be heavily scored—such as lack of judgment. Percentage to be given under each heading to be determined. Positions differ. Some positions will have a score for executive work, and some for teaching, and others will not. This will involve grouping and reporting such positions separately, but any man's abilities in any of the above matters should be noted even if not marked on a score.

168 CUNTON STREET

WHAT IS MEANT BY HOSPITAL EFFICIENCY AND SOME OF THE FACTORS WHICH ARE OFTEN RESPONSIBLE FOR LACK OF EFFICIENCY.*

By WINFORD H. SMITH, M.D.,

BALTIMORE, MD.

THERE was a period when I was thoroughly tired of the word sanitary, and to have a method or an article urged upon me on the ground that it was sanitary was almost more than I could stand. I have reached somewhat the same state of mind with regard to the use of the term efficiency.

We have heard so much about hospital efficiency and the views expressed have been so different that I venture, with due apologies, to comment briefly upon the question, What is meant by hospital efficiency? and to mention a few factors which are commonly responsible for lack of efficiency. Those who are prone to discuss this subject have measured efficiency in many ways—by the per capita cost, by the number of patients treated, by the number of operations performed, by the average length of stay in the hospital, by the mortality rate, by the amount of research done, by the use of follow-up systems, by the surplus or deficit and so on. Now any one of these may be a factor in, or the result of, but not the measure of efficiency.

The number of patients treated and the number of operations performed may indicate to some extent the volume of work done, but they tell you nothing as to the character of the work done or of the results obtained.

The mortality rate may be an interesting item, but it is meaningless unless you know something as to the character of the service—whether acute or chronic, or what percentage of the patients was medical, what surgical, and how many were moribund on admission.

A follow-up system may or may not be an important factor. If it gives you information that enables you to finish a job which was not finished, although you thought it was; if it enables you to draw conclusions helpful to the development of a better technique, or a better treatment, then it is a factor of efficiency. If, however, it simply collects a mass of statistics, some useful but for the most part of no value, and with the latter concealing the former, which is often the case, then it is anything but efficient.

The average length of stay in the hospital may indicate a slow or rapid movement of population, but what is its significance? It means nothing unless we know all of the facts. Was the service acute or chronic, or both? Were the patients possibly discharged too soon, and what were the final results of treatment?

The surplus or deficit is a valuable index in judging the efficiency of a commercial enterprise, but it tells you nothing about the efficiency of the hospital, except as the result of a careful investigation. It simply indicates that the hospital does or does not need more money with which to meet the demands made upon it. If only those hospitals were efficient which show a surplus, then few could qualify.

Then there are those who would measure efficiency by the amount of research done. While re-

*Read before the Harvard Medical Society, New York, January 22, 1916.

search is a legitimate and important factor and should always play a part in the development of the larger sphere of usefulness of the hospital, the fact remains that the patient is the first consideration, and research may be over-emphasized at the expense of the patient. Only when research is carried on in a manner consistent with the best interests and the best possible care of the patient can it be said to occupy a legitimate place in hospital procedure.

Then there is that all-important factor in the minds of many—the per capita cost. While used generally as a basis of comparison, the per capita cost really tells you nothing, except as applied to the particular institution under consideration. Comparisons on this basis are footless, unless one is familiar with the methods of computation and with the character and scope of the work done in the institutions under comparison. The methods of determining the per capita cost may be and usually are radically different. Two institutions may be very different in character and scope of work; one acute, the other chronic; one largely medical, the other chiefly surgical; one maintaining a large and expensive private service, the other having no private service; one spending much on such features as laboratories, x-ray, social service, adequate nursing service, salaries to staff, and in upkeep of the plant, while the other may spend little or nothing on such features, merely skimping along with an incomplete equipment and an inadequate staff in a rapidly deteriorating plant. Therefore, the per capita cost, while it may indicate efficiency or the reverse, can only be properly interpreted by one thoroughly familiar with all details.

I recall some statements on this subject by a prominent surgical authority. Among other things he cited a hospital with a per capita cost of \$1 per day as a standard and proceeded to condemn all hospitals with a higher cost as wasteful and extravagant. It would be about as sensible to state that because one surgeon can perform an amputation in ten minutes, any surgeon taking longer than that is incompetent.

And so we might continue discussing single factors or results without answering the question, What is meant by hospital efficiency? The term efficiency used in any sense implies a power capable of producing a result, implies somewhere a productive energy. Following that thought for a moment, the primary purpose of the hospital is the treatment and care of the patient, and the end result should be all that modern knowledge and skill, supplemented by the necessary facilities, can accomplish at the hands of the carefully selected individuals composing the organization. The organization then, given the facilities, is the power which produces the result. The thoroughness and completeness with which the work is done should be the gauge of hospital efficiency rather than, or as well as, the ratio of production to energy expended.

I have said that the patient is the prime consideration. It has sometimes seemed to me that institutions in their efficiency programmes have eliminated too much of the human element, and that the danger of efficiency systems as applied to hospitals is to consider them too much as cold, mathematical problems. Hospital efficiency, as I choose to interpret it, means thoroughness, with sympathetic consideration and uniform kindness.

It means the courteous reception of the patient when he presents himself, with due consideration of his claims to charity; prompt, skillful medical and surgical attention; careful and skillful nursing; thorough study not only of the symptoms and findings, but of the bearing which these have or may have on the problems of the disease under consideration—all of which means accurate and complete records; the discharge of the patient at the proper time, with a full knowledge as to his ability to carry out instructions and of the suitability of his home surroundings for continued convalescence, and the machinery with which to make proper arrangements when necessary; and throughout the whole course of hospital procedure a careful attention to business detail, economy of time, effort, and materials, at the same time avoiding any tendency to look upon individuals as mere cases or numbers, but rather to maintain an atmosphere of sympathetic, human interest, encouragement, and harmony throughout.

I wish to refer to a few factors which are commonly responsible for lack of efficiency. The part which lack of funds plays needs no comment. Poor planning is too often responsible for waste of funds both in construction and management, for waste of effort on the part of all workers, for lack of comfort, if not actual discomfort to the patient. Indeed, poor planning often renders it actually difficult to adapt the buildings to the purpose for which they were built.

In large cities, hospitals are located with too little consideration of the needs of the section selected, with the result that some sections have more hospitals than are required, while other large sections are absolutely without hospital provision, necessitating long trips in order to get to a hospital, with consequent loss of time and of energy often at low ebb.

Organization, first and last, is one of the most important factors. Consider for a moment boards of trustees. The board of trustees is the governing body and the final authority, and should, therefore, be formed with the greatest care. Yet how frequently this board is composed of men who have no qualifications for the office other than social standing, money, or political influence! Boards so constituted either take no interest whatever, or what is equally bad or worse feel it a duty to take an active part in the detailed management of affairs foreign to their experience, with the result of confusion and lack of harmony. For detailed management, some boards divide into committees on every possible phase of the work. My only comment on this custom is to quote from a speech by President Butler: "A committee is an American invention for evading responsibility and postponing action." The board of trustees should be the final authority, and should supervise and control and conserve the financial resources of the institution, but should leave the detail of management to the officers and staff and hold them responsible.

The staff organization is no mean factor in hospital efficiency, and much can be said on the subject. First, I wish to say that no member of the staff should be eligible to the office of trustee. With regard to appointments to the staff, it cannot be too strongly emphasized that such appointments should be made on merit alone—the merit of achievement, of recognized ability, the best man for the place. Appointment should not de-

pend on local residence, political influence, social standing, or length of service, which may have been and often is a service of questionable merit. One thing more—the staff member who fails to recognize the necessity of co-operation, of team work, who has an eye only to self-advancement, is a stumbling block, no matter what his ability as an individual performer.

The superintendent! He, too, is sometimes a stumbling block, sometimes difficult. He is an important factor and should be selected with the utmost care. A trained medical administrator is preferable, because of his broader point of view. He should be the executive officer of the board of trustees and the medium of communication between that body and all other departments. He should have the authority as well as the responsibility, and should at all times receive the support and backing of the trustees and of the staff. I am sorry to say, however, that this support is frequently conspicuous by its absence. 'Tis sad but true that the superintendent usually enjoys about the same degree of popularity as the umpire at a ball game. That he is often difficult, lacking in tact, and overbearing, I must admit. He should be a director who harmonizes and coordinates, but not a dictator.

Now let me emphasize, by way of example, a few individual sins. There is the surgeon who persistently orders for operation more cases than he can possibly do, with the result that some who have been through the pleasant experience of starvation, preparation, and nervous prostration have forced upon them the pleasure of further anticipation. This is neither efficiency nor even fair play.

Then there is the surgeon who is never on time and who, not infrequently, fails to come at all, without sending any message to that effect. This results in tying up a whole force of assistants and nurses, and oftentimes keeps a patient under anesthesia for an indefinite period to no purpose, which is inexcusable.

I would not seem to be partial to the surgeons, therefore I wish to mention the medical men who drop in casually for formal rounds at any time, usually during the serving of the patients' meals. Some medical men are subject not infrequently to acute exacerbations of energy, or are stung by the research bee and order all sorts of specimens saved and measured, only that they may be thrown out later unexamined. It is difficult to understand their efficiency ideas. These are merely examples, the list of which could be made much longer, but these will serve to recall others I am sure, if you care to think about it.

Hospital internes, fresh from medical school, find it difficult to bring their superior minds down to the consideration of the (to them unimportant) practical routine of institutional life, and are often intolerant of the lamentable lack of knowledge on the part of their seniors and are impatient at the inability of the responsible authorities properly to manage affairs. They need to learn to suffer patiently, as their seniors have done, and, therefore, they need a good example, the lack of which is my point.

I recall, too late I fear, a maxim that "A man may say too much even on the best of subjects." The whole purpose of these remarks has been to emphasize that many factors enter into the creation of hospital efficiency, and that all of us who

form a part of the organization must do our part, with due regard to the interest of our fellow workers, being ready to receive as well as to give advice and criticism, and always to bear in mind that the keynote is harmony.

JOHNS HOPKINS HOSPITAL.

NOTES ON THE ETIOLOGY OF THE RECENT EPIDEMIC OF PSEUDO-INFLUENZA.*

BY WM. WHITRIDGE WILLIAMS, M.D.

AND

WARD BURDICK, M.D.,

DENVER.

In the early part of November, 1915, an epidemic made its appearance in various parts of this country which closely simulated the epidemic of influenza occurring in 1900. During the latter part of this month it began to invade Denver, following, we were informed by the local weather bureau, a prolonged dry spell which was suddenly terminated by severe windstorms. During the height of the epidemic it was estimated by physicians competent to judge that there were about 50,000 cases in Denver. It was accompanied by serious complications, such as nephritis, myocarditis, arthritis, bronchopneumonia, otitis media, etc., and was responsible for markedly increasing the death rate.

Simultaneous with the beginning of the epidemic there began to appear in the sputa and other discharges which were placed in our hands for bacteriological diagnosis a peculiar streptococcus. These notes are based on the examination of eighty-seven specimens. In ordinary smears of the specimens the germ appeared as a lanceolate diplococcus, Gram-positive, surrounded by an indefinite halo, suggestive of a capsule, and not to be differentiated from the pneumococcus in appearance. But chain formation took place when grown in neutral broth. It was pathogenic for both white and brown mice and no capsules were demonstrable surrounding the germs recovered from the heart-blood. Inulin-serum-water was not fermented, but some of the strains of this germ produced acid. They were insoluble in bile and bile salts. Growth in many of the anaerobic tubes was more profuse than in the aerobic. Twenty-four-hour growths on human-blood-agar plates showed pin-point colonies surrounded by a very slender zone of hemolysis. Rabbits inoculated intravenously with this germ developed definite symptoms characterized by a sudden rise of temperature to 102°-103° F., drowsiness, loss of appetite, etc. Post-mortem examinations on these rabbits killed forty-eight hours after inoculation revealed in most instances a tracheal and bronchial inflammation, thus suggesting a selective action. No such selective action was manifested after four or five generations of subculture. After repeated cultivation the colonies on blood-agar became larger and more hemolytic, and anaerobicity disappeared as well as the acidulation of inulin-serum-water. Complement fixation tests made with the blood serum of pseudoinfluenza patients, using as antigen a suspension in salt solution of the streptococcus isolated from the sputa, gave positive results in all cases.

Thus we have another example of the streptococcus possessing temporary labile, cultural, and pathogenic properties. The almost innumerable strains of this microorganism evidently owe their tempo-

*From the laboratory of the National Jewish Hospital for Consumptives, Denver, Col.

rary pathogenic and cultural characteristics to environment and rapidly revert to ordinary forms when grown under the conditions of artificial culture media. Rosenow (*Jour. Am. Med. Assoc.*, 1915, LXV, 1687), in a recent article making a preliminary report of some research being done by him on the streptococcus, gives other splendid examples of this by the demonstration of specific selective action manifested by various strains of this germ which had been isolated from divers pathological conditions.

Medical Notes.

Expert Testimony Need Not Be Based on Personal Observation Alone.—The Circuit Court of Appeals, Fourth Circuit, holds that the knowledge of medical experts or of experts in any science or art would be extremely limited if it extended no further than to inferences from phenomena falling within their own experience. Their testimony is admitted as valuable because based on their special knowledge, derived not only from experience, but from the experiments and reasoning of others, communicated by personal association or through books or other sources. It is more or less valuable according to the source from which it comes, but the general proposition that it is of no value unless based on personal experience is not sound. The principle is well stated in 1 Wigmore on Evidence, 782, in the discussion of the reasons for the admission of physicians as experts: "To deny the competency of a physician who does not know his facts from personal observation alone is to reject medical testimony almost in its entirety. To allow any physician to testify who claims to know solely by personal experience is to appropriate the witness stand to impostors. Medical science is a mass of transmitted data; the generalizations are rare which are the result of one man's personal observation exclusively; and the law cannot expect its petitioners to obtain these rare persons. The law must recognize the methods of medical science. It cannot stultify itself by establishing, for legal remedies, a rule never considered necessary by the medical profession itself. It is enough for a physician, testifying to a medical fact, that he is by training and occupation a physician; whether his source of information for that particular fact is in part or entirely the hearsay of his fellow practitioners and investigators is immaterial."—*Perkins v. United States*, C. C. A., 228 Fed. 408.

Expert Testimony in Murder Case.—In a prosecution for murder it was held to be error to allow a physician to testify as an expert to the relative positions of the deceased and the person who shot him, deduced from the nature and direction of the wound, since the jury was equally capable with the physician of drawing proper inferences from the facts proved.—*Noble v. State*, Alabama Court of Appeals, 70 So. 187.

X-Rays as Demonstrative Evidence.—In an action for malpractice, where there was positive testimony that the plaintiff's arm was in the same condition when x-ray photographs were taken as it was when treated by the physician, it was held that such photographs were admissible in evidence notwithstanding there was other testimony as to an intervening injury to the plaintiff's arm.—*Ligon v. Allen*, Kentucky Court of Appeals, 181 S. W. 656.

Practising without Authority—Compensation.—In a prosecution of a physician for practicing without authority, evidence of a witness that the defendant treated his wife and received his board and lodging as compensation therefor is admissible.—*Young v. State*, Texas Civil Appeals, 181 S. W. 472.

Expert Testimony—As to Whether Shot Was Self-Inflicted.—In a prosecution for assault with intent to commit murder in the first degree, it appeared that the accused's wife was shot in the left side of the head and also in her left arm above the elbow. She herself said she remembered nothing of the occurrence. On appeal from a conviction, it was held to be error to allow a medical witness to testify that it would not have been possible for the injured woman, who was found with a revolver in her hand, to have shot herself in the manner in which she was shot. He might have testified as to his opinion as to the range of the bullet. But the ques-

tion whether a delicate woman can reach around with the right hand and shoot herself in the left side of the head, or whether she can do so, at the same time shooting herself through the left arm, is not peculiarly a matter of expert learning on the part of a physician, and was for the determination of the jury. The conclusion was one which the ordinary practical mind might reach, as well as the trained physician, and could be more readily reached by one trained in the use of firearms. It was not a question of anatomy, but of the physical use of the hand and arm with a Colt's 25 automatic revolver. The doctor might have known very little about the use of such firearms.—*State v. McCravy*, Tennessee Supreme Court, 181 S. W. 165.

Expert Testimony as to Effects of Blows on Live and Dead Bodies.—In an action for wrongful death of a man who was run over and killed by a train on the defendant's railroad, the plaintiff placed on the stand a physician of standing and experience. He had no knowledge of the facts in issue, and had not seen the deceased's body. He was put on as an expert, and testified that if the body of the deceased was bloody, with bruised places on it, or discolored or blue places, and the skin red in other places, then, in his opinion, the man was alive when struck, because, owing to the circulation of the blood in a live body, blood will flow from a wound and will settle and discolor a bruised place, and will make the skin red in places; whereas, in a dead body, the blood is not in circulation, and hence these manifestations will not appear. It was held that this testimony was properly admitted. There was evidence that blood was found when the deceased was struck. The undertaker testified that the body was much bruised; that he had to wash the blood off, and after doing so the skin was red and discolored. The doctor's testimony was merely to the effect that this redness of the skin and discoloration showed that there was circulation of the blood through the body at the time the man was struck, and this circulation showed that he was then alive. This did not invade the province of the jury. It was upon a scientific subject, and dealt with the difference in the effects produced by a blow on a dead body and on a live one, arising out of the different states of the blood under these conditions.—*Friemuth v. Kansas City, St. L. & C. R. Co.* (Mo.), 180 S. W. 1063.

Hearsay Evidence.—In an action for personal injuries in alighting from a moving train a doctor was allowed to testify that the plaintiff told him a day or two before the trial and some months after the injury that he was still spitting blood. It was held this was erroneous. It was, of course, competent for the plaintiff so to testify, but that did not make it permissible for the doctor to repeat this self-serving statement.—*St. Louis, I. M. & S. Ry. Co. v. Bostic*, Arkansas Supreme Court, 180 S. W. 988.

Prisoner's Consent to Physical Examination.—In an action for assault with intent to rape a child of nine, the State established that about one or two weeks after the assault was alleged to have been committed the prosecutrix was found to be suffering from gonorrhea, and it introduced the evidence of two physicians, which tended to show that at the instance of the prosecuting attorney they went to the county jail, where the defendant was confined, and there made a physical examination of his privates. They testified that this examination disclosed that the defendant was also afflicted with gonorrhea, a circumstance tending to strengthen the chain of evidence against him. It appeared that the prisoner had not been apprised of his rights to resist his examination and was merely silent when he was informed the physicians were there to make it, instead of positively consenting thereto. It also appeared that he had been expecting a physician sent by his own attorney to examine him before the attorney would agree to represent him and that this physician arrived immediately after the examination began and took part therein. It was held that the evidence of the two physicians was inadmissible.—*State v. Matsinger*, Missouri Supreme Court, 180 S. W. 856.

Privileged Communications.—Under the Missouri statute declaring that a physician shall be incompetent to testify as to any information which he may have acquired from any patient while attending him professionally, which information was necessary to enable him to prescribe as a physician, it is held that a physician's testimony, in a prosecution for abortion, that the prosecutrix had made statements to him as to the cause of her condition, was competent.—*State v. Carryer*, Missouri Supreme Court, 180 S. W. 850.

BREAD AS A FOOD.

BREAD has always been known as the "staff of life," and among those who live in temperate climes is the synonym of food. It is the staple diet of the poor in that part of the globe inhabited by the members of the white race. Consequently, it is obviously of the greatest importance that food of such universal use should possess the highest nutritive value possible. Of recent years, investigations in various countries have demonstrated the fact that a certain content of a diet is essential to the maintenance of good health. This content is known as vitamine content, and when it is absent from a diet, it may bring about one of the so-called deficiency diseases. For instance, rice is the staple diet of the majority of Asian people. When the rice is highly polished (that is, deprived of its outer husk) it is also deprived of its vitamine content, the superpericarpial or aleurone layer containing this necessary constituent. The continued consumption of such rice will result in beriberi unless articles of food in which vitamins are present, although only in minute quantities, are added to the diet. When undermilled rice is substituted for the highly milled variety, the disease is not nearly so apt to break out.

In Public Health Reports for April 14, 1916, Drs. Carl Voegtlin, M. Sullivan, and C. N. Myers, United States Public Health Service, have a paper dealing with the changes in the vitamine content and nutritive value of bread with reference to the occurrence of pellagra. There have been several theories with respect to the etiology of pellagra, and the results of the investigations reported by the above trio of workers refer particularly to conditions prevailing in the United States, and are the outcome of studies on the cause of pellagra in this country. Up to the year 1880, or thereabouts, bread was made from flour or corn meal, from which the coarser particles of bran were only partly sifted out, and which therefore contained practically all of the nutritive elements of the whole grain. With the introduction of the roller-mill system into the United States, the highly milled flour products came into vogue. The germ and bran were largely discarded as human foods. While the highly milled products keep better, they are often deficient in the accessory food substances, designated as vitamins. Myers and Voegtlin have amply demonstrated the

point that, whereas the corn meal and wheat flour made by the old-fashioned process, which is still in use to some extent in the South, contains to all intents and purposes, all of the vitamins of the whole grain, the highly milled products are markedly deficient in these substances.

Experiments on fowls have proved that if these animals are fed exclusively on highly milled products, they will die within a month of polyneuritis, a disease very similar to beriberi. Thus, there seems to exist a perfect analogy between the well-known relation of the polishing of rice to its nutritive value, and that of the milling of wheat and corn to the nutritive value of wheat flour and corn meal. The destructive action of baking soda on the vitamine content of corn meal is also referred to at some length by the authors.

However, the conclusions reached by them with respect to the bearing of their findings on the occurrence of pellagra in the South are of special interest. It has been suggested by several investigators that pellagra belongs to the group of the so-called deficiency diseases, meaning that the diet which gives rise to pellagra is deficient in vitamins, having no direct relation to the protein, fat, and carbohydrate content of the diet. This hypothesis is based on the observation that the diet of people who develop pellagra seems to be made up of foods which are not rich in vitamins, and in a general way the dietary studies in Southern families made by the Experimental Station of the Department of Agriculture and recounted in Bulletins No. 38, No. 71 and No. 221 of that department and some unpublished more detailed investigations by Voegtlin and Miss Nesbit appear to corroborate this observation. At any rate, it is plainly obvious that a satisfactory solution of the cause of the increase in pellagra which has been endemic in Spartanburg County, South Carolina, for the past seven or eight years is intimately connected with the etiology of this disease. It is important in a high degree that a satisfactory answer should be found as to how the dietary conditions of the population of the South changed previously to the great increase there in pellagra. The authors in conclusion point out that several factors seem to have played a rôle in the reduction of the vitamine content of the diet of the people of Spartanburg County during the past twenty years. Most prominent among these influences are: First, the reduction in the diet of vitamine-rich foods—fresh milk, eggs, and meats; second, the introduction of highly milled cereals, and third, the use of baking soda, which has been shown to exert a destructive action on the vitamine content of bread. The staple of diet among these people is wheat biscuits made from highly milled wheat flour, and corn bread made with baking soda without the addition of buttermilk which would counteract the injurious effect of the alkali on the vitamins.

It certainly appears to be something more than a coincidence that the above mentioned influences, which have undoubtedly reduced the vitamine content of the diet, made themselves felt a relatively short time before the rapid increase in the pellagra incidence in this section of the country, and fur-

nishes evidence of considerable weight in favor of the vitamine-deficiency theory of pellagra. Of course, further and more exhaustive investigations will have to be prosecuted ere any intimate connection can be traced between the increase of pellagra in the South and the consumption of highly milled corn and wheat, and, indeed, of other food substances lacking in vitamins.

THE HEALTHFULNESS OF HARD WORK.

Do we work too hard and play too hard? Are nervous breakdown and increase in mental disease due to the high tension at which we live? This has so long been the accepted slogan that we wonder when we began this increase of speed and this unnatural output of energy. G. F. W. Patrick has set the matter before us recently¹ in a plea for the proper forms of relaxation, reminding us that the earlier physiological forms of reaction demand attention and, denied it, will sooner or later assert themselves in such violent reversionary tendencies as are now ablaze in Europe. We are concentrating too intently, he says, upon the higher nervous centers and overdeveloping them in the modern straining for efficiency and success in achievement. Even when we do allow relaxation we do not know how to attain it but carry the same ill-balanced intensity into our seeking there and run with a certain madness to one form of amusement or another.

Patrick's book brings timely warning. The ideal must be that nice adjustment between work and play, between serious effort and sufficient indulgence in relaxation which enables one to be the best that one can be in oneself and toward society. The question, however, is one of larger adjustment than this. It is not too great an amount of work nor too great concentration upon the higher centers involved in it that conditions nervous and mental collapse. What if this complex striving after efficiency is in reality the strain and disturbance of conflicting infantile tendencies? Then there is failure of adaptation to social cultural demands. Too much of effort utilized in all directions in the serious business of the world is founded or at least lost in jealousy, envy, greed, opportunity for self indulgence, toil to-day for more ease and luxury to-morrow. These tendencies are disguised and concealed, and pass recognition.

But there is a different form of work which makes for psychic health. It does not deny self-interest, but it unifies the whole nature in one dynamic aim, which is creative in desire and purpose. It finds its relaxation without effort, for all forms of this, too, it draws within its circle and animates with the controlling vital motive. It does not bend all toward a goal of acquisition nor even of some great and glorious future of perfected inactivity. That also is infantile phantasy. This kind of work is nothing less than the outflow of the immortality implanted in the depths of human nature. This is a force which cannot be checked, but it can be frustrated by misdirection into channels of self-seeking. Flowing free, however, in its proper productive

¹The Psychology of Relaxation, Houghton Mifflin Company, 1916.

course, it makes for perfect health. This is that interest which harmonizes work and play into one purpose with successful adjustment. Nor is it unattainable.

THE ROLE OF THE DENTIST IN THE MAINTENANCE OF HEALTH.

It is in the nature of things more or less of a necessity to have good teeth. Without sound teeth, either mastication is ineffective and the food is ingested in such a condition that it gives rise to disorders of digestion, or soft foods are eaten which require little or no mastication and throw little or no work on the organs of digestion, so that the latter in course of time from lack of use lose their efficiency.

With regard to mastication it is interesting to note that it is essentially the vegetable portion of our food which demands thorough chewing. As Dr. Harry Campbell points out in an article in the *Lancet*, April 8, 1916, the carnivora do not masticate their food, while, on the other hand, all the vegetable-feeding mammals are laborious masticators. This is because vegetable food consists of a cellulose framework more or less dense, which it is necessary to break up, so as to liberate the contained nutrient particles and allow them to come under the action of the digestive juices.

Man, as is shown by a study of the teeth of primitive man and of our ape relatives, is a masticating animal, but the work of the miller and cook in civilized life has to a great extent relieved us of the laborious work. The vegetable food we eat nowadays is for the most part served in pulpy, pappy, pultaceous, and spongy forms; it is not properly mixed with the saliva, a most necessary process of good digestion, and the teeth and salivary glands are cheated of their normal work. Mastication, then, is all important if health is to be preserved and maintained at a high standard. The best way to secure adequate mastication is to choose foods which invite or even compel mastication, and this advice or warning applies, in particular, to the cereal foods. As said before, however, proper mastication is difficult or impossible if the teeth are defective. If they are not capable of doing their work effectively, a dentist's aid must be called to remedy the defects. False teeth, well put in, are better by far than a lack of teeth or defective teeth, but undoubtedly a good deal of the trouble with teeth could be avoided by insisting that children should eat foods which exercise the teeth and salivary glands adequately. Finally, it may be said that the health of a people depends largely upon the condition of teeth and mouth. The teeth should be not only sound but they and the mouth should be kept in a thoroughly sanitary condition. Therefore, the rôle of the dentist is most important.

DISAPPEARANCE OF DEXTROSE FROM THE BLOOD AFTER INTRAVENOUS INJECTION.

IN the study of carbohydrate metabolism it has been shown that when dextrose is injected intravenously, even in large amounts, it disappears rapidly from the blood. This disappearance takes

place even if the ureters are tied so that the excess is not eliminated by the kidneys. It is not accompanied by a sufficient increase in the glycogen of the liver to account for it. Kleiner has therefore attempted (*Jour. Exper. Med.*, 1916, xxiii, 507) to discover what becomes of this excess of sugar. He found that this disappearance of dextrose from the blood took place in nephrectomized animals, in those in whom the aorta and the vena cava were ligated immediately below the diaphragm, and even in dead animals whose only circulation was produced by massage of the heart. He was able to show that there was a notable increase in the carbohydrate content of the muscles and obtained some evidence of the existence of higher carbohydrates, as if the glucose were in part polymerized in this tissue. In all his calculations, however, there was a certain percentage of dextrose which remained unaccounted for. In the experiments with whole dead animals he was able most nearly to solve this problem. In these he found about sixty per cent. of the injected glucose in the muscle tissue and only six per cent. unaccounted for. The phenomenon is, therefore, apparently independent of vital processes and of important abdominal organs. It is possible that analysis of other soft tissues would reveal the storage place of the remaining sugar, but the experiments certainly emphasize the importance of the muscles in carbohydrate storage. Certainly a large amount of glucose is burned by this tissue. It would be interesting to apply Woodyatt's results in the continuous injection of dextrose into animals to this problem as carried out by Kleiner, to see whether the accumulation of dextrose or the substance into which it is changed would be sufficiently marked to make its recognition easier.

News of the Week.

City Death Rate.—During the week ending April 29, the death rate in New York City was 0.8 of a point lower than the rate for the corresponding week of last year, the respective rates being 14.83 and 15.63 per 1,000 of population. This decrease was equivalent to a saving of 86 lives. The total number of deaths during the week was 1,588. Noteworthy decreases occurred in the number of deaths due to measles, scarlet fever, diarrheal diseases, pneumonia, pulmonary tuberculosis, and heart disease. For the first eighteen weeks of 1916 the death rate was 15.44 per 1,000, as compared with 15.65 for the corresponding period of last year.

Deaths of Oldest Graduates.—By a curious coincidence three physicians whose deaths are noted in the obituary columns this week had attained the distinction of being among the oldest living graduates of their respective colleges. Dr. David Fisher Atwater of Springfield, Mass., was born in 1817, and was graduated from Yale University in 1839 and from the Yale Medical School three years later; Dr. Samuel F. Coues of Cambridge, Mass., was born in 1825, and was graduated from Harvard College in 1845; and Dr. George A. Quinby of New York was born in 1831 and was graduated from the New York University Medical College in 1856.

College Raises Entrance Requirements.—The Long Island College Hospital, Brooklyn, announces that after January 1, 1918, the completion of two years of study in a college of liberal arts or science will be required for admission to the four-year

medical course leading to the degree of M.D. At present the requirement is one year only of college work. Beginning in the fall of 1916 Columbia University, New York, will conduct a pre-medical college year at the Long Island College Hospital.

Street Accidents.—The report of the National Highways Protective Society for April states that during the month forty-two persons were killed on New York City streets, twenty-three of whom were children. Thirty-two were killed by automobiles, five by trolleys, and five by wagons, as compared with twenty-one by automobiles, seven by wagons, and ten by trolleys during the corresponding month of last year.

Class Dinner.—More than forty physicians, members of the class of 1896 of the Medical Department of New York University, celebrated on May 6 the twentieth anniversary of their graduation by a dinner at the Biltmore Hotel. Dr. Hiram Williams of Passaic, N. J., presided as toastmaster, and addresses were made by Dr. Frederick L. Brush, superintendent of the Burke Relief Foundation, Dr. Sinclair K. Royle, and Dr. Lester M. Hubby.

Jacobi Dinner.—The directors of the Dispensary and Hospital for Deformities and Joint Diseases, New York, on May 3 gave a dinner at the Ritz-Carlton Hotel to Dr. Abraham Jacobi in celebration of the eighty-sixth birthday of the "dean of the medical profession" in New York. At the same time announcement was made of the receipt of gifts amounting to \$112,000 to be used for the new buildings of the hospital, for which it is estimated one million dollars will be needed. The work of raising this sum will be begun at once.

Red Cross Hospitals.—The New York County branch of the American Red Cross, having received gifts amounting to the \$50,000 necessary, has placed orders for the equipment of two military base hospitals in this city. Each hospital will be equipped with 500 beds. Three full staffs of surgeons, nurses, and orderlies have already been organized for base hospitals, under the direction of Dr. George E. Brewer, Presbyterian Hospital, Dr. George D. Stewart, Bellevue Hospital, and Dr. Charles L. Gibson, New York Hospital, and efforts are being made to obtain sufficient money to cover the equipment of the third hospital.

United Hospital Fund.—The sum of \$110,000 was distributed on May 1 by the United Hospital Fund, formerly the Hospital Saturday and Sunday Association, among forty-five hospitals in New York. This is the largest sum ever distributed by the organization, and is a proof that the demands of the war sufferers have not been met to the detriment of local charities. To the eighteen general hospitals in the city, \$57,737.77 was given, those receiving large grants being:

Mt. Sinai	\$8,745.16
New York	8,113.75
St. Luke's	7,931.17
Post-Graduate	7,843.25
German	7,322.87
Roosevelt	4,738.55
Lincoln	3,745.88

Eleven special hospitals received \$19,689.36, distributed as follows:

Orthopedic	\$1,449.02
Ruptured and Crippled	3,032.60
Deformities and Joint Diseases	1,006.10
Manhattan Eye, Ear, and Throat	1,975.29
Eye and Ear Infirmary	1,810.04
Ophthalmic	788.06
Knapp Memorial	442.75
Skin and Cancer	2,056.74
General Memorial	1,374.24
House of Rest	2,147.04
Neurological	607.48

The hospitals for women and children received

\$19,223.23, of which \$5,129.12 went to the Lying-In; \$2,867.67 to St. Mary's Hospital; \$2,295.64 to the Woman's Hospital; \$2,079.21 to the Infirmary for Women and Children; \$1,638.15 to the Babies' Hospital, \$1,542.53 to the Sloane Hospital, and \$1,196.31 to the Nursery and Child's. Grants were made to five hospitals for incurables and convalescents amounting to \$13,344.64. The Montefiore Home received \$8,949.67, the largest grant made to any institution; the Home for Incurables \$2,257.31, and the Isabella Heimath \$1,064.61.

Gifts to Charities.—By the will of the late Miss Martha H. Andrew of New York, the New York Skin and Cancer Hospital receives a bequest of \$50,000, the Home for Incurables and the Hahnemann Hospital receive \$25,000 each, and St. Luke's Hospital receives one-fifth of the residuary estate.

By the will of the late Miss Caroline Willard of Auburn, N. Y., the Auburn City Hospital receives a bequest of \$15,000.

Trinity Hospital, New York, receives a bequest of 100 shares of stock in the Alexander Realty Company, the value of which is not stated, by the will of the late Alexander Campbell of Brooklyn.

St. Luke's Hospital, New York, receives a bequest of \$100,000 by the will of the late Mrs. D. Willis James of this city.

Connecticut State Medical Society.—The 124th annual meeting of this society will be held in Bridgeport on May 17 and 18, under the presidency of Dr. Max Mailhouse of New Haven. Three scientific sessions will be held and an interesting program has been prepared, including the presidential address on "Some Defects and Inconsistencies in Connecticut Statutes and Medico-Legal Procedures." All the meetings, as well as the annual banquet on May 18, will be held at the Hotel Stratfield.

Medical Society Elections.—**WORCESTER NORTH DISTRICT (MASS.) MEDICAL SOCIETY:** Fifty-eighth annual meeting at Fitchburg on April 25. The election of officers resulted as follows: *President*, Dr. Alfred A. Wheeler, Leominster; *Vice-President*, Dr. Elmer G. Fosgate, Ashburnham; *Secretary*, Dr. Curtis H. Jennings, Fitchburg; *Treasurer*, Dr. Frederick H. Thompson, Jr., Fitchburg.

CALIFORNIA STATE MEDICAL SOCIETY: Annual meeting at Fresno on April 19 and 20. Officers elected: *President*, Dr. George H. Kress, Los Angeles; *First Vice-President*, Dr. Lamont R. Willson, Fresno; *Second Vice-President*, Dr. John C. Yates, San Diego; *Secretary*, Dr. Philip Mills Jones, San Francisco. The convention of 1917 will be held in San Diego.

LITCHFIELD COUNTY (CONN.) MEDICAL SOCIETY: 152d annual meeting at the Litchfield County Hospital, Winsted, on April 25. Officers elected: *President*, Dr. David D. Reidy, Winsted; *Vice-President*, Dr. Charles H. Turkington, Litchfield; *Secretary*, Dr. Thacher S. Hanchett, Torrington.

MEDICAL ASSOCIATION OF GEORGIA: Annual convention at Columbus on April 20 and 21. Officers elected: *President*, Dr. Jarvis G. Dean, Dawson; *Vice-Presidents*, Dr. J. M. Anderson, Columbus, and Dr. C. K. Sharp, Arlington; *Secretary*, Dr. W. C. Lyle, Augusta.

Obituary Notes.—Dr. WILLIAM ALEXANDER CHRISTIE, formerly of St. John, N. B., a graduate of the Bellevue Hospital Medical College, New York, in 1893, died in Montclair, N. J., on April 29, aged 55 years.

Dr. JOHN J. BRINCKERHOFF of Minooka, Ill., a graduate of the College of Medicine of the Univer-

sity of Illinois in 1897, and a member of the Illinois State Medical Society and the Grundy County Medical Society, died at St. Joseph's Hospital on April 4, following an operation on his throat, aged 47 years.

Dr. JOHN FERDINAND BATES of Setauket, N. Y., a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1860, died at his home, on April 19, aged 82 years. Dr. Bates was a member of the Associated Physicians of Long Island.

Dr. DAVID F. ATWATER of Springfield, Mass., a graduate of Yale University Medical Department, New Haven, in 1839, and the oldest graduate of the University, died at his home on May 2, aged 99 years.

Dr. SAMUEL F. COUES of Cambridge, Mass., a graduate of Jefferson Medical College, Philadelphia, in 1849, and formerly a medical director in the United States Navy, died at his home on May 1, aged 91 years. Dr. Coues entered the naval service as assistant surgeon in 1851, was made medical director in 1876, and was retired with the rank of rear admiral in 1887. At the time of his death he was the second oldest graduate of Harvard University.

Obituary.

SAMUEL MAX BRICKNER, A.M., M.D.,

SARANAC LAKE, N. Y.

DR. SAMUEL M. BRICKNER, formerly of New York, died in Saranac Lake, after a long illness, from tuberculosis, on May 4, aged 49 years. Dr. Brickner was born in Rochester, N. Y., and was graduated from the University of Rochester in 1888, and from the College of Physicians and Surgeons, New York, in 1891. He served on the house staffs of the Sloane Maternity Hospital and of Mt. Sinai Hospital, and was connected with the latter institution continuously until ill-health compelled his retirement in 1913, at which time he was associate gynecologist to the hospital. He was a member of the American Medical Association, the Medical Society of the State of New York, the New York Obstetrical Society, and the American Association of Anatomists, and had written many articles on medical subjects. At the time of his death he was the editor of the *Medical Pickwick*.

GEORGE A. QUINBY, M.D.,

NEW YORK.

ON May 3 there died at his residence, in this city, Dr. George A. Quinby, a practitioner of medicine whose sterling ability was well known to the elder members of the profession. Born at Parsippany, N. J., March 4, 1832, Dr. Quinby attained the ripe age of eighty-four years. He was the oldest alumnus of New York University, and had been intimately associated during his active years with the work of various hospitals in this city, and more especially with surgical undertakings. In 1856 he was appointed surgeon on the staff of New York Hospital, and eight years later became a member of the medical staff of St. Luke's Hospital. For some years he had practised in Morristown, N. J., with much success, and this success was continued after he had taken up his residence in New York. Dr. Quinby was a man of impressive personality, a linguist, and a traveler. He was a brilliant conversationalist who cast a delightful spell upon all his hearers.

Correspondence.

IS THE PROFESSION PREPARED?

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—This seems a pertinent and timely question to ask of the profession at large and of the younger members especially in these dark hours when the question of military preparedness is asked of everyone. From the purely civic standpoint fundamentally each one of us is a citizen, and as such is constitutionally liable to military service in time of war, and unless chaos reigned we would be called to serve in the Medical Corps, owing to the special equipment we possess by reason of the advantage of our medical education. From the humanitarian standpoint we have already enlisted in the battle against disease, pain, and suffering, and nowhere is this to be found more poignant and urgent than in actual battle; so that we have here a double responsibility to arouse us to answer any call to arms. The cause of the medical man in war is *always* just.

The next point is: Is his service to be efficient? Certainly not, as the profession now stands. Efficiency in military service is to be obtained only through system and cooperation, and what two matters are further from the daily practice and habit of the doctor? This is only natural, considering the fact that his life is made up of the individual contact of the doctor with the patient and the irregular calls that are made upon him. It is only in the last few years in the larger hospitals and centers that any real system and cooperation have been built up, and at best they are only partial and comprehended by only a small part of the profession. This is the crux of the matter. Efficiency in military medicine as elsewhere equals cooperation plus system.

A medical volunteer may be able to give the best possible treatment to an individual case, but when that volunteer becomes a medical officer he becomes a part or cog of a huge machine, and it depends on his success or failure as a cog as to whether the huge salvage mechanism runs smoothly or is crippled or breaks down, and not on his professional accomplishments. He is primarily an officer with unaccustomed duties of administration, command of hospital attendants, orderlies, stretcher corps, ambulances, hospital equipment, and a thousand and one other matters which must be promptly and properly attended to before the accustomed medical problems have even to be faced. A man may be able to meet splendidly one emergency at a time in his practice, but how about the hundreds, yes thousands of emergencies which in war time will fall upon his untrained hands all in one moment? Here is where system and efficiency count. The problem of the line officer is to maneuver, provision, and use the healthy, able-bodied men in his command. The problem of the medical officer is to collect, transport, maintain, protect, and treat disabled and crippled soldiers. Which is the more difficult problem? And the line officer has the right of way and transport for what he wants, while the medical officer has to yield the road to men and munitions if necessary and make use of what he can lay his hands on to help out his ambulances in the task that is always too big. And yet it takes a man four years in West Point to get his lieutenancy, while in time of war the volunteer doctor gets his lieutenancy practically for the asking. In the Spanish War, look at the

records of death and disability from wounds and disease—camp sanitation and care of sick as against leadership and tactics. The dysentery of Gallipoli as against the charge of the Light Brigade. Which cost more? Which, therefore, should demand more training?

Now what can be done to meet the crying need for training of medical men along military lines, to give them a smattering at least of the fundamentals and essentials, and to inculcate the esprit de corps and the great primary essential understanding—the conception of cooperation and system and their absolute necessity? Aside from the regular Federal medical services we have: (1) The Medical Corps of the organized militia. (2) The Medical Reserve Corps and the training camps and courses connected therewith. (3) The development of this branch of medical education in the medical schools and the extension of the Plattsburg idea to medical students in their line of special training.

It is to the last two that we can turn most hopefully for the widespread education of the profession, especially the younger men. It is to this group of younger men that the need of training applies most, for it is this group upon whom it will fall to do the active field work, the harder physical and rougher medical work that is to be done near the front, where the conditions to be met will be most radically different from their previous practical experience. The older men who serve at the base hospitals will not find the conditions so rudely different from their accustomed work. These young doctors can easily affiliate with the Medical Reserve Corps, and in many cases take advantage of the active training given in the summer camps or by correspondence courses. For the third and fourth-year students let me recommend a profitable use of a small part of the long summer vacation in going to the training camp for medical students, at Tobyhanna, Pa., which is now assured. This is a new opportunity for students this summer, being a direct extension of the Plattsburg idea to the medical sphere, and the course to be given will correspond practically to that given the regular Medical Reserve officers.

Finally, let us all, the younger men in particular, take to heart the matter of equipping ourselves for the joint service of our country and our fellowmen, and see to it that we do our best in that direction while there is yet time, for, if through our neglect or laziness the profession is caught by a crisis unprepared for this vital function, others—many others—will have to pay the heavy price of unnecessary suffering and unrewarded sacrifice and death.

ROBERT W. JOHNSON, JR.

BALTIMORE, MARYLAND.

EXTRACTION OF THROMBUS FROM THE PULMONARY ARTERY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the "Fifty Years' Progress of Medicine and Surgery" contributed by me to the anniversary number of the MEDICAL RECORD, appears a reference to the Trendelenburg operation for extraction of a thrombus from the pulmonary artery as "a most intrepid and often successful emergency procedure." This statement, although cautiously worded, has been criticized on the part of competent judges, such as Drs. Matas and Vincent, as mislead-

ing and not in conformity with facts. Owing to the technical difficulties of the operation the survivors so far have been restricted to hours rather than days after this interference. Undoubtedly a vastly greater amount of benefit has accrued through the progress in vascular surgery represented by the intrasaccular aneurysm operation, not only in the preservation of life, but also of a useful existence, through the prevention of gangrene, and the rescue of otherwise doomed extremities.

F. ROBBINS, M.D.

NEW YORK

THE METHOD OF TRANSFUSION OF BLOOD TREATED WITH SODIUM CITRATE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In regard to Dr. Richard Lewisohn's letter in the MEDICAL RECORD of April 15, 1916, I have the following to say:

I claim to be the originator of the "Method of Transfusion of Blood Treated with Sodium Citrate" as my experiments on rabbits were done successfully during the first week of January, 1914, and were related to members of the staff of St. Francis Hospital before any publication concerning the safe use of sodium citrate in blood transfusion was made.

Through my animal experiments I have proved conclusively that sodium citrate is not toxic as it was formerly believed to be to animals and naturally also not to man when injected in proper quantities. If Dr. Lewisohn will examine the solutions used by me for transfusion in animals and man he will find that his and my claims for the determination of the proper dose of sodium citrate to be used for blood transfusions are practically identical the only difference being that I was nine or ten months ahead of him. These facts and my opinion in regard to them cannot be changed.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

PSYCHOLOGY OF RUMOR—INFANT MORTALITY—RUSSIAN MEDICAL MISSION—BELFAST HOSPITAL—BIRMINGHAM MATERNITY—DEATH ATTRIBUTED TO AIR RAID ALARM—OBITUARY.

LONDON, April 15, 1916

WE have been talking at the Royal Society of Medicine on a subject somewhat out of the usual run—the psychology of rumor. It was started by Dr. Bernard Hart in the section of psychiatry, which he opened by the provisional definition of the transmission of a report through a succession of individuals, the product of the narratives of a series of witnesses. The reliability of any rumor depended on the accuracy with which such statements were transmitted; ultimately on the accuracy of the first reporter, who was assumed to have seen or heard for himself the occurrence. This is evidence, and its investigation logically precedes that of rumor. Formerly the moral character of the witness was regarded as a criterion of reliability; now each individual statement is separately estimated, including unconscious action or bias. Experimental investigations upset the popular notion that evidence given with the best knowledge and interest is certainly correct, or that if incorrect it is proof of culpable carelessness or of falsehood. Completely

correct reports are exceptional. One investigator found only 2 per cent. to be errorless. Even attestation is not a perfect guarantee of accuracy, for in sworn testimony one investigator discovered 10 per cent. of errors. Increase of the time interval from the event to the report showed range and accuracy were both lessened, but the confidence of the reporter showed surprising constancy. Hence, readiness to swear to the truth of his assertions depends rather on the character of the person than on the quality of his memory. Children's evidence is to be received with great caution; their assurance is high but their capacity for reproducing what they have seen is very low. The psychological factors leading to the perversion of evidence were next considered by Dr. Hart under the divisions of perception, conservation, and reproduction, and then the "complexes" as to each. Afterward he referred to the social phenomenon of rumor and its relation to the psychology of the crowd. Its susceptibility to the action of a "herd instinct" explained the readiness to embrace non-rational opinions and beliefs. During a great war this instinct was stimulated to the maximum degree and the prevalence and vitality of rumor were accordingly also enhanced.

In the House of Commons the latest figures for last year on infant mortality were officially stated on the 5th inst. Under one year of age the rate was 110 per 1000 births; in the previous 10 years it amounted to 115. In 1914 it was 105; in 1913 it was 108. Local expenditure has been generally carefully supervised with a view of restriction, but there is equal activity in the direction of lessening infant mortality and promoting generally their welfare. Some local authorities have appointed health visitors, who advise mothers, and in the larger towns maternity and child welfare centers have been established at which nursing or expectant mothers can obtain medical aid; in others accoucheurs and further assistance is provided for necessitous mothers and children. A Parliamentary grant of over £40,000 was distributed among such cases in the last financial year.

At an inquest on the 5th inst. a medical man attributed the death of a child two months of age to shock from air raids. He had seen several others. The coroner professed respect for the doctor's opinion, but could hardly think that a child of two months would be so susceptible, though he could understand the effect on the unborn.

A Russian medical mission is now in England investigating our military hospital régime and the care of the wounded. The inquiries will be subsequently continued in France.

The Belfast Royal Victoria Hospital had its annual meeting on the 31st ult., when it was stated that 3,189 new cases were admitted and 258 remained from the previous year, making a total of 3,447 in-patients treated in the year. The average daily number was 266.8, an increase from the previous year, which was 238.1. There were many sailors and soldiers from active service, who did remarkably well. Many others were admitted for operation found necessary before enlistment.

The medical officer of health for Birmingham reports between 4,000 and 5,000 fewer births last year than in 1914. The governors of the Maternity Hospital report 544 admissions, compared with 640 in 1914 and 532 in 1913. Members of the Infant Health Committee visited 249 infants, paying 1,908 visits.

The Central Medical War Committee has determined not to call up practitioners under the enrollment scheme unless and until 75 per cent. of those of military age on January 5 and not holding a commission have since that date been accepted for His Majesty's forces.

Sir A. R. Simpson died on the 6th inst. He succeeded his uncle, the late Sir James Y. Simpson, in the chair of midwifery at the Edinburgh University, retiring in 1905. At the general elections in 1910 he contested unsuccessfully the seat for Edinburgh and St. Andrews universities.

Dr. David Hooper, who was formerly curator of the Economic and Art Sections of the Indian Museum at Calcutta, has been elected president of the Pharmaceutical Conference.

Sir Geoffrey Cornewall and Mr. Almeric Paget, M. P., have been elected governors of Guy's Hospital.

Dr. W. B. Richardson died suddenly on the 30th ult. at Blackpool, where he was in practice about 40 years. He was 69 years of age and honorary surgeon to the local hospital for about 20 years.

Sir T. B. Crosby, M.D., died on the 7th inst. He was the first doctor to be Lord Mayor of London. He graduated at St. Andrews, was at one time on the Senate of the London University, president of the Hunterian Society, and held other honors. He gathered a conference of the mayors of the chief cities to consult on the great coal strike during his mayoralty, and on the loss of the *Titanic* he raised a Mansion House Fund, which reached £300,000, for the relief of the sufferers.

Dr. H. W. Fitzgerald-Powell, member of council of the Gynecological Society, and formerly surgeon to the Throat Hospital, died on the 5th inst.

1. Chronic Backache. Herman W. Marshall.
2. Fracture of the Lumbar Vertebrae and Transverse Processes. James Warren Sever.
3. Occupation as a Remedial Factor in Hospitals for the Mentally Sick. Emily L. Haines.
4. Alcohol in Relation to Mental Disease. A. J. Rosanoff.
5. Cerebral Syphilis. James B. Ayer.

1. Chronic Backache.—Herman W. Marshall reviews the different types of back trouble, citing cases illustrative of static back strain, low back strain associated with injury, back strain in adolescents due to anemia and relaxed muscles, backache due to flexed scapula, postural shoulder strain, sacro-iliac strain with permanent lateral and forward list of the body, hypertrophic arthritis of the spine and infectious arthritis of the spine. The writer then discusses the significance of anatomic variations in lumbar spines and sacra, relaxed sacro-iliac joints and physiological variations of strengths of back muscles. He thinks that many lumbosacral symptoms may be due to minute relaxations representing more than mild strains which are without any ligamentous stretchings, but on the other hand, less than obvious relaxations that can be made out on superficial, hasty examinations; and that corresponding with these microscopic laxities, presumably there are minute displacements which cannot be distinguished on examination, but which patients appreciate and speak of frequently as sensations of something giving away in their backs. The strength of muscles and ligaments are dependent upon the variable qualities of the blood and theoretically, any deleterious influence of the blood may be a remote cause of muscle strain and postural

back weakness. It seems probable on physiological grounds that vascular causes are fairly numerous. Therapeutic procedures at least should be directed always toward restoring the blood to its usual standard in addition to prescribing physiological exercises and mechanical orthopedic supports for weakened or irritated muscles. Rarer causes of backaches are local pressures produced by metastatic cancerous growths in vertebrae and by fibromata of the coverings of the spinal cord. Neuritis of the peripheral nerves is caused by toxic influences of the blood sometimes, and must be considered especially in the group of sciaticas. Diseases of the nerve cells must also be included in the complete list and herpes zoster and intercostal neuralgia as well as the psychomyalgias and the hysterical manifestations must also be mentioned. In considering the treatment of these various kinds of backaches the variable efficiencies of orthopedic treatment and surgical measures are discussed more particularly. The writer says he thinks it is safe to manipulate sacro-iliac joints gently when muscles are relaxed by ether. Success sometimes attends these efforts, and if perfect replacements are not secured no harm is done if care is used, because new strains produced in unsuccessful gentle handling will subside during the period of recumbency at the time plaster supports are worn. Severe chronic cases are the ones to be subjected to this form of treatment.

3. Occupation as a Remedial Factor in Hospitals for the Mentally Sick.—Emily L. Haines describes the various kinds of occupational work in which the patients in the hospitals for the insane in Massachusetts engage and shows what ends may be attained by occupation as a means of treatment. By the varied modes of this treatment the patients may become gradually vitalized with interest, the dull monotony of their days alleviated and they are sent on their path toward recovery. In some instances they have left the institutions prepared to practice as a profession or trade the work in which they have become interested, and more or less expert during the course of their treatment. To further the work of therapeutic occupation eight hospitals in Massachusetts last year gave a course of instruction in occupation to nurses as a part of their regular training school course. It has been found that this is not only a benefit to the patient and the institution but is of value to the nurse herself. In closing the writer says that occupation, as a remedial measure, is a field of wide and far-reaching possibilities. In its exercise it draws upon all the arts, and presents a fair horizon by which many may wander, and by various paths, to the desired goal of peace and restoration.

4. Alcohol in Relation to Mental Disease.—A. J. Rosanoff sums up an address on this subject by saying that even moderate drinking, especially when it becomes a daily habit, though not likely to make one insane, is sure to reduce physical and mental efficiency, thus killing the best that is in one as long as it is indulged in. Many persons who have an inborn predisposition to mental disease, but who, had they abstained from alcohol, might have avoided an actual breakdown, have been brought to hospitals for the insane by habits of intemperance. Much larger numbers have been brought to hospitals by the same cause who, we know for certain, would never have developed their insanity were it not for their intemperance. This is only the mental side; on the physical side is the part played by alcohol in the production of diseases such as chronic gastritis, cirrhosis of the liver, inflammation of the nerves, etc. Nor is this all, we have in addition the relationship which exists between vice, crime, pauperism and other social evils.

9. Medical Questions in the Pennsylvania Compensation Act. Harry A. Mackey.

1. Constitutional Conditions Caused by Oral Sepsis.—

Judson Daland reviews the numerous constitutional diseases and secondary infections that may be produced by mouth sepsis and calls attention to the shortcomings of dental restorations. He says that some dentists are of the opinion that 90 per cent. of their work is mechanical, and that too little attention has been given to the septic relationship of the mouth to the body in general. Physicians view every capped, dead or loose tooth as suspicious; a dead tooth is always a candidate for infection. The object of this communication is not only to point out these well-known facts but to stimulate interest in the far reaching and sometimes vital importance of dental sepsis; to encourage the prevention or prompt detection and removal of septic foci; to emphasize the necessity of making dentistry a specialty in surgery, and to urge a closer friendship between the physician and the dentist. In the writer's opinion it is the duty of the dentist promptly to communicate with the physician should a patient show evidence of oral sepsis. The physician upon discovering evidence of the infection, which he believes may be dental in origin, must depend upon the skill of the dentist to determine the existence or absence of such lesion. The dentist should not be oversensitive when requested to re-examine his own work, or feel that such a request reflects upon his professional skill. Steps should be taken to make dentistry a specialty in surgery, on the same basis as other specialties in medicine, by so arranging the course of study for future students in dentistry that he shall receive the degree of Doctor of Medicine, thereby bringing about that close relationship between medicine and dentistry which is so urgently necessary.

2. Syphilis in Epilepsy.—William T. Shanahan, J. F. Munson, and A. L. Shaw quote figures on the occurrence of syphilis in the general population and among the feeble-minded and insane, and then report the results of their observations on 1,473 epileptics in the Craig Colony for Epileptics. They find that syphilis was demonstrated by the Wassermann reaction in less than 2 per cent.; by clinical data in 3.4 per cent., and by the luetin test in about 12 per cent. This proportion is not very different from that in the general population. In 600 brains examined at autopsy there were syphilitic lesions in only two, both of which were gummas. Thus far they have not been able to find any characteristic mental picture for the syphilitic cases. The variations in this group are exactly those found in the entire group of epilepsies. It should be remembered that an epileptic with syphilis is not necessarily a patient with syphilitic epilepsy. The treatment of an epileptic with syphilis is unsatisfactory, owing probably to the lateness of its beginning. In many cases the diagnosis is exceedingly doubtful and should be supplemented by examination of the patient's parents, brothers, and sisters, not forgetting the use of the Wassermann and luetin tests. There is no type of syphilitic epilepsy, but syphilis is one of the many agencies which produce the disorder we call epilepsy.

8. Teacher's Vitality as Indicated by the Blood Ptosis Tests.—I. H. Goldberger believes that toxic fatigue

products act upon the vasoconstrictor nerves of the sympathetic nervous system, which supply the circular muscles of the splanchnic system and that a general fall in vasotone results, depending upon the degree of poisoning. Vasotone is a function essential to life and is an important indication of the condition and vitality of the whole body. Employing the blood ptosis test devised by Crampton the writer conducted a series of vitality tests on teachers in the elementary schools of the city of New York, to show the beneficial or depressive effect of various conditions supposed to affect health. He finds that the school day is fatiguing to teachers to the extent of 9.3 per cent., and the work of the school year is equally so. Long vacations are more beneficial to teachers (12.1 per cent.) than short vacation like week ends (1.7 per cent.), Easter holidays (3.6 per cent.), etc. Teachers who went away for their vacations gained in efficiency 12.1 per cent. Teachers who worked in summer schools or vacation centers showed a loss of efficiency of 20.8 per cent.

13. Slate Pencil in Cecum. F. R. Williams.

2. Coccidioidal Granuloma.—Samuel T. Lipsitz, G. W. Lawson, and E. M. Fessenden report this case which they believe is only the third instance in which this disease has been found in a patient who has not been in California. This patient was a negro, 28 years of age, who when first seen was believed to be suffering with an early tuberculosis. The disease progressed much more rapidly than usual, the patient succumbing in fifty-two days from the onset of his illness. As the disease progressed nodules appeared situated both subcutaneously and intramuscularly. They were distributed over the front of the chest, abdomen, forearms, thighs, and legs. The case was similar in most respects to those already reported, except that in this instance there was a high, sustained fever and a marked leucocytosis, whereas most of the other cases were characterized by an irregular fever and a very moderate leucocytosis. As the disease advanced the nodules grew smaller and a walling off process seemed to take place. The writers believe that this would tend to show that some healthy reaction was going on in the region of these focal lesions. The pulmonary involvement progressed rapidly, taking on the characteristics of an active bronchopneumonia, which was most probably an active factor in the fatal termination. In this case the treatment recommended for blastomycosis was of no avail. The writers find that coccidioidal granuloma is more rapidly fatal than systemic blastomycosis, and that, except for one or two cases reported to have been treated successfully by surgical measures, this disease does not appear to be amenable to any form of treatment.

4. Hemoglobin Estimation.—Theodore Kuttner has endeavored to remedy some of the errors in the Sahli-Gower method for hemoglobin estimation, due to the fading of the color standard tube, as well as to lack of uniformity of the diameter and graduation of the cali-

brated tubes. He makes use of a pocket microcolorimeter, comprising uniformly calibrated tubes, and employs various stable standard color tubes of solutions of inorganic salts, one of these tubes being identical with the acid hematin color. This tube is equally adapted to artificial light and to daylight. Dr. Kuttner has also added a prism arrangement producing the optical effect of bringing the two observation fields in close proximity, thus facilitating the color comparison. The standard contains the equivalent to 15 gm. of hemoglobin per 100 c.c. of blood, this being the average amount found in normal individuals. This standard also reads directly instead of 80 being considered 100 per cent. as in the Sahli tube, and thus avoids the recalculations necessary with the latter's hemometer. The writer says that the most suitable time for the collection of the blood for hemoglobin estimation is before breakfast. The change in blood and plasma volume is of great importance. Hourly determinations of hemoglobin show fluctuations synchronous with the fluctuations of plasma volume.

7. Ether; Simplicity in Its Administration.—Isabella C. Herb advocates simplicity in the use of drugs to produce anesthesia. She uses the open method of etherization in all operations except those of the head and neck. In mouth, jaw, nose, and throat operations she employs the intrapharyngeal method. For this a very simple apparatus is employed, consisting of an electro motor which forces air through a tube extending to the bottom of a bottle containing ether. The vapor is carried through a second tube which extends just through the stopper of the bottle, and is several inches from the surface of the ether. A valve controls the density of the vapor. In other operations about the head and neck what is termed a sterile anesthesia is given. All the anesthetic appurtenances are sterilized and the anesthetist wears a sterile gown and gloves. The writer concludes as follows: As much air or oxygen as is consistent with narcosis should be allowed. That there is any distinct advantage in warming ether vapor is very doubtful. The conservation of body heat during anesthesia is of great importance. With the open method of etherization, the patient's blood is well oxygenated throughout the most difficult operation, and patients leave the operating table with normal color and normal respiration. There is less injury to the lung epithelium when an abundance of air is allowed with the ether.

11. The Detection of Pulsus Alternans.—Paul D. White and Lawrence K. Lunt state that during the year and one-half prior to February, 1916, 129 patients with pulsus alternans were seen at the Massachusetts General Hospital. Of this number 29 showed the condition constantly, and the remainder only after premature beats. Since several minutes sometimes elapsed between the appearance of these premature beats, the use of the auscultatory blood pressure method was more laborious and uncertain than the use of the sphygmograph. A constant alternation has not been found in some of the patients who showed by sphygmogram slight to moderate alternation only after premature beats. Bigeminy due to very late premature contractions, so late as to be confused with alternation of the pulse, was found in seven patients during the course of the same year and a half. The proportion of cases with premature beat pseudo-alternation to cases with true constant alternation is 1:5.3. About one in six times we would make the error of confusing pseudo-alternation with true alternation in using the auscultatory blood pressure method. In this series of cases the importance of this error has not been great because of the serious myocardial damage present in the pseudo-

alternating patients, while in cases of constant alternation the auscultatory blood pressure method is a useful procedure. It affords the earliest means of detecting constant alternation in patients who exhibit it to only a slight degree.

7. On the Connection Between "Soldier's Heart" and Hyperthyroidism. Florence A. Stoney.
8. Food Economics in Relation to the War. Harry Campbell.

1. The Use of Stock Vaccine in Infection by the *Bacillus Typhosus*.—T. H. Whittington analyzes the effect of stock typhoid vaccine in a series of 230 cases, 115 of which were treated with the vaccine and 115 without it. He has tried to be certain of the following essentials: (1) Proof of infection by *B. typhosus* in all the cases, including the controls. (2) Accurate selection of the control cases—that is, (a) as far as possible the classes of cases and groups of cases compared are of the same degree of severity; (b) there is the same state or lack of inoculation in the cases compared; (c) all the cases occurred in the same season of the year, and in the same climate and locality; (d) all were of the same sex, and of about the same age and previous health; and (e) other modes of treatment, nursing, diet, etc., were similar. The total mortality in the 230 cases was 52, or 22.6 per cent.; 29 deaths occurred among the vaccinated cases, or 25 per cent.; 23 deaths occurred among the unvaccinated cases, or 20 per cent. The average length of the primary period of pyrexia (neglecting fatal cases) was 27.5 days. The average date on which the temperature settled was the 29th day in the vaccinated cases and the 26th day in the unvaccinated cases. The total number of cases having a relapse was 22, or 9.5 per cent.; of these 12 occurred among the vaccinated and 10 among the unvaccinated. The total number of cases with complications or sequelæ of some kind or other was 111, and of these 58 were among those who had vaccine and 53 among the unvaccinated. Hemorrhage from the bowel was the case of death or the deciding factor in six of the vaccinated cases and five of the controls. It was noted that in some of the cases the hemorrhage started just after a dose of vaccine or recurred after a dose. In summarizing, the writer says that good results with the use of vaccines were more often obtained where good results can be expected by ordinary methods of treatment alone. Those cases which had much bronchitis or bronchopneumonia ran the severe course which is usual and vaccine appeared to be of no avail. It appears that it is in just those cases in which the physician so much requires help that vaccine is disappointing. It seems that vaccine neither shortens the fever nor reduces the number of complications, and there is a decided suspicion that vaccine increases the incidence of hemorrhage. It seems, therefore, that the use of stock vaccine cannot be recommended as a routine measure in the treatment of typhoid fever.

3. A New Apparatus for the Isolation and Cultivation of Anaerobic Microorganisms.—James McIntosh and Paul Fildes point out the defects in the usual methods

at present in use for the isolation and cultivation of anaerobic bacteria. Many of these methods they have tried without success when they noticed that Laidlaw had suggested the use of platinized charcoal and colloidal platinum to remove the oxygen from anaerobic cultures. Their results with this technique were so successful that they determined to work out the method in greater detail, and have succeeded in producing an apparatus by which isolated colonized or anaerobes may be obtained upon the surface of ordinary laboratory media with great facility. This method consists briefly in inclosing the culture medium in an air-tight vessel which has suspended in it a piece of asbestos wool impregnated with palladium black. The vessel is then attached to a hydrogen generator and hydrogen is allowed to pass in, when it will be occluded by the palladium and combined with any oxygen present. A negative pressure thus develops inside the vessel and hydrogen will pass in until no oxygen remains. The apparatus is then detached from the generator, but the action still continues and any trace of oxygen which diffuses from the medium itself will be rapidly removed. Thus a more or less complete vacuum toward oxygen is obtained. This method is clean, rapid, and suited for use with any laboratory medium. It will grow the strictest anaerobes with great rapidity upon the surface of a solid medium.

4. Gunshot Wounds of the Spine and Their Surgical Aspect.—Donald Armour classifies spinal injuries and considers the questions which will arise in reference to the advisability of operative interference. He expresses the opinion that the patient's life will not be endangered where operation seems advisable if a proper estimate has been made of his general condition beforehand. The chief and most frequent contraindication is a general septic condition arising from the state of the kidneys and bladder, with persistent high temperature and perhaps rigors and a weak and irregular pulse. There is an added danger where the intercostals are paralyzed. As to whether any benefit will result from operation, he says that it will relieve pressure, or remove any doubt as to whether continued pressure exists. If the spinal cord be not totally destroyed, continued pressure may succeed in completing its destruction. Therefore operation is indicated: (1) To relieve pressure from depressed or displaced fragments of bone; (2) to relieve pressure from blood-clot or from extensive hemorrhage, either extradural or intradural; (3) to relieve pressure and prevent further destruction from edema by enlarging the constricted bony canal; (4) to remove the future danger of pressure from exudate and inflammatory thickening. No operation will restore a cord in which complete transverse section has taken place; nor will any operation benefit cases of concussion. Since there is no symptom-complex which establishes beyond a doubt that the injury to the cord is irremedial we should give our patients the benefit of an operation which neither materially endangers his life nor adds to his discomfort.

- 1 Penetrating Wounds of the Abdomen. John Fraser and H. T. Bates.
- 2 A Method of Treating General Peritonitis with Obstruction, and Its Application to Military Surgery. W. Sampson Handley.
- 3 Traumatic Gastric Ulcers. T. R. Elliott and Herbert Henry.

1. Penetrating Wounds of the Abdomen.—John Fraser and H. T. Bates have lately had the opportunity of observing the operative results of a number of cases of penetrating wounds of the abdomen and are convinced that in the vast majority of these cases operative

measures offer the best chance of success. They qualify the statement, however, by excluding from the category uncomplicated wounds of the liver and certain wounds of the kidney. When a wound affects the hollow viscera of the abdomen, they are satisfied that it is only as the rarest exception that a spontaneous recovery occurs. When these cases arrive at the hospital they are almost universally in a state of intense shock and, therefore, they have found it advisable to wait for a period of from one to two hours, until the increased shock of the journey has subsided. To this rule they make one exception—those cases which show evidences of rapid and progressive hemorrhage; in such cases the risks attendant on immediate operation are taken. They limit the pre-operative stimulation to getting the patient thoroughly warm and administering 1 c.cm. pituitary extract. During the operation every precaution is taken to minimize the degree of shock; the theater is thoroughly heated, the table is provided with a hot-water bed; and lately they had found it advantageous to operate on these cases while they are in the Trendelenberg position. Immediately before the operation is begun, the administration of subcutaneous saline by a Lane's bag is begun, and it is continued throughout the operation; three or four pints of fluid are given in this way. They describe the operative technique which they employ. Throughout the operation speed is an important factor, coupled with every avoidance of shock. The post-operative treatment is similar to that of every other abdominal operation.

2. A Method of Treating General Peritonitis with Obstruction.—W. Sampson Handley says that if there is a condition in surgery which is stamped with the word hopeless, it is that stage of a general peritonitis when, in spite of pelvic drainage, cessation of the passage of flatus and persistent foul vomiting indicate that complete obstruction has supervened. The rigid abdominal muscles have been forced to yield by the pressure of fluid poured out into the paralyzed intestine, and the abdomen is uniformly and tightly distended like a drum. The pulse becomes running, the extremities cold, and the patient realizes the horrible certainty that he is in the inexorable grasp of death. Is it inevitable that cases of general peritonitis should reach this condition? Is the problem presented by such cases really hopeless of solution? There are certain indications that these problems may not prove insoluble: (1) General peritonitis is rarely universal. (2) General peritonitis usually begins at the lower limit of the peritoneal cavity and spreads rapidly upward. (3) The persistent vomiting indicates that the stomach and upper bowel retain their contractile power to a late stage. The writer is convinced that in the vast majority of cases of general peritonitis a cautious investigation of the upper abdomen would show it to be uninvaded. Hence certain points may be emphasized which will guide us in attempted treatment: (1) In general peritonitis which, in spite of drainage, has produced signs of intestinal obstruction, a stage now regarded as hopeless, we can rely for a time on the functional activity of the muscle of the stomach and of the upper part of the small intestine. (2) In such cases the upper part of the abdomen may be regarded as for some time longer free from peritonitis. In this district we may provisionally assume that surgical operations may be undertaken which postulate the power of repair, such operations, for instance, as intestinal anastomosis. In discussing this question of treatment the writer returns to the subject of ileus duplex—paralytic obstruction due to pelvic peritonitis. Here, in his opinion, lies the key to the treatment of general peritonitis; he has found that recovery can be secured by anasto-

mosing the suprapelvic ileum to the ascending colon, and then opening the cecum by a cecostomy. The parts of the alimentary canal which are still unparalyzed, and therefore available for constructing the suggested emergency alimentary canal, are the stomach, the jejunum, and probably the transverse colon. All the rest of the intestine, small and large, is paralyzed. His scheme of treatment is as follows: (1) For pelvic peritonitis and intestinal obstruction (ileus duplex) consequent thereon—ileocolostomy to the ascending colon with cecostomy. (2) For so-called "general peritonitis"—that is, unlocalized peritonitis with intestinal obstruction (hypogastric ileus)—jejunocolostomy to the transverse colon, with cecostomy. In all cases pelvic drainage must be provided.

3. Traumatic Gastric Ulcers.—T. R. Elliott and Herbert Henry say that the surgical work with the army in France during the last six months has proved conclusively the value of early operation in gunshot wounds of the abdomen. In their summary they state that the evidence related in the paper negatives the assumption that wounds of the stomach are less likely to be fatal than wounds of any other part of the intestinal tract. A perforation or a contusion of the stomach wall by gunshot wounds is liable to be followed by the development of a spreading gastric ulcer, which in certain anatomical positions will erode vessels and determine a fatal issue from secondary hemorrhage. Hematemesis and melana occurring in the second week after a wound are generally to be regarded as the outcome of such a traumatic ulcer. These symptoms are very rarely due to hemorrhage from a nontraumatic ulcer produced indirectly as the result of septic wounds elsewhere in the body. If a stomach wound has not been repaired by operation within the first twenty-four hours after the injury has been received, or if there is reason to suspect the possibility of such a wound being present, the diet should be rigidly controlled on such lines as will lessen the active secretion of free gastric juice.

Renal Affections in Troops.—Albu and Schlesinger state that not much has been added by war experiences to the knowledge of the internist. So-called "war heart" has proved to be nothing new—only a long known expression of a neurosis. Notable cumulative incidence of renal affections, however, may prove to possess elements of novelty, comparable in this respect with cumulation of cardiac neurosis. These renal lesions have no single cause, such as trench life, for in a large proportion of cases the victims had not been in the trenches. Certain psoriastides used against lice are able to cause hemorrhagic nephritis under favorable circumstances (naphthalin preparations, etheral oils), but most of the victims had not been submitted to antilouse sterilization. In regard to the possibility of infections of whatever nature as causes of nephritis, many victims had gone through anginas, dysentery, diarrheas. The disease, however, never resembled a septic nephritis. The most plausible factors to invoke are dietetic—a marked change in the nutriment, along with irregular meals, and especially absence of representatives of certain classes of foods, such as fresh fruits, fresh vegetables and fatty substances. The preserved foods of the diet contain an excess of salt, and their protein content is known to have undergone notable changes which are not without effect on the metabolism. But these views cannot be pushed too far, as nephritis is not a deficiency disease, nor is it associated with food poisoning. The victims were young or middle

aged, for the most part with excellent negative histories. The symptoms comprised backache, prostration, pressure in the head, very often associated with olegaria and dropsy. In some cases there were no symptoms, the diagnosis having first been made from urinary findings. Pallor and edema were the chief objective finds. The blood pressure was subnormal, heart area usually normal, no changes in fundus oculi. The chemical and microscopical examination of the urine gave a great variety of data, but red blood corpuscles seem to have been invariably present, and, with residual albuminuria, they persisted in the urine for prolonged periods, so that the prognosis became questionable. The treatment could be summed up in two terms, rest in bed and liquid diet. Aside from headache and occasional nausea there was nothing to suggest uremia, which was as good as absent throughout. After the edema and oliguria had yielded to milk diet (reinforced with cream), the patients were placed on a salt-free regimen until all blood had disappeared from the sediment. Meat was only gradually introduced into the diet, which consisted chiefly of cereals, vegetables and preserves. When mild uremia seemed present saline or grape sugar solutions were given as drip enemata. Diaphoretic procedures accomplished little, while diuretic—notably theocin—were regarded as contraindicated. Hot drinks are safe diuretics. If we attempt to fix the status of the lesions we find that these belong rather under the nephroses than the nephritis, with the notable exception that the constant presence of blood speaks for nephritis. Hence if the teachings of Volhard on this point are sound, these patients must have had a primary nephritis and secondary nephrosis, i.e. in this instance a secondary lipid infiltration of the kidney epithelium. In an appendix the author describes a late cumulation of cases through which he is able to corroborate and somewhat expand his original conception of the disease. Some of the cases were severe, and there was often a notable absence of formed elements in the urine save blood corpuscles which were uniformly present, thus confirming the conception of a primary nephritis. The author seems to have lost but one patient, and he undoubtedly had had an old lesion when the disease first appeared.

Rupture of the Common Exterior Tendon of the Fingers as a Result of Gonorrheal Taendovaginitis.—Melchior relates a case of gonorrheal tenosynovitis in a woman of 47, the lesion having appeared six weeks before as one symptom of an articular rheumatism. The site of the lesion in question was the back of the hand, and a superficial incision was made to ease the severe pain. Only blood came away at first, but later pus appeared in the wound, and when first seen by the author there was a large, undermined ulcer *in loco*. Pressure about this lesion caused pus to exude. The patient was wholly unable to extend her fingers, which were in slight flexion. Examination of the pus revealed the pressure of the gonococcus, so that in the absence of bone and joint lesions, as shown in an x-ray, one could only conclude that an abscess had formed about the tendons. There was a history of old cystitis and gonococci were found in the cervical secretions. The patient's husband confessed to an old gonorrhea. Inability to extend the fingers was regarded as the result of adhesions, and intervention was made to free the tendons. As the incisions were amplified and deepened a further pus pocket was found and granulation tissue which lined the same was curetted away. The discovery was made that the tendon sheaths and dorsal ligament of the wrist had disappeared, while the continuity of the tendons was lost in a mass of granulation tissue. They had doubtless been the seat of a

degenerative tenditis. The wrist joint was quite intact. There was no history of a trauma, although a very slight one would have sufficed to provoke a rupture of the tendons. The condition must be regarded as a destructive phlegmon, not of the subcutaneous cellular tissue but of the tendon sheaths.

Deutsche medizinische Wochenschrift.

March 2, 1916.

Tetragenus Sepsis After Typhoid Fever.—Welz and Kalle mention first the saprophytic behavior of the tetragenues under ordinary circumstances. It is found harmless in the mouths and throats of consumptives and victims of other chronic infectious diseases and only rarely has it been known to enter the blood and cause sepsis. This process may, however, often pass unrecognized, perhaps masked as a relapse of typhoid. The author reports three cases in all of which the cocci were found in the blood of convalescents from typhoid. As a result the patients developed chills with markedly remittent type of fever. But two other papers have ever been published on this subject. The absorption of a few of these cocci from the mouths or throats of convalescents may cause the one day rise of temperature sometimes met with. The fever curve is quite unlike the typhoid curve as shown in the tracings in which the last week of typhoid is followed by complete defervescence and this in turn by three or four steep rises and falls at irregular intervals. Immediately after this sudden rise the blood tests were made and repeated at the next rise. In a serious infection with the tetragenues, the ulcerated intestine may be the port of entry. A peculiar clinical feature was a bronzing of the skin and mucosæ in circumscribed areas which must be set down to the agency of the tetragenues.

Capillary Bronchitis in Nurslings.—Peiper states that this affection shares with alimentary intoxication the ill repute of being the most dreaded disease of the nursing period. The great swelling of the mucosa and the occlusion of the bronchioles with mucopurulent secretion causes such a notable damage to the lungs, pulmonary circulation and heart that life becomes quickly imperilled. If we do not find much evidence of mischief in the chest we must in no wise hold aloof from energetic treatment. The physical signs are certain to become more pronounced, as the inflammation diffuses itself and causes atelectases and bronchopneumonic foci. The face, pale at the outset, becomes dyspneic—blueish green or livid red. The child becomes drowsy, and can be roused to nurse only through hydiatric measures, as wet compresses. Naturally dyspnea must interfere greatly with nursing or feeding; and at last nourishment is refused outright. Diarrhea is a common complication, and when associated with fasting quickly leads to death. The more common termination is pulmonary edema and collapse. The mortality is 35 per cent. to 40 per cent. In a bronchitis with foci of bronchopneumonia it is impossible to state to what extent the latter affect unfavorably the prognosis. The chief indication for treatment is to drive the blood in the engorged thorax to the surface. To fill this indication mustard packs must be used. The technique of this resource must be carried out in full. Other measures may hardly be required if this is successful. Two handfuls of mustard flour are made into a paste with 1 liter of hot water in an earthen vessel, stirring well, and covering with a towel until the penetrating mustard oil is sensed above the latter. A napkin of suitable size to reach from the head to the feet of the child is dipped into the paste, wrung out, and wrapped about the child so that it ends at the chin. The face should be protected from the mustard fumes by a piece

of gauze. Around the mustard cloth a piece of flannel is wound. A small pocket handkerchief wrung out in cold water is now placed on the forehead. The child remains for twenty or thirty minutes in the mustard poultice until it is as "red as a crab." The envelopes having been removed the child is now washed in warm water, wrapped in flannel and left alone for two hours. At the end of this time it will be found perspiring, and should be gently dried. During the entire period it must be possible to control the heart's action, for children have been known to collapse in the mustard pack. Should such an accident occur the wrappings must come off at once and camphor or caffeine injected. One packing may suffice, but usually it must be repeated in twenty-four hours, and as often afterward as necessary. If reaction does not follow it is because of the cardiac weakness. The only resource left is to puncture or even sever a vein and allow 50—100 cc.m. of blood to escape. Leeches may, however, be tried if consent is refused. For cardiac failure natrobenzoate of caffeine may be injected, or perhaps given internally, while camphorated oil is injected. Oxygen inhalations are useful. Should expectorants be indicated—as when attacks of asphyxia are due to accumulations of mucus—some form of artificial respiration should be used, such as Schultze's swings. Emetics are virtually contraindicated, for they depress the heart's action. However, they may be given early in the disease (antimony and squills) to clear the passages. The drugs should be given in emetic doses and not as expectorants.

Iodine in Tetanus.—A. T. MacConkey and S. S. Zilva, after a series of experiments on guinea pigs, are forced to the disappointing conclusion that iodine injected subcutaneously has no effect upon tetanus toxin which has been also injected subcutaneously in a different place. They find that we cannot hope to influence favorably an attack of tetanus by injections of iodine alone, nor does iodine have any effect in enhancing the power of serum, but can only be of use when applied to the infected focus, so that it can come into direct contact with the toxin before absorption. —*British Medical Journal*.

The Prognosis in Sympathetic Ophthalmia.—Percy Dunn protests against the use of the term "sympathetic ophthalmia" since every ophthalmologist is agreed that the disease is not due to sympathy, but to a process of infective origin. Still, while this fact is generally conceded, the old misleading term is retained. Though the microorganism upon which the disease depends has not been isolated, the facts that sympathetic ophthalmia is becoming rare with time, that this increasing rarity corresponds with the practice of aseptic and antiseptic principles in wound treatment, and that the virulence of the disease has been greatly modified so that it has become curable point unmistakably to its infective origin. It was formerly axiomatic that "sympathetic ophthalmia once, sympathetic ophthalmia ever, all the time that a patient lives." This tragically axiomatic conclusion of former days would cease to become a stumbling block in respect to the prognostic significance of the condition were the disease endowed with a terminology more accurately expressive of its modern conception. The writer also shows how relapses and sympathetic irritation may be explained on the basis of infective origin, the toxin being conveyed by the medium of the blood from one eye to the other and causing symptoms in accord with its virulence. He believes effective treatment lies in the discovery of a vaccine. Pus infections do not cause sympathetic inflammation, the reason being that perhaps with one exception, they do not produce a toxin.—*Lancet*.

Insurance Medicine.

Liquor and Life Insurance.—For many years opinions were greatly divided as to whether alcohol used in moderation tended to shorten human life. Up to the year 1904, figures of a reliable nature were lacking with regard to the subject. In that year, however, the sixty years' experience of the United Kingdom Temperance and General Provident Institution was made public (Lawrence M. Cathlee, *Texas Medical News*, March, 1916). When the first insurance companies were formed in Great Britain, the applicant only had to appear before the Board of Directors, and it depended upon the impression he made upon these gentlemen whether or not he was granted insurance. Little attention was paid to the applicant's habits, personal or family history. The delicate scientific tests, such as blood pressure and chemical analyses were unknown, and the more liquor the applicant was able to absorb without seemingly disastrous effects, the stronger and better life insurance risk he was supposed to be.

In the early days of insurance, if a man weighed more than the average for his height, it was considered that his food agreed with him better than with ordinary mortals, and his additional avoirdupois argued greater strength than that of the average man, with a more favorable prospect of living to a ripe old age.

Opinions on these points have undergone a change and it may be laid down as an axiom that drinking men are not good life insurance risks. Saloon keepers cannot obtain life insurance protection at standard rates from any conservatively managed life insurance company in the United States. The companies which do accept saloon keepers, bartenders, keepers of hotels in which liquor is sold, and men in close connection with the liquor business are few in number and accept such risks for assurance only upon special terms which the average man would consider extremely onerous.

Applicants for insurance are nowadays required to answer specific questions as to their habits with regard to or connection with liquor somewhat as follows: Are you now or have you ever been either directly or indirectly concerned in the manufacture or sale of any kind of alcoholic beverage? Do you ever drink wine, spirits, or malt liquors? If so, which of these and to what extent? If a total abstainer, how long have you been so? Have you ever taken any medicine or treatment of any kind for alcoholic or narcotic habit?

Briefly, the attitude of life insurance companies toward the liquor business and those who indulge in intoxicating liquors may be roughly summed up as follows: Indulgence to the extent of the physiological limit stated by Abel (three-quarters of an ounce of absolute alcohol) will not ordinarily disqualify for insurance if the applicant's other habits, personal health, family history, environment, etc., are good. Indulgence in excess of the physiological limit, say three glasses of beer a day or more, if a regular habit, disqualifies. All persons actively engaged in the sale or manufacture of intoxicating liquors are barred from insurance by the great majority of life insurance companies.

With respect to the point as to whether total abstainers are better life insurance risks than moderate drinkers, there is little difference of

opinion among experienced life insurance physicians.

Mr. R. M. Moore, actuary of the United Kingdom Temperance and General Provident Institution, states in his introduction to the mortality experience of this institution published in 1904 that "excess, as compared with moderation in the use of alcohol, is prejudicial in every way, is a proposition hardly to be disputed. And many authorities who have given the matter careful consideration contend that even as moderation is superior to excess, so is total abstinence from alcohol superior to moderation." The conclusions arrived at by Mr. Moore were as follows: 1. That the non-abstainers insured by his institution proved themselves to be good average lives, generally equal to the best accepted standard. 2. That the abstainers show a marked superiority to the non-abstainers throughout the entire working years of life for every class of policy and for both sexes, however tested. 3. That this superiority was not brought about by transferring from the abstainers' section to the non-abstainers' those abstainers who, after obtaining their insurance, did not continue to abstain. Figures showed that out of the same number of abstainers and non-abstainers insured only three abstainers died to every four non-abstainers. Taking the death rate among non-abstainers as 100, the abstainers' experience at the different ages is as follows:

Ages.	Death Rate.
20-24	69.9
25-29	70.1
30-34	56.5
35-39	54.8
40-44	57.2
45-49	58.5
50-54	62.4
55-59	70.6
60-64	78.5
65-69	84.0
70-74	86.5

There are quite a number of life insurance companies in the United States which make a specialty of insuring total abstainers in the belief that they are generally better risks for life insurance than those who do not wholly abstain from the use of alcoholic liquors, but who, nevertheless, drink so little that they are considered safe risks.

So far as the writer knows, there is no volume of statistics which can compare in reliability with those of the United Kingdom Temperance and General Provident Institution. Comparative rates of mortality given by the Manufacturers' Life Insurance Company of Toronto, Canada, which maintains an abstainers' section at rates of premium approximately 5 per cent. lower than those charged to non-abstainers, are as follows:

Year.	Abstainers' Section.	General Section.
1905	36.95	74.23
1906	35.90	57.33
1907	37.81	69.15
1908	39.88	81.75
1909	33.50	48.45
1911	46.07	77.89
1912	46.51	70.90
1913	40.42	44.94

All the evidence obtainable on the subject points one way and leads to the inevitable conclusion that among a body of men who totally abstain from intoxicating liquors there will be fewer deaths during the vigorous productive years of life than among a similar body of men who are not total abstainers.

Book Reviews.

PRACTICAL CYSTOSCOPY AND THE DIAGNOSIS OF SURGICAL DISEASES OF THE KIDNEYS AND URINARY BLADDER. By PAUL M. PILCHER, A.M., M.D. Consulting Surgeon to the Eastern Long Island Hospital; Late Surgeon to the German, Seney and Samaritan Hospitals of Brooklyn, N. Y.; Associate Surgeon to St. John's Hospital of Brooklyn; Attending Cystoscopist to the Jewish Hospital of Brooklyn. Second Edition, Thoroughly Revised. Octavo of 504 pages with 299 illustrations, 29 in colors. Price, cloth, \$6.00 net; half morocco, \$7.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

WHEN the first edition of Pilcher's Cystoscopy appeared, about four years ago, its popularity was soon assured, for it covered the ground in a thoroughly practical way and much more exhaustively than most of its contemporaries. During the past four years the cystoscope has assumed an ever increasing importance in the diagnosis of lesions of the urinary tract, and with added experience the coefficient of error in the interpretation of findings upon cystoscopic examination, ureteral catheterization and pyelography, in the hands of the expert, has been gradually diminishing; while its sphere of usefulness from a therapeutic standpoint has been much widened. Appreciating these facts, Pilcher has thoroughly revised his work, added considerable new material, and brought the book up to date in every sense of the word.

This book, based on the author's extensive experience, should be of great value to practically all those interested in cystoscopic proficiency; for it covers not only what the novice must have in the way of armamentarium, the technique of all branches of cystoscopic work, and the description of the normal findings, but also much that can be appreciated only by the man who has become reasonably expert in the use of the cystoscope and its accessories and is somewhat acquainted with the cystoscopic findings in disease. There are comparatively few cystoscopists who will not find many suggestions which, if followed, will increase their efficiency in this work, point out new therapeutic possibilities, or help clear up a diagnosis.

THE OPERATIONS OF SURGERY (Jacobson). Sixth Edition. By R. P. ROWLANDS, M.S. Lond., F.R.C.S. Eng., Surgeon to Guy's Hospital; Lecturer on Anatomy to the Medical School; and PHILIP TURNER, B.Sc., M.S. Lond., F.R.C.S. Eng., Surgeon to Guy's Hospital; Teacher of Operative Surgery to the Medical School. Two octavo volumes of 1030 and 934 pages respectively with 797 illustrations (40 in colors). Volume I, The Upper Extremity; The Head and Neck; The Thorax; The Lower Extremity; The Vertebral Column. Volume II, The Abdomen. Price per set, \$13.00 net. New York: The Macmillan Company, 1915.

JACOBSON'S "Operations of Surgery" was written to supply the demand for a book on operative surgery that would be something more than a mere illustrated recital of operative technique with meager details as to the conditions under which the various operative procedures were to be employed. The subject was therefore treated upon broader lines and in far greater detail than had been customary. Originally published as a single volume edition in 1889, subsequent revisions have resulted in continual additions to the authors' text and to the quotations and other references to the literature, so that now two large octavo volumes are necessary to present the material thought to be essential in order to carry out the original design of the work. As a result we find a veritable storehouse of information concerned not only with the technique of most of the operations in the fields of general and special surgery which the general surgeon may be called upon to perform but also, often in great detail with the incidence, symptoms, diagnosis, indications for operation and reasons for the choice of particular methods under varying conditions, directions for the handling of various complications that may be encountered during the progress of the operation, and often a discussion of other complications and sequelæ.

There are, however, many omissions of material that seem important and many statements which are incorrect. For instance, we find the statement on page 35, Vol. I, that "direct transfusion of the blood is now practically never employed, its place being taken by infusion

of a saline solution." Not only is no mention made of the direct introduction of the needle without preliminary incision and exposure of the vein, but the only description of transfusion is by Aveling's apparatus, and the description of blood-vessel surgery in general is woefully inadequate. We also find nothing on fascia and fat transplantation and nothing on modern methods of bone grafting; while in the discussion of operations on the brachial plexus the latest references to the literature are to articles published twelve or more years ago, no references being made to the work of A. S. Taylor and others whose results in recent years have been far better than those referred to. Again we find that the section on gunshot wounds of the abdomen is far from up to date in spite of the interest naturally attached to this subject at present. Here we find but one reference as late as 1908, some of the others going back as far as 1887. In general we are impressed with the preponderance of references to articles published ten or more years ago, when much later literature is often available which more truly reflects current opinion and results following the use of present day methods of action, is barely mentioned in a footnote. We also find Stead's 1894 statistics in complete operation for cancer of the breast still be quoted when recent statistics covering much larger series of cases are available?

One is surprised, in reading the excellent section on cancer of the breast, to find that while Halsted's work is accorded due appreciation, Willy Meyer's all-important modification in the technique, resulting in what is now generally referred to as the Halsted-Meyer operation, is barely mentioned in a footnote. We also find occasional carelessness in the citation of references and many typographical errors. For example, one article is referred to in one place as having been published in the MEDICAL RECORD on March 15 and in another as on April 15 of the same year.

In spite of these criticisms these two volumes are of great value. Most of the illustrations are exceptionally good and the author's text usually seems to have been thoroughly revised and is replete with valuable suggestions and observations. The second volume, devoted to the surgery of the abdomen, is especially noteworthy, and has evidently received the lion's share of attention in the general revision for this edition.

SELBSTMORDVERDACHT UND SELBSTMORDVERHÜTUNG. Eine Anleitung zur Prophylaxe für Aerzte, Geistliche, Lehrer und Verwaltungsbeamte von Dr. PLACZEK, Nervenarzt in Berlin; pp. 272. Price, 6 Marks. Leipzig: Verlag von Georg Thieme, 1915.

THIS work, as its title denotes, is not devoted to suicide as such, but rather to the kind of man who is most likely to destroy himself. It is in fact a series of essays on the motivation of suicide. The technique of the latter receives but scant attention, and the book possesses no value as a reference work on actual self-slaughter. This could not be otherwise, for it is devoted very largely to prevention of suicide by means other than the penal code and forbidden sale of poisons. In the long run it is the tendency to suicide which dominates. We note that the problem remains the same through the ages. Suicide is either coldblooded or physiological on the one hand or due to mental weakness of some form on the other hand. The physiological form is relatively stable, while the pathological type varies with the changing viewpoints of race advance and race deterioration.

THE STARVATION TREATMENT OF DIABETES, with a Series of Graduated Diets used at the Massachusetts General Hospital. By LEWIS WEBB HILL, M.D., Children's Hospital, Boston, and RENA S. ECKMAN, Dietitian, Massachusetts General Hospital, Boston. With an Introduction by RICHARD C. CABOT, M.D. Second Edition. Price, \$1.00. Boston, Mass.: W. M. Leonard, 1916.

THE second edition of this little book has been much enlarged by the addition of a number of case reports and a series of recipes for dishes suitable for diabetics. In other respects it is the same as the first edition. Whatever objections may be raised to the Allen treatment of diabetes, it is the popular one of the day. The greatest difficulty in the administration of this treatment by the average practitioner is the lack of exact knowledge of food composition and caloric value, and this lack will be removed by Hill and Eckman's book. The details and directions are all that could be desired and it should afford substantial aid to all who have not had opportunity of working out the progressive series of diets which should be used after the starvation period.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 6, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE evening was devoted to the consideration of alcohol.

The Investigation of the Influence of Alcohol on Man, with Special Reference to Psychological Effects. — Dr. FRANCIS G. BENEDICT, Director of the Boston Nutrition Laboratory of the Carnegie Institution, read a paper which he illustrated by lantern slides. He said that in accordance with its widely distributed "Tentative Plan," the Nutrition Laboratory of the Carnegie Institution had organized and initiated an exhaustive experimental study of the physiological consequences of the ingestion of small doses of ethyl alcohol in man. The first year's work under the psychological part of that plan was devoted to an investigation of the effects of alcohol on a selected group of interrelated processes covering the fundamental neural activities at various levels of the cerebrospinal system, from the simplest reflexes of the lumbar cord to the most complex cortical arcs that they could accurately measure by available laboratory techniques. The selection of the particular group of neuromuscular processes for measurement was determined by the following experimental demands: (1) The systematic demand for coordinate data covering as many as possible of the fundamental psychophysiological operations. (2) The interpretative demand for the least possible inclusion of unknown and uncontrolled factors. (3) The practical demand for natural reaction forms which would be comparable in a large number of individuals without special practice, and would show relatively little practice effect as a result of the experimental repetition. (4) The technical demand for dependable quantitative methods of stimulation and registration. Of the simple arcs which were available for experimentation, the patellar reflex and the protective lid-reflex were chosen, chiefly because of their similar latency and the accuracy of the modern technique for their measurement. The measurements of these reflexes included data concerning their latency, the extent of the muscle contraction, and the relative duration of the refractory phase. Of the more complex cortical arcs the following were selected: (1) Eye-reactions to sudden peripheral stimuli, a thorough practised phase of each individual's spatial adjustment; (2) speech reactions to visual word stimuli; and (3) free associations. The last two were characteristic phases of the individual's adjustment to his social environment. The fundamental preservation tendency was measured by the partial memorization of series of words. Sensory changes were indicated by Martin's faradic-threshold measurements. Morot coordination was studied in the velocity and accuracy of eye-movements, and in the reciprocal innervation of the antagonistic muscles of the middle finger. Finally, pulse records (chiefly electrocardiograms from body leads) were taken either continuously or at homologous points in the various experimental processes. The subjects consisted of two groups: a main group of college graduates who were very moderate users of alcohol, and a smaller group of outpatients in the Psychopathic Hospital who had been under treatment for delirium tremens. Normal base lines in all cases included two normal experimental days for each subject and for each kind of experiment. One normal day came before and one after the experimental days on which alcohol was administered. In addition a "normal of the day" was recorded for each experimental process on the days on which alcohol was given. Two alcohol doses were used, one containing approximately 30 c.c. and the other 45 c.c. of absolute alcohol. All the measurements showed more or less rhythmic variations. In their statistical theory they assumed that, given a sufficiently large number of measurements, the normal rhythmic and arrhythmic variations would tend to compensate each other, leaving the average experimentally conditioned change relatively unaffected. In their data these average results showed two particularly significant marks of reliability: (1) Similar processes were similarly affected and in similar degree; (2) in general the larger the dose of alcohol the greater experimental effect. The effect of alcohol was calculated in all cases by comparing the differences between the "normals of the day" and subsequent periods on the normal and on the alcohol days. The greatest percentile effect was found in the reflexes. In the patellar reflex alcohol

increased the latent time 10 per cent., while it decreased the amount of quadriceps thickening 46 per cent. In the protective lid-reflex it increased the latent time 7 per cent., while it decreased the extent of lid-movement 19 per cent. It increased the latent time of the eye-reactions 5 per cent. and that of the speech reactions 3 per cent. Memory and the free associations were only slightly affected. Sensitivity to faradic stimulation decreased 14 per cent. after alcohol. The number of finger movements decreased 9 per cent. and the velocity of the eye-movements decreased 11 per cent. as a consequence of the ingestion of alcohol. Quite in contrast to the general depression of the neuromuscular processes at all levels of the cerebrospinal system was the effect of alcohol on the pulse rate. Under all experimental conditions alcohol produced a relative acceleration of the pulse. In only a few cases with a large dose did this relative acceleration become a positive acceleration, so that the pulse rate in the periods subsequent to the ingestion of alcohol was faster than during the normal of the day; but in practically every instance alcohol prevented the regular pulse rate retardation that accompanied the successive periods of mental and physical work on normal days. This relative acceleration averaged approximately 3 per cent. While this effect was intrinsically small, its regularity, the large number of records, and its concomitant variation with the size of the dose gave the results a high degree of probability. The effort to determine which of the antagonistic heart-regulating mechanisms was responsible for the relative acceleration demanded an analysis of the pulse data. A comparison of the relative changes in the duration of systole and diastole (method of Hunt) led to a thoroughgoing consideration of the variations in the pulse cycles during the different experiments. The records showed a consistent tendency of alcohol to decrease the mean variations amounting to an average of 19 per cent. Since the rhythmic and arrhythmic pulse changes within the limits of their 12-second records could not have been conditioned by the relatively slow-acting accelerator, it seemed necessary to regard the decrease of the mean variation after alcohol as caused by a decreased responsiveness to the inhibitor. There was some evidence in the records that this paralysis of the inhibitor was not an exclusive effect, and it was probable that various natural and experimental conditions might be found which would shift the preponderance of paralysis to the accelerating mechanism. The small amount of change, its purely relative character, and the probability that both regulating mechanisms were affected doubtless gave the conditions for the confusion of the scientific traditions concerning the effect of alcohol on the pulse rate. In conjunction with the pulse acceleration, the general neuromuscular depression might be regarded as presumptive evidence of the effect of alcohol on organic efficiency. In none of their data was there any indication of a pure facilitation effect of alcohol. Contrary to the theory of Kraepelin, they not only found no facilitation of the motor processes, but the depression of the simplest forms in the finger and eye movements seemed to be one of the most characteristic effects of alcohol. Indeed, it was exactly these effects that correlated most closely with the average of all the effects for the several subjects. Practically it seemed to follow that these processes might serve as a readily accessible indicator of individual susceptibility to alcohol. Theoretically it seemed to follow that the effect on the motor coordinations indicated a central tendency of alcohol. A full presentation and discussion of the various techniques and the resulting measurements were given in Publication No. 232 of the Carnegie Institution of Washington.

Prof. C.-E. A. WINSLOW of Yale University emphasized the great difficulty of discussing this subject from a detached and scientific viewpoint. He said it was difficult to consider the evidence on its merits, since each new fact was apt to fit into and be modified by a preconceived picture, of which the center was either the Demon Rum or the genial god Dionysus. Our treatment of alcohol as a habit-forming drug was complicated by the fact that there were not only the confirmed addicts to be considered, but those who gave way only occasionally to excess, and the also steady, moderate drinkers. If there were signs of opium parlors on every street corner, or if hypodermics were passed at the close of dinner parties, our view of these drugs would be similarly complicated by a century-old atmosphere of social respectability, although of course the danger of habit-formation would be quantitatively

greater than in the case of alcohol. It must be freely granted that alcohol was technically a food, and that it might be and was oxidized in the body. It might be granted that in moderate amounts it was a source of pleasurable indulgence. The question was whether this food value and this indulgence were not too dearly bought. It was unnecessary to emphasize to physicians the relation of steady drinking to diseases of the liver and kidneys and to mental diseases, and its unfavorable influence upon the prognosis of such infections as pneumonia. Alcohol in large and continuous doses produced more or less serious pathological effects, in some instances constituting a principal contributory cause of death; and the extent of the danger varied widely with individual predispositions. There were also to be considered the many secondary effects of alcohol in connection with the causes of disease and death. Alcohol played a large part in automobile accidents and those occurring in factories. The relation of alcoholism to venereal disease was far-reaching and sinister. The taking of alcohol with meals promoted overeating and tended to overload the alimentary canal with food which would putrify and cause auto-intoxication. The net effect of alcohol upon health had been approximately measured in a number of statistical studies by English and Scottish life insurance companies and more recently in the admirable medico-actuarial investigation conducted by Arthur Hunter. This study showed a mortality 86 per cent. in excess of the normal among steady users of two ounces or more alcohol a day, 74 per cent. in excess of the normal among those who had committed alcoholic excesses within two years, 32-35 per cent. in excess of the normal among reformed persons of formerly intemperate habits, and 18 per cent. in excess of the normal among moderate, steady drinkers (lower limit defined as two glasses of beer, or one glass of whiskey a day). These results could not be considered extravagant when it was remembered that the same study showed an excess mortality of 13 per cent. for persons showing albumin in the urine, 20 per cent. for those who had suffered from acute articular rheumatism within two years, and 72 per cent. for those who had had an attack of gout within ten years. Passing from actual damage to the question of lowered efficiency, one must take into account the laboratory studies of Kraepelin, Vogt, Aschaffenburg and others, and the remarkably clear and convincing investigations reported by the junior speaker, Dr. Benedict. There were individuals who had lived long lives and done good work and who had consumed enormous amounts of alcohol. But if a responsible man had anything important to do he did not take alcohol before doing it. A surgeon about to perform a delicate operation did not take alcohol before entering the operating room. No man about to undertake severe, exact mental work would take a drink of whiskey beforehand. When one wanted cool, concentrated energy one laid drink aside. The same thing had been most clearly indicated by the changed attitude of European nations toward alcohol during the war. As Russia, France, and England reached the point where they needed to reach a maximum of efficiency they faced this as one of their greatest obstacles. On March 9 last David Lloyd George said of the alcohol problem: "It will be so much better to settle this question by general consent. If we do, the war, horrible as it is, will have paid for itself. There are many things which I hope we can accomplish through this war. There are many changes at home, changes in the outlook in the nation, changes in its temper, changes in its attitude of mind, changes in its industries; but this will be the greatest and most beneficent change of all if we succeed in carrying it through. If we can possibly convince the nation that success in the great task which it has undertaken depends very largely upon removing this drag on its efficiency, then I feel confident that at the end of the war, however successful we may be in a military sense, we shall regard this as the greatest triumph of all." No one method of fighting against alcohol was endorsed. There were grave criticisms of many of the methods that had been proposed. The best way to restrict the use of alcohol as a problem in itself, but from a standpoint of public health and efficiency that way should be found. Public health departments were not limiting themselves to the prevention of specific diseases and of death, but were developing their work along hygienic lines; not alone warding off epidemics, but building up health and vigor. Whether this country kept out of the war in Europe or not, the world's stage was swept for a conflict of ideals, standards, and civilizations. The

old ways would no longer serve. There must be national efficiency in a sense never dreamed of before. Alcohol, though a pleasure to a few, was a serious danger to many and on the whole a drag and detriment which took off the keen edge of national effectiveness, and the best way to deal with it should be earnestly sought in the interests of public health and national well-being.

Dr. CHARLES R. STOCKARD of Cornell University gave a few of the results of experimentation on the effect of alcohol on the developing embryo and on the descendants of animals treated with alcohol which he illustrated with lantern slides. In order to study the chemical effect of alcohol on the development of human offspring of those addicted to its use, it was necessary first to study its effect on animals. It was of vast importance to know how the children of alcoholic parents were affected and whether the taking of alcohol by the pregnant woman endangered the make-up of the child. The first experiments were made on the eggs of fishes and of hens. In the former, the eggs were placed in a weak solution of alcohol and water and the eggs never developed normally, the abnormalities, being confined chiefly to the central nervous system; 90 per cent. had eye abnormalities. Magnesium chloride had much the same effect. Hens' eggs, if placed over a funnel containing alcohol fumes for a few hours before incubation, developed abnormal chicks. The question whether the embryo developing within the body of the mother could be affected by the mother being treated with alcohol was solved by experiments on guinea-pigs; this also applied to the effect on the offspring of the father being treated so as to change his cells. The effect of alcohol was watched on five generations and comparisons were made with the offspring of the same strain, which were not treated, as well as of other strains. A father treated with alcohol was mated to an untreated mother and *vice versa*; of one generation of offspring the father or the mother or both were treated; the untreated offspring of the first descendants of a treated father or mother were mated, but only the one generation was treated. There resulted an unusual number of abortions, still-births, and abnormalities, and there was also much abnormal sterility among the children, grandchildren, and even great-grandchildren from alcoholized ancestors. The worst complications resulted from the inbreeding of animals poisoned; they produced dwarfs, deformities, paralysis agitans, cyclopean monsters, and blindness. Fifteen per cent. of inbred descendants from alcoholics were defective; some had no eyeballs, others had only one eye, lacking also the optic nerve, the optic tract, and optic fibers. It was not claimed that these experiments could be transferred to man; they were made to see if it was possible to control embryonic development, whether defects due to alcohol could be transmitted by male or female or both, and it had been shown that such effect was possible whether it occurred in man or not.

Dr. BERNARD SACHS said that he could not be expected to discuss the addresses previously made, as everyone must have been benefited by hearing them and he admired their originality. If anyone believed alcohol innocuous, Dr. Stockard's experiments would disprove such belief. As a clinician he was interested, as well as the laboratory workers, in the effect of alcohol and he shared the belief that unless the body was sound the individual could not prove himself efficient. A few months ago, there was a symposium at the Academy on syphilis in its relation to disease and alcohol was the subject of to-night's meeting; both these severe poisons had an effect on the nervous system. In regard to alcohol, it was unfortunate in one respect that it was not possible through laboratory experimentation to discern, as in syphilis, the early effects on the nervous system; at the present time by examining the spinal fluid of the person suspected of syphilis, a diagnosis could often be established before the poison had brought about any actual changes. That was not the case with alcohol unless the disease had reached the stage where positive symptoms appeared. In view of the interesting statements of Prof. Benedict, it was possible that some day the reaction time of alcoholic individuals might give early warning of impending changes just as did the cytological changes in the cerebrospinal fluid, and there might thus be given a clue to the early inroads alcohol made on the human system. There was one thing about alcohol which made it in a sense worse than syphilis; syphilis began as an exudative process, whereas alcohol was a destructive process; it produced degenerative disease more effectively and chronically than syphilis and the effects were as noticeable from long-continued

use of moderate doses as from the occasional use of excessive doses. Another unfavorable point was that the signs and symptoms of it were noticeable long after the habit ceased. The reason why alcohol was indulged in to such a great extent was the need of occasional stimulation. For certain duties and for the continuation of work, the ordinary fatigue of the day had to be neutralized in some way and for this purpose many resorted to alcoholic stimulants, beginning with small doses. The habit was then continued until it was difficult to break. It would be well if it were more generally known that the best substitute for alcohol was coffee, which would give the necessary immediate stimulation. On the whole, coffee was not injurious, though even that might be continued until it became a pernicious habit. It was to be regretted that coffee had been so maligned and that its value as a stimulant had been greatly underestimated.

Dr. HAVEN EMERSON, Health Commissioner of New York City, said that though impartiality had been advised in the discussion and in the analysis of the facts presented by the laboratory experts, it was difficult for any physician to be impartial if he had treated in homes, dispensaries, and hospitals, the victims of alcohol. When the title of the Bureau of Infectious Diseases was changed to the Bureau of Preventable Diseases it indicated a change in the point of view which had been going on throughout the country in the interests of public health. If one considered the possibility of the prevention of congenital defects of infants due to the use of alcohol by the parents, one must admit that it was within the sphere of public health officials to take up the propaganda against alcohol. It was admitted that the death rate from infectious diseases was higher among alcoholics; infectious diseases were more easily acquired by alcoholics, and recovery was in a smaller ratio among them. This was strikingly illustrated in pneumonia, typhoid fever, and septic conditions. The incidence of diseases due to alcohol itself and the results from its use in diseases of the central nervous system and of the assimilative organs justified an energetic campaign against its use. The question of economic efficiency could not be considered as part of the public health, yet the attitude of large employers of labor indicated that they were in accord with all efforts to diminish the use of alcohol, whether from an altruistic point of view, or from the standpoint of profit and loss. For the present, the educational method seemed to be the one which would finally prevail; permanent results could not be accomplished by legislation or police enforcement. The country would respond to educational enlightenment and the demand for alcohol would diminish as the knowledge of its dangers increased.

Dr. FREDERIC S. LEE of the Physiological Laboratory of Columbia University said that during recent years the subject of the physiological action of alcohol had received much attention, but the experimenters had strangely neglected the action of this drug on muscle. Robert (*Archiv für experimentelle Pathologie und Pharmakologie*, 1882, xv, p. 73), experimenting on frog's muscle, maintained that alcohol, when given in large doses, greatly diminished contraction, but that this did not occur with small or medium quantities. Later Lombard, Frey, Destrée, Kraepelin and his pupils, and Schäffer obtained with the ergograph interesting and valuable results with the drug in the human being; but such an organism was too complex to afford a solution of the problem at hand. His work had been performed on isolated muscle and had yielded positive results. He had found that the action of alcohol on muscle varied with the relative quantity of the drug employed. In small quantity ethyl alcohol did not appear to exert any action on the frog's muscle. In medium quantity it exerted a favorable action, which was characterized by a quickening of the contraction; a quickening of the relaxation; a power of making a larger number of contractions and of performing a larger amount of work in a given time; an increase in the working time or, in other words, a delay of fatigue; and the power of making a larger number of contractions and of doing a larger amount of work before exhaustion set in. This action was exerted directly on the muscle protoplasm itself, not on the intramuscular nerve tissue. In a large quantity ethyl alcohol exerted on frog's muscle an unfavorable action, which was, in general, the reverse of that caused by medium quantities of the drug and was characterized by a decrease in the extent of the contractions; a decrease in the working time or, in other words, a hasten-

ing of fatigue; and a power of making a smaller number of contractions and of doing a smaller amount of work before exhaustion set in. In conclusion he stated that ethyl alcohol when administered to frogs in moderate quantities was capable of augmenting the working power of the skeletal muscles.

Dr. JOHN H. KELLOGG expressed his appreciation of the invitation to make a few remarks on the absorbing subject of alcohol, from the depths of his experience both at the Battle Creek Sanitarium, with chronic invalids made so by the pernicious effects of alcohol, and in connection with Settlement work in Chicago. From his observations, he felt that it would eventually be proven that it was entirely possible to dispense with alcohol as a drug, as the results sought to be secured by it could be better obtained in other ways, and the great increase seen in chronic disease in this country could to a large extent be attributed to alcohol, especially the increase in diseases of the heart, blood-vessels, etc. Dr. Lee's experiments hardly seemed to have a direct bearing on the subject of the use of alcohol by human beings as they showed the effects of alcohol on muscle only, and not on the nerve centers and the nerves themselves, and might be due to increase of muscle irritability. The experiments of Parkes and others had shown that alcohol in ordinary doses diminished decidedly man's working capacity.

Dr. ABRAHAM JACOBI said that so many diverse opinions had been expressed that one or two more would not be amiss. He had felt in listening to Dr. Stockard that there could be no doubt of the affirmative answer of those guinea-pigs, could they reply to the question "To be, or not to be." His experience of over fifty years in practice gave strength to his positive assertion that there was no remedy to equal alcohol in cases of mixed infection. There were septic diseases that could not be treated or cured unless large doses of alcohol were given. Mixed infection in diphtheria could not be cured by antitoxin, but treated with large doses of alcohol the sufferers might be saved. He had seen many such living, dying, or moribund patients since 1858 who had absolutely recovered through taking whiskey; they were not guinea-pigs, but human beings.

The Treatment of Genitourinary Tuberculosis with Rosenbach's Tuberculin.—A. Hyman reports on the results obtained in a series of 13 cases of genitourinary tuberculosis treated with Rosenbach's tuberculin and kept under observation for periods ranging from six months to a year and one-half. Two of these patients showed improvement; the other 11 were absolutely unimproved; a few developed additional tuberculous foci during the course of treatment. From this experience he concludes that Rosenbach's tuberculin is of no definite value in the treatment of tuberculosis of the genito-urinary tract.—*Journal Am. Med. Association*.

Cancer Metastasis.—Guthrie McConnell discusses the problem of metastasis formation in carcinoma, especially why secondary growths are common in some parts of the body and very unusual in others. It might be thought that all that is necessary is that several cancer cells become lodged in a lymphatic or blood capillary in order that a new tumor should develop. Such is not the case. Certain tissues of the body show a more or less marked immunity to the growth of secondary cancer. On the other hand certain types of tumors show a special affinity for certain tissues. There is evidently an organ affinity and an organ immunity. It is a well known fact that a primary malignant tumor in almost any part of the body will soon give rise to an infiltration of the liver. There is evidently something either present or absent that makes this organ especially suitable for the development of malignant tumors. Yet the liver, though nearly always involved secondarily, is very rarely the site of a primary tumor. On the other hand the spleen is rarely attacked, although its blood supply is great, and there can be no doubt that many cancer cells gain entrance into its sinuses. The explanation of the definite organ immunity may be that there are protective ferments adapted to break down the complex molecule of the cancer protein. The writer thinks we must get away from the idea that metastasis is a simple transplantation of tissue, but confesses that we are about as far as ever from the solution of the problem, and believes it is permissible to conclude that when cancer does develop it is on account of the lack of some substance that normally is present in most persons.—*New York Medical Journal*.

SOME MECHANICAL FACTORS IN COLONIC STASIS.*

BY CHARLES H. PECK, M.D.,

NEW YORK.

SURGEON TO THE ROOSEVELT HOSPITAL.

I WISH to state at the outset that I am not an advocate of removal of the colon in whole or in part, nor of ileocolostomy for constipation, and that I have never performed either operation for that condition. I also wish to say that it is not the purpose of this paper to attempt to cover completely the subject of the surgical treatment of constipation or intestinal stasis.

I simply wish to report a few cases of incomplete obstruction of the large intestine, due to mechanical causes, which have come under my personal observation during the past two years, and which may help to throw some side lights on one phase of this complex and extensive subject.

CASE I.—On March 30, 1915, I first saw in consultation a lady 55 years of age who for many years had suffered from a marked degree of chronic constipation, with its attendant symptoms of chronic intestinal toxemia. She was referred to me by a well-known gastroenterologist who had labored with the condition at intervals for several years with varying success for periods but no permanent relief. Headaches, lassitude, and depression interfered greatly with her social duties and daily routine of life, and she was more or less miserable a good part of the time. She was naturally energetic, businesslike and highly intelligent, not at all of the indolent, pampered, "sick-abed lady" type, and the fact that she so often felt below par and unequal to the daily demands upon her time distressed her greatly. Physical examination was practically negative; radiographic studies of the intestinal function showed a marked delay in the passage of bismuth through the ileum and head of the colon. Her physician felt that the probability of the presence of some mechanical obstruction of the colon or lower ileum warranted advising an exploratory operation. The patient herself had studied the situation rather exhaustively, had become impressed with the rather widespread publicity which the subject of intestinal stasis has been accorded of late, and was disposed to expect and accept the loss of a goodly portion of her colon as the only procedure likely to offer relief of her symptoms. After careful consideration of the evidence I agreed with her physician's view of the situation, though not entirely with her own, and advised an exploratory operation. This was performed on April 14, 1915. Through a right rectus incision the right side of the abdomen and pelvis were thoroughly explored and the entire interior of the abdomen was palpated. The stomach, liver and gall-bladder, and pelvic organs were all normal. The appendix had undergone obliterative fibrosis and was fixed by adhesions, binding down the cecum but not in a manner to cause the obstruction. The terminal ileum was free from kinks or adhesions. The real lesion was found in the form of a firm sheet or band of adhesions binding the lower two-thirds of the ascending colon

*Read at a meeting of the Practitioners' Society of New York, April 7, 1916.

firmly to the lateral abdominal wall, rotating it to the right on its longitudinal axis about 90°, so that the anterior longitudinal band was directly external and firmly adherent to the parietal peritoneum. Contraction of the bands had also drawn its upper and lower segments together on the anterior aspect in such a manner as to cause sharp buckling or angulation about underway between the cecum and hepatic flexure, causing a marked degree of obstruction at this point. This angulation, together with the fixation and interference with normal peristaltic movements, seemed quite sufficient to interfere seriously with the normal propulsion of the fecal current. Division of the bands allowed the colon to snap forward and straighten out in a very striking manner. The appendix was removed, though it was felt to be a negligible factor in the production of symptoms. Operative recovery was prompt, and before the patient left the hospital the increased freedom of bowel action was quite evident and the patient said that she felt more comfortable than she had for many years. Better still, the improvement has continued and relief from the constipation and the constitutional symptoms of stasis bids fair to be permanent.

This case illustrates a type of colonic obstruction, the so-called Jackson's membrane, which has a definite pathology and is not uncommon. The fixation of the colon, in a position of sharp rotation to the right, associated with longitudinal buckling or angulation, I have seen in a number of cases. The rotation is sometimes so great that the ileocecal junction looks directly forward instead of in the normal direction. The buckling I have seen so marked as to prevent the bismuth clyster from reaching the cecum. The degree of obstruction varies, and in a considerable percentage of the cases persistent, variable pain and discomfort may be the prominent symptom rather than stasis. I have recently had a case of this type in a vigorous non-neurotic young man of 24, operated upon four years ago for appendicitis, with persistence of pain, frequent and severe enough to interfere seriously with his work, and make him a semi-invalid, without symptoms of obstruction. While this latter case is too recent to report a permanent cure, division of the band has been followed by such complete relief as to warrant the hope that the seat of the trouble has been reached.

The relatively frequent occurrence of this condition, and its importance both as an obstructive and pain-producing lesion, have led me to search for it as a matter of routine in all cases, especially those of chronic type, in which the right abdomen is operated upon, whether for supposed appendicitis, gall bladder trouble or other conditions.

CASE II.—On March 15, 1915, I saw in consultation, in a neighboring city, a gentleman 59 years of age who gave a history of chronic obstruction of the bowels of about two weeks' duration, with sharp abdominal pain located in the left upper quadrant at the onset. On the day of the consultation he had for the first time in five days passed considerable quantities of gas and some fecal matter, and the wave-like colicky pain and abdominal distention were much relieved. He had suffered for years with obstinate constipation, but had

never before had an attack of actual obstruction. X-ray plates taken by a very competent radiologist seemed to show evidence of obstruction at or near the hepatic flexure, with great dilatation of the ascending colon and cecum. The picture did not seem characteristic of a neoplasm, though the presence of such a lesion was suspected on account of the patient's age and the gradual onset. On account of the temporary improvement and hope of further relief of the distention it was thought wise to defer operative interference for a time. One week later, on March 22, 1915, as no permanent relief had occurred, operation was performed. Exploration through a right rectus incision failed to show any evidence of obstruction or disease in the region of hepatic flexure. The ascending colon and cecum were so distended that the peritoneal coat had actually cracked in three places and the recent lymph of repair was demonstrable. The entire transverse colon was greatly distended and strong peritoneal bands could be felt in the region of the splenic flexure. A second incision was made through the left rectus muscle and a definite obstruction, due to strong peritoneal and omental bands, was found at the splenic flexure. The descending colon below this point and the sigmoid were collapsed. There was no evidence of neoplasm. The bands were divided, freeing the splenic flexure and allowing it to be brought forward, and gas immediately passed into the bowel below, with relief of the tension in the proximal gut. With no further operative procedure on the bowel, the wounds were closed and the patient made a prompt and uneventful recovery, with complete relief of the obstructive symptoms. He has remained perfectly well and his former constipation has been greatly relieved.

This case illustrates mechanical obstruction by bands at the splenic flexure, which after a long history of partial occlusion had become practically complete, and which was entirely relieved by a relatively simple operative procedure. The sharp angulation of the gut at this point, combined with its fixation by the bands and interference with normal peristaltic movements was undoubtedly an important mechanical element in the production of obstructive symptoms. The acute bend which the colon normally takes at this point, favors such a condition if adhesions and fixation occur.

Another example of obstruction at the splenic flexure is illustrated by the following case.

CASE III.—In October, 1915, a young woman 30 years of age consulted me for chronic constipation of a severe type. Catharsis had little effect and infrequent movements of the bowels were obtained by the use of enemas or irrigations. She suffered from headaches, general debility, and symptoms of auto-intoxication, which interfered greatly with her occupation as a stenographer and secretary. She stated that she would at times go as long as three weeks without a movement, and this was corroborated by her physician and nurse. Careful x-ray studies of the colon showed redundancy and dilatation of the entire colon, but especially of the sigmoid flexure and transverse colon, with evidence of incomplete obstruction in the region of the splenic flexure. She had undergone prolonged and conscientious medical treatment, including periods of several weeks' duration in a sanatorium, and had reached a point where she practically demanded that some surgical effort be made to afford relief. Her physician also felt that the degree of stasis, its resistance to medical treatment, and the marked impairment of her general health made some surgical procedure imperative. Operation was performed on Oct. 14, 1915, through a left rectus incision. Adhesions at the splenic flexure caused sharp angulation and fixation of the bowel at this point, though the degree of obstruction was not as great as that described in the preceding case. The sigmoid flexure was unusually long and redundant. The transverse colon was long, much dilated, and dropped well into the pelvis, though there was no displacement at the flexures, *i.e.* the condition was not one of general enteroptosis. While division of the bands and adhesions at the splenic flexure freed the bowel to some extent, I feared to trust this procedure alone on account of the length and redundancy of the colon above described. The left limb of the transverse colon lay in contact with the sigmoid loop, and lateral anastomosis between these two portions of the gut was decided upon and performed.

A 3-inch opening was made by suture, and after exploration of the rest of the abdomen and pelvis, with negative result, the wound was closed. Prompt recovery and immediate marked improvement in the constipation followed, and recent reports state that the improvement has continued and that the constitutional symptoms are much relieved.

The long sharply angulated left half of the colon was thus short circuited, relieving to a large degree the chief mechanical obstructive factor in this case. Whether the relief will be permanent and adequate or not time will alone show.

CASE IV.—A lady 49 years of age was seen in consultation with her physician, a prominent gastroenterologist, on May 20, 1915. Her history was one of obstinate chronic constipation, dating back many years, resistant to medical treatment which had been tried by many physicians, and of late approaching a degree of actual obstruction with chronic ileus. Radiographic studies seemed to show a rather definite obstruction in the descending colon. Constitutional symptoms were marked, general depression, debility, nervous exhaustion, headaches, the typical syndrome of chronic auto-intoxication. Operation was performed on May 27, 1915. Strong omental and peritoneal bands crossing the descending colon in its upper part caused a marked degree of constriction and fixation of the bowel at this point, and on their division the gut snapped forward and the obstruction seemed quite relieved. Exploration of the rest of the abdomen was negative except for a fibroid appendix, which was removed. The abdomen was closed without further operative procedure. The colon in this case, except for the dilatation above the obstruction, was practically normal. The operation was followed by prompt improvement in the constipation, which has continued to the present time, and marked improvement in her general health.

The four cases cited form concrete examples of non-malignant partial obstruction of the colon, amenable to surgical procedure of a comparatively simple and safe type, and of a degree quite sufficient to warrant advising an attempt at surgical relief.

Far be it from me to advise surgery for every case of constipation, nor for any case that has not had careful and intelligent medical treatment, and has been studied with all the modern diagnostic aids at our disposal. When this has been done a group of resistant cases will remain in which mechanical obstructive factors will warrant exploratory operation and in some of which operative results will be most satisfactory.

Cases in which general enteroptosis has been the dominant factor have in my hands been most unsatisfactory, and I do not mean to assume that the cases cited illustrate more than a small portion of the entire field of colonic stasis. They do, however, give a slight gleam of encouragement in the study of this most baffling and difficult condition.

30 WEST FIFTEEN STREET

GOLFER'S FOOT.

BY CHARLES CROSS, M.D.

SAN FRANCISCO.

IN view of the widespread interest that is being manifested in golf in this country it might be well at this time to consider an ailment that may afflict any one who plays that game.

Golfer's foot is a term I have applied to a very troublesome affliction which may occur to any golfer. It is an acute condition due to distortion of the foot as a result of broken arch in the anterior metatarsal curved area. The affliction is very easily acquired, it is often neglected, and sometimes becomes very troublesome. To add to the aforementioned discomfort, golfer's foot makes the player fretful and it interferes with play. If neglected, the con-

dition is liable to lead to a chain of efficiency-reducing ailments, the cause of which may be entirely overlooked. At the beginning of the season, or when beginning to play, all golfers should give their feet special attention, and be very careful to

FIG. 1 Machine showing the foot upon which excess of weight comes in making a drive.

keep them in good condition. In playing golf, and in practically every other work or play in life, foot-efficiency is essential.

When playing golf the anterior portion of the left foot, in right-handed players, and vice versa in left handed players, is brought into unusual service. This point is illustrated in the photograph (Fig. 1), which shows the machine used at a demonstration in a London golf school. The same may be demonstrated by any player taking particular notice of the manner in which the body weight comes over on the anterior portion of the left foot when making a right-handed drive.

Some players turn on the inside of the foot, resting the weight on the anterior portion, on the fulcrum of the great toe. (Fig. 2.) Players of this class are very liable to develop a large callus on the inner side of the great toe about opposite to the bed of the nail. (Fig. 3.) This is specially liable to occur if shoes are a bit short or tight. The cause of the callus appears to be irritation put on the side of the toe, and the toe over-riding the edge of the insole. Careful palpation on the inside of the shoe usually reveals the edge of the insole slightly prominent at the point of impact.

As the drive is made the weight of the body is brought back upon the foot, that has been elevated in the upswing, and it is brought back with great force. A great part of the force is distributed to the outer half of the anterior portion of the foot, or to the portion of the ossa fulcra made up of the heads of the metatarsal bones of the third, fourth, and fifth toes. The third and fourth metatarsals are generally the least used part of a foot and consequently, like the ring finger in the hand, they usually form the weakest portion. They are the first to give way when under strain. (Fig. 4.) The same undue strain occurs when the entire ossa fulcra or anterior portion of the foot is used instead of the

side. (Fig. 5.) When the whole front of the foot is used there appears less likelihood of injury because the strain is supported by the entire ossa fulcra, or the metatarsals and toes of the entire foot. Spikes in shoes are not a necessity in playing golf if the feet are properly used. At any rate wearing spiked shoes necessitates turning the foot on the side, and prevents use of the entire ossa fulcra, or front part of the foot. However, Golfer's foot is liable to occur in any foot not strong enough to bear the strain. For that reason all golfers should be very careful with their feet, especially at the beginning of the season, or at the beginning of play, or after an absence from the links. When a foot gives way in the region described it should have immediate and scientific attention.

Acquired foot distortions have not received the scientific attention to which they are entitled. Patients are more to blame for this neglect than physicians. It has been the custom for people afflicted with any sort of foot trouble to seek everywhere but the right place for treatment.

A specialty has been developed which covers the field of acquired foot ailments in a thoroughly scientific manner. It covers the neglected ground between conditions rightly treated by the chiropodist and those treated by the orthopedic surgeon. This new specialty does not encroach upon the domain of either the chiropodist or the orthopedic surgeon, but it does encroach upon the domain of the set of incompetents who have long mistreated feet.

The specialty of Practical Podology is practised by physicians, the graduates of recognized and standard medical colleges. Only such specialists should be consulted for foot ailments. To emphasize the statement I will repeat again that this work has no connection with chiropody nor orthopedics.

The condition found in golfer's foot is not of necessity confined to golf players. It is a very common distortion and may occur in any foot that is overused. The reason it is termed golfer's foot in this paper is because it is so liable to occur to golfers that their attention should be specially called

FIG. 2 A stance which may cause golfer's foot.

to it, so the distortion can be avoided. In this instance, an ounce of prevention is worth more than a ton of cure.

There comes what I call "period of reduced efficiency" to all persons who play golf, or any other

game. Champions suffer from this condition as badly as the merest tyro. Something goes wrong, and when players suffer for a month or more I have named this disease "perversion of intention." The game is "off." Apparently no amount of practice,

FIG. 3.—Golfer's toe; also showing bad effect on ingrowing toe-nail.

no amount of coaching, and no amount of analysis of technique have any effect on the player who is afflicted with "perversion of intention." They know what to do, how to do it, and why it is done, but when it comes to execution their intention is perverted.

"Perversion of intention" is a condition wherein the subjective portion of the individual's mentality fails to permit the muscles to act in unison, or in the regular sequence, necessary to do what the individual intends to do at the time he desires to do it. If golf is a game of nerves, as some experts put it, the feet are very likely to upset the equilibrium of that system. In fact, it may be safely stated that the feet derange the adjustment of the nervous system more often than any other part of the body brought into use while playing golf.

When the above condition occurs, it might be well for the golfer to have his feet thoroughly examined by an expert. Finding no trouble there, it will be well to have investigations made as to the blood-pressure, the condition of the kidneys, and the hardness of the arterial system. In nine cases out of ten there will be found some foot trouble. By this I do not claim that "perversion of intention" and all "off-play" are due to bad feet, but I do claim that bad feet and improper use of the feet are responsible for a great amount of "off-play." The feet of a golfer should be examined with the same care and frequency with which they have their teeth examined. Patients suffering with golfer's foot are liable to get an abundance of gratuitous advice and especially is this true around the 19th hole. It is well for the afflicted always to remember that 19th hole consultations are dangerous. The proper diagnosis and treatment of golfer's foot is an ailment requiring the highest skill in scientific podology. It is not a case for the chiropodist, the shoe-clerk, or the shoemaker, nor is the 19th hole a proper place for consultation, because in this instance a consultation without the most careful examination is worse than useless.

Golfer's foot is often overlooked, entirely neglected, or ignorantly treated until much harm has been caused, not only to the foot but to the general efficiency of the individual. (See Fig. 6, and note

the calloused soles and papillomas on soles.) How advantageously patients can neglect themselves for the benefit of some member of the medical profession is well illustrated in acquired foot distortions, and especially in golfer's foot. The golfer who hobbles through a season with an ailing foot is sure to suffer much-reduced efficiency. He is on the direct road to an attack of lumbago, or frequent attacks of lumbago, painful back, which may be diagnosed by the unskilled as rheumatism or sciatica, sprained ankle, sacroiliac disease, painful knee, or painful foot. (Fig. 7.)

The greatest art in the practice of medicine is to prevent disease. Therefore, it is to be hoped that what is here written may aid in some degree to prevent the efficiency-reducing and distressing ailments that often follow a case of golfer's foot. (Fig. 8.) Under appropriate headings the condition is fully described below.

Synonyms.—Broken anterior arch, distorted anterior arch, strained foot, sprained foot, gout foot.

Definition.—Distortion downward of the heads of the second, third, or fourth metatarsals, or any one of them.

Causes.—Undue strain, or unusual service imposed upon the anterior portion of the foot, is liable to produce relaxation or rupture of the ligaments supporting the anterior metatarsal arch. This is

FIG. 4. X-ray of golfer's left foot. Showing distorted heads of 3rd and 4th metatarsals.

followed by downward distortion of the heads of one or more metatarsals, or broken arch. In playing golf the anterior portion of the foot is brought into hard service, thereby causing undue strain upon the anterior metatarsal curved area or anterior arch.

(Fig. 9.) Another cause is changing to shoes with heels of different height. Persons who toe outward when they walk, thus using only part of the *ossa fulcra*, are very prone to injure the anterior portion of the foot.

FIG. 5.—Stance to protect the foot.

Symptoms.—The first evidence of golfer's foot is usually a slight symptom of discomfort at the base of the third or fourth toes, or between them. It is not exactly a pain, but the toes and the feet may feel fatigued, or misplaced in the sock, and the sock may appear too short or the toes appear too long. Any of these symptoms should arrest the attention of every golfer, otherwise the condition may go on and become a very severe case of metatarsalgia, Morton's painful toe, or chronic anterior broken arch. Slight swelling on the dorsal surface between the third and fourth toes may be noted. (Fig. 8.) There is sometimes severe pain on pressing the head of the third or fourth metatarsals. Placing the thumb on the plantar surface of the foot below the head of one of the metatarsals and with the finger on dorsal surface of the toe, and forcibly flexing the toe gives evidence of pain in golfer's foot. There is some degree of inflammation in every case of distorted feet. The feet being farthest from the central nervous system and the heart they present, as evidences of distress, symptoms different from distortion or inflammation in other parts of the body. The first symptom of golfer's foot or any other distortion may be a feeling of irritability, burning, or fatigue. Pain, if it ensues at all, is liable to be a late symptom, and it is wonderful what punishment feet can stand without pain.

Physical Signs.—One of the features of golfer's foot is the absence of physical signs. Comparing both feet, the afflicted with the well foot, there is, to the uneducated eye, practically nothing to be seen. An outline tracing of the foot with careful measurements with calipers may reveal that the afflicted foot is slightly wider over the ball of the foot. Few persons are able to discern any difference in the feet, yet the patient knows there is a difference. Over the heads of the metatarsals mentioned there may be slight evidence of swelling, or a little more prominence of the extensor tendons of the toes. On the normal foot there is no callus on the sole under the heads of the metatarsals. The presence of callus is evidence of a chronic distortion, or chronic broken-arch. Careful palpation denotes to the ex-

perienced hand the degree of distortion and the area of the affliction.

Diagnosis.—Golfer's foot is to be diagnosed from chronic anterior broken-arch or chronic metatarsalgia, or Morton's toe. The absence of callus on the sole, the history of the acute condition, and the absence of other foot distortions make the diagnosis very certain.

Prognosis.—The outlook in a case of golfer's foot depends upon the golfer and the treatment. In all cases a guarded prognosis should be given. The symptoms may appear slight to the patient because "it is only in one foot." Treatment is liable to be neglected until the condition has become chronic. Even then the patients seem to think any kind of treatment, shoes, supports, etc., that they can select themselves, or that are recommended by friends, will cure the condition. This is a feature about patients with golfer's foot that is beyond the specialist. So long as people with distorted feet desire to treat themselves, they generally make matters worse and have no one to blame but themselves. It is a misfortune, but it is an advantage to some physician every time a golfer's foot is neglected. It will require treatment some time, and the cure will be delayed because of the patient's neglect early in the case.

Treatment.—The treatment of golfer's foot is a matter of great importance. Even with the best treatment some feet are never as good as before they were injured. Upon recognition and treatment in the earliest stages will depend much of the future efficiency as golfers, or in any other walk in life.

There are three indications to be met: (1) Correct the positions of the distorted heads of the metatarsals in the anterior curved area, or arch. (2) Maintain the heads of the metatarsals in proper position. (3) Remove inflammation and tone up the tissues to support the bones in their normal position.

FIG. 6. Efficiency reducing the distortion in the neglected golfer's feet.

The first indication is best met by a method to relax thoroughly the muscles, which are liable to be in a state of contraction. This can be accomplished by application of dry heat by means of a Tyrnauer baker, or "L-Ray" electric heater. Heat

applied in this manner penetrates the tissues deeper than by the application of moist hot packs. It has the advantage of being cleaner and giving a heat more uniform in temperature. It should be applied for about fifteen minutes daily, or every other day, for one or two weeks or until the tissues maintain the normal curve of the arch. Some cases relax very quickly while others are very difficult to relax.

The second indication is to be met by the application of flexible support composed of cork, rubber, or leather.

The support used in my treatment of these cases is made of cork and rubber. The proper elevations can be made to support the metatarsal or metatarsals which require adjustment. The supports, when correctly adjusted, are to be worn in the shoes

and swelling in the feet. All distorted feet are in some degree inflamed and swollen.

The boot is made up of a piece of gauze 1 yard wide by $2\frac{1}{2}$ yards long, a piece of oil silk, oil muslin, or other waterproof material 24 inches by 36

FIG. 8.—Golfer's feet. Right shows slight swelling over 2nd and 4th metatarsals, just above toes. Left shows slight swelling over 2nd, 3rd, and 4th metatarsals.

inches, and a large towel for each foot. The gauze is moistened with a solution of a heaping tablespoonful of magnesium sulphate, or other indicated medicament, to a pint of warm water. The gauze is squeezed gently so it will not drip and then wrapped around the entire foot and ankle, to about as high as the shoe top. Over the gauze the waterproof covering is applied, and over that the large towel is applied and secured with safety pins. The dressing should remain on the foot over night, and should be applied as often as ordered by the specialist.

Walking with toes outward is a habit that has been drilled into children long enough to make busi-

FIG. 7.—View of golfer's foot (right). Lower downward distortion of head of 4th metatarsal.

until they can be removed with safety. Removal of supports requires as much care and judgment as does the application of the support.

The third indication is to be met by the use of the same heat mentioned above.

The feet should be exercised nightly in the way of picking up small objects like a marble, a cork, or a knife.

As golfer's foot is usually an acute condition there are present more or less swelling and inflammation. These should be removed by the treatment mentioned above which is to be supplemented at night by application of the Charing Cross boot.

The Charing Cross boot is a plan of treatment devised and used in the Charing Cross Clinic, San Francisco. Its purpose is to reduce inflammation

FIG. 9.—A well balanced position to protect the feet. Posed by Mr. Hughes, Instructor, Hotel St. Francis Golf Course, San Francisco.

ness for all the scientific podologists for a generation to come. Almost all persons who toe out when they walk are on the road to some degree of foot distortion. The proper method of walking is to toe straight, or if anything to toe slightly in. Walk-

ing in this manner brings into use the entire ossa fulcra of each foot and maintains development of the entire foot and leg. In walking with toes out, the metatarsal of the great toe is the only one used as the fulcrum; the others become weakened from slight use or non-use.

Changing from shoes with high heels to low heels is a dangerous procedure. When playing, the golfer should wear shoes with heels about the height to which he is accustomed. If low-heeled shoes are worn during play they can be built up inside and this prevents any distortion which may be brought about by changes. All shoes should be carefully examined to see if they are wide enough and long enough.

There are numerous appliances on the market which are intended to correct distorted feet and broken arches. In some cases they may appear very well, but there is no ready-made plate that will give the desired result in more than 8 per cent of the cases. In the meantime a golfer's foot may be all but ruined.

There is just as much difference in people's feet as there is in people's faces, and any support used should be constructed according to the conditions of each individual foot and should be made of a flexibly material. No plaster casts nor other mucky, messy stuff is necessary for measuring a foot if the specialist understands what is indicated.

The use of metal arches or foot plates for this condition is to be condemned. Metal appliances of all kinds splint the foot and prevent proper functioning of the muscles and ligaments. Such inactivity causes atrophy from disuse. An exactly opposite condition is required in the successful treatment of golfer's foot. It is necessary to have a good pair of feet to stand upon, to work upon, and to play upon to be a good golfer.

275 POST STREET

A REVIEW OF ONE HUNDRED AND THIRTY-TWO CONSECUTIVE OPERATIONS FOR FIBROID TUMORS OF THE UTERUS.*

BY EDWARD G. JONES, M.D., F.A.C.S.,

AND

DEAN F. WINN, M.D.,

ATLANTA, GEORGIA

THE operations analyzed represent only our own work, and are consecutive. Every patient presenting herself was operated upon.

The list comprises: Abdominal hysterectomy, 120; abdominal myomectomy, 4; vaginal myomectomy, 5; vaginal and abdominal myomectomy, 2; celiotomy without removal of tumor (evident sarcomatous degeneration with involvement of mesenteric glands), 1; total, 132.

Ninety-one were married; eleven were single; there is no information concerning thirty, though it is probable the majority were married.

Of 118 patients, the youngest was 21; the oldest 65; the average age was 35.

I. Prior Symptoms.—*First:* Pelvic pain; 95 complained of such pain, 24 did not so complain, 13 no record made. Unless there were complications, such as pyosalpinx, etc., the pain was usually more of a pelvic discomfort than positive pain.

Of the 24 patients who did not complain of pain, seven had subperitoneal tumors; six had protrud-

ing polypi only; one had polypus and small interstitial tumors; three had only small interstitial tumors; two (Nos. 67 and 83) had extensive adhesions to large tumors fed by enormous, highly atheromatous vessels (Fig. 1); the remaining histories give no information as to the kind of tumor, but the presumption is in favor of subserous growths, as there was no irregular or profuse hemorrhage.

Second: Hemorrhage; no record, 13 patients; irregular and profuse, 51; neither irregular nor profuse, 41; irregular, 8; profuse, 19.

Of the forty-one women who did not so complain, twenty-five had either single subserous tumors or one or two more or less large subserous and small interstitial growths. Four of the remaining sixteen had diseased appendages, but no record was made as to the location of tumors.

Third: Leucorrhea; no record, 13 patients;

FIG. 1. Large multiple tumors fed by enormous highly atheromatous omental vessels.

marked leucorrhea, 88; slight leucorrhea, 8; no leucorrhea, 23. Of the eighty-eight women with marked leucorrhea, twenty-two are recorded as having had no hemorrhage. Of the twenty-two, twelve had diseased appendages; three had multiple or intraligamentous tumors with no other pathology recorded; one had a large calcareous pedunculated growth; one had subacute gonorrhea; and there is no history concerning the pathology of five. The remaining sixty-six, and the eight who complained of only slight leucorrhea, had either profuse menstruation or irregular and profuse hemorrhage.

It may be noted that, with five exceptions (Nos. 4, 37, 83, 125 and 128), the twenty-three women who had not marked leucorrhea also had no profuse or irregular hemorrhage. In the case of Nos. 4 and 37, the hemorrhage is recorded as profuse but not irregular; in No. 128 as irregular—which may have been normal for these women. In the case of

*Read before the Fulton County Medical Society, February 17, 1916.

No. 83 the cavity of the uterus was enlarged with several growths projecting into it. No. 125 had small subserous fibroids, and the hemorrhage was from other causes. She bled rather profusely from the cervical stump for three days following operation.

Fourth: Vesical irritation; no record, 13 patients; troublesome irritability, 66; slight irritability, 8; no irritability, 45. Of the seventy-four patients with troublesome or slight irritability, eighteen had large or multiple fibroids; seventeen had tumors impinging directly upon the bladder or so situated as to press the cervix against the bladder; three had gonorrhea; four had only a few small fibroids and offer no explanation for the bladder symptoms; four had polypi; there is no record of the pathology bearing upon the bladder symptoms in the remaining twenty-eight women, though it is probable they had intrapelvic pathology to account for them.

Of the forty-five without bladder symptoms, twelve has subserous fibroid growths (two had in addition subserous tumors; one had small interstitial tumors and a small fibroid of right ovary);

FIG. 1. An unusual type of fibroid tumor, causing difficulties in its removal.

nine had intrapelvic pathological conditions which would lead one to expect vesical irritability, and no explanation appears for its absence; of the remaining eighteen there is no pathological condition recorded.

Fifth: Abortions and miscarriages; full term pregnancies without abortions, etc., 35; full term pregnancies with abortions, etc., 22; only abortions or miscarriages, 10; never pregnant, 40; no record, 25.

There are data as to the bearing of children by one hundred and seven of these women. Sixty-seven women have borne a total of one hundred and forty children, with a total of fifty-five miscarriages or abortions. Eleven of them were unmarried and had no children, and twenty-nine, who were married, have never been pregnant—their average age at the time of operation being 34 years. Of these twenty-nine, sixteen had irregular or profuse hemorrhage or both. There is no record of No. 35 as to hemorrhage or pathology. Of the remaining twelve, Nos. 1, 41, 43, 53, 62, 75, 89 and 106 had no hemorrhage, and there is insufficient record as to the path-

ology of the tumors, but all of them had diseased ovaries and tubes. No. 114 had a moderate sized subserous fibroid and complete procidentia for fifteen years. (Inquiry failed to develop adequate explanation of her prolapse; she had always been healthy, never had had hemorrhage and had never been pregnant.) Nos. 77 and 107 had subperitoneal tumors. No. 132 had a small subserous tumor and double pyosalpinx.

Eighteen had aborted or miscarried oftener than they had gone to term; twelve of these had marked metrorrhagia. Of the six exceptions, there is no record of the pathology in No. 27; No. 51 had a bilateral intraligamentous tumor and involved tubes and ovaries; No. 54 claims to have had twenty-five miscarriages in seventeen years (probably periodical hemorrhage); No. 58 had extensive adhesions and both ovaries and tubes diseased; No. 100, with left sided pus tube, had no uterine hemorrhage for five years prior to operation, her miscarriage occurring fifteen years before; No. 108, tumor intraligamentous to both pelvic walls, had two abortions and then went to term eight years prior to operation.

Twenty-nine women had borne two or more children with no miscarriages, or relatively few miscarriages. Of these, in nineteen the tumor appeared some time after the last child was born. Nos. 37, 55, and 65 are recorded as having intraligamentous tumors; the remaining women had an average of forty-two years, so that presumably they bore children before the tumor began to grow. In the case of No. 33, aged 32, no explanation appears. No. 37 had syphilis and Nos. 85 and 123 had well-advanced pellagra.

II. Postoperative History.—First: To the question, "Is the general health satisfactorily improved since the operation?" the answer is: Yes, for one hundred patients; two patients were operated on too recently for the information to be of value; seventeen women have not been heard from. No. 79 is no better—she had pellagra. No. 100 returned eighteen months after operation to be treated for "ovary trouble." The second operation revealed dense adhesions between bladder, sigmoid, and right ovary (the bladder having been accidentally opened at previous operation) and a large par-ovarian cyst. She left the hospital cured more than a year ago. No. 120 has better general health, but is very nervous and suffers with insomnia.

Second: Is there a hernia in the wound? Information is at hand concerning all but twenty-five patients. No hernia developed in any instance.

Third: At any time since the operation has there been a bloody vaginal discharge; and, if so, how many separate times has this happened? There is no information from thirty-one patients. Of the remaining eighty-five upon whom hysteromyomectomy was done (omitting myomectomy, etc.) a bloody vaginal discharge simulating menstruation is reported several times by two patients, once by four, three times by one, twice by three, four times by one. Two were operated on too recently to make information valuable. No. 87 claims to have had hemorrhage quite a number of times, but only when having sexual intercourse. Efforts to get further information relative to the cause of this hemorrhage have been fruitless. No. 93 reports eighteen months after operation: "I have all the symptoms I used to have except there is no clot or pure blood. The discharge has lasted four or five days every month until the last two or three

months, when it has been scanty and lasting only a day or two." This patient had a very large fibroid which protruded through the cervix and required supravaginal hysterectomy. It is possible and probable that a high amputation of the cervix was done, but no record was made of it, though for the last two years the discharge has not appeared. No. 98 claims she began to have hemorrhage about nine months following operation, that it occurs as a small monthly flow lasting two days and resembling the discharge during the last days of a normal period. Examination eighteen months after operation disclosed a cervix normal in appearance and freely movable. There was not an unusual amount of cervix left. No explanation appears for her symptoms. No. 125 had considerable hemorrhage from the cervical stump for three days after operation.

Fourth: Does the patient suffer from troublesome leucorrhea which was not present before operation? No information is at hand from thirty patients, and two were operated on quite recently. Seventy-seven answer in the negative. Of these, twenty-one reported no leucorrhea before operation. In six women it is still marked, and in eight women it is less troublesome than before. Two patients (Nos. 79 and 100) report leucorrhea which was not present before operation. In the case of No. 79 it is said to be due to vaginal irritation from pellagra. No. 100 is the same patient who returned for operation for abdominal adhesions and parovarian cyst.

Fifth: Does the patient suffer with bladder irritation now? There is no information concerning thirty patients, and insufficient time has elapsed in two cases. Fifteen patients complain of irritability—one of these answered "no" four months after operation and "yes" a year later. Eleven had bladder symptoms before operation. Of the three women who had no trouble before operation, but who now complain, No. 79 has pellagra; No. 89 claims to be unable to hold urine when desire comes; and No. 108 has leakage of urine on account of a cut ureter. The remaining women report no trouble. No. 114, who had complete procidentia, came to operation for relief of bladder symptoms. She reports no trouble now, though procidentia is still present, suspension of the cervix by suturing it to the round ligaments having proved inadequate.

Sixth: (1) Does this patient now, or did she for a while, suffer from natural menstrual discomforts monthly without actually menstruating? (2) Did the nervous and circulatory disturbances of the menopause follow the operation, and, if so, (a) How soon after the operation did they begin to appear? (b) How long did they last? (c) Were they more severe or less severe than the symptoms of the natural menopause?

We have been anxious to get just as accurate information as possible upon the question of the effect upon the general health and on the menstrual function in these operations of leaving one ovary or both ovaries.

In this series of cases the ovaries have usually been conserved if their condition seemed to warrant it, though very frequently the indications were that it was wiser to remove them, and it was done. Operators of experience almost universally note the presence of pathologic ovaries with uterine fibroids, so that their ablation is perhaps wiser in the majority of instances. The younger the woman the more care we have exercised in leaving one good ovary if possible.

Of course, usually, probably always, unless some

corporeal endometrium has been left by a rather high amputation the actual flow of blood at the menstrual period will be stopped promptly, as previously noted in this review, whether the ovaries be left or not; but whether the other menstrual phenomena persist through the natural menstrual life when one or both ovaries are left is affirmed by some and denied by others—presuming the ovary or ovaries to be fairly normal. The truth appears to be that too little reliable study has been given to the subject in question, the profession taking largely for granted that the preservation of good ovaries *does* postpone the disturbances of the menopause—without actually knowing this to be so. Our efforts to get the truth with regard to these questions from the patients here discussed have been somewhat disappointing up to date. With doctors, as well as with patients, the postoperative amenorrhea is too frequently confused and made synonymous with the actual menopause.

In reviewing the answers of the seventy-six patients about whom we have information we find that thirty-one are recorded as having nervous and circulatory disturbances and that forty-five report no such trouble. Nine of the twenty women in whom *both ovaries were removed*, with an average

Fig. 7. —Large fibroid, partially delivered, showing adhesions containing troublesome vessels.

age of thirty years (none over forty), answer "yes." Of the remaining eleven who report no trouble, one patient had passed the menopause before operation and one was over 45 years. The others have an average age of 37 years.

In thirty-five patients both ovaries, one ovary, or a part of one or both ovaries was conserved. Twelve of these answer "yes." Their average age was 34 (none over 40 years). Twenty-three answer "no"; two had passed the menopause before operation, and only three were above 45. There is no information at hand concerning the removal of ovaries in twenty-one patients. Eleven (only one above 45 years) answer "no"; ten report "yes," of whom five were over 40 years of age.

All but two women report the symptoms as being *less* severe than those accompanying the natural climacteric. One (No. 79) has pellagra, which is thought to be responsible for her symptoms. One of her ovaries was resected. The other (No. 120) is extremely hysterical. Neither ovary was removed in her case. Eighteen of those claiming symptoms of an artificial menopause also report having menstrual menses without actually menstruating; fifteen do not so complain. Seventeen who *did not* suffer with climacteric disturbances *do*

report menstrual discomfort. In nine ovarian tissue was left; in four no record was made.

Women over the age of 45 years have suffered just as severely as those of a younger age. Mandl and Buerger also note this fact in a series of one hundred cases. It would, therefore, seem that, if the leaving of ovaries does obviate or mitigate the symptoms, the ovaries should be retained at all ages and not confined to those under 45 years.

These statistics would hardly lead one to the conclusion that the conservation of apparently normal ovaries will prevent or postpone the appearance of an artificial menopause, since the majority of those in whom no trouble is reported, and in whom both ovaries were removed, and all of those who do report trouble, but in whom ovarian tissue was left, were around the age of 36. The severity of the symptoms seem also not to be affected, since it will be noted that in the two women who claim their symptoms more severe than those of the natural menopause ovarian tissue was left. These facts lead one to inquire if it is not probable that other factors, such as trauma to the pelvic sympathetic

FIG. 1. Type of intraligamentous tumor calling for special attention to the ureter.

nerves incident to the operation, are active in producing the climacteric syndrome.

Another question which claims our attention with reference to this matter is the likelihood of cystic degeneration taking place in the retained ovaries. Too often, perhaps on account of the conviction that the conservation of an ovary will ward off an artificial menopause, or for sentimental reasons, unhealthy ovaries are left by an operator. It is unfortunate that so few cases of second operations for removal of diseased adnexa following supravaginal hysterectomies have been reported. In this series only one case has returned for operation. This woman had a large parovarian cyst. No. 98 returns complaining of left side pelvic pain. She has a small mass which is probably a cystic ovary. It is possible that ten of the women (mentioned under question eight), who report having had postoperative abdominal pain, had symptoms dependent upon diseased appendages since ovarian tissue was left in all of them. We can recall operating upon three or four other patients for cystic ovaries in whom hysterectomy had been done by other surgeons.

Seventh: Has any serious mental disturbance developed? Nos. 79 and 123 have mental symptoms due to pellagra. No. 97 has cerebral syphilis. No other patients have shown such symptoms. No. 70 is cured of hysteria, which rendered her a bed-ridden invalid for five years prior to operation.

Eighth: Is there any pain which may be due to abdominal adhesions? No. 5, four years after operation, was thought to have chronic appendicitis. At that time she was passing the menopause. No. 10, four years ago, complained of vague left iliac pain, but now has none. Nos. 12, 26, 43, and 87 answer "yes" to the question; these were all clean cases, and no explanation is offered. No. 41 answered "no" in 1911, but now claims to have slight pain radiating to back. This is a patient whose wound opened on account of catgut absorbing too quickly. No. 60 complained of slight pain in upper right quadrant four months after operation. No. 68, extensive adhesions and double pyosalpinx, complains of slight pain in side. Nos. 79 and 123 have symptoms which are attributed to pellagra. Nos. 106 and 110 reported "yes" a few months after operation; a year later they answered "no." It is possible that the symptoms of some of these women were due to cystic degeneration of retained ovaries and to adhesions. No. 100 is the only woman who returned for operation. She had extensive adhesions and a parovarian cyst. Her bladder had been opened at the first operation. A number of other patients whom we would expect, rather than the above, to have such pain because of adhesions, pelvic peritonitis, etc., evident and troublesome at operation, seem surprisingly clear of it. There is no information from thirty-one patients.

Ninth: Is there any unfavorable symptoms not present before operation? There is no report of thirty-two patients and two were operated on too recently for their answers to be valuable. No. 4, four years after operation, had some swelling in her left leg—a relic of postoperative phlebitis. No. 28 claims to have "poor circulation," which she attributes to a later operation for goiter. No. 79 has many nervous symptoms due to advanced pellagra. In the case of No. 97 symptoms of cerebral syphilis have become worse. No. 100, with postoperative adhesions (mentioned above) is now well. No. 108, whose ureter was cut, still suffers from dribbling urine (ureterovaginal fistula). No. 113 has articular rheumatism in hip and shoulder. No. 120 complains of nervousness and insomnia. No. 124 is said to have gallstones.

Tenth: Is the sexual appetite affected? There is information concerning only sixteen patients (all negroes). Eight report unaffected, four report diminished, one reports lost completely, three report increased. Of the eight reporting unaffected, three had both ovaries removed; four had one ovary removed (one of these, No. 113, had no appetite for seven years and has none now); and of one there is no record. All five women with diminished appetite had both ovaries removed. No. 10 lost all desire completely, and, as a consequence, her husband left her. Two women (Nos. 106 and 115), one ovary transplanted and both ovaries removed, respectively, had diminished appetite for one year following operation, but now say it is increased. No. 103, one ovary removed, reports appetite increased now because intercourse is no longer painful.

Eleventh: If this patient has died since operation do you know the cause of her death? Three

patients are known to have died since operation: No. 36, æt. 50, from pellagra, three years after operation; No. 42, æt. 41, from cancer of the breast, four years after operation; and No. 17, æt. 49, cancer of the uterus. Only an exploratory operation was done upon the latter, and it was evident at the time that malignant degeneration had taken place with involvement of the mesenteric glands.

Complications.—Extensive adhesions, 22 cases; moderate adhesions, 22; large proliferating ovarian cyst, 2; intraligamentous fibroids, 14; intraligamentous cysts (bilateral), 1; intraligamentous cyst (single), 1; ureter over tumor, 3; dermoid cyst, 1; sloughing tumor, 1; appendix adherent (removed), 20; cystic degeneration, 1; pregnancy (six weeks), 1; umbilical hernia (repaired), 6; hyperthyroidism (exophthalmic goiter), 1; extreme obesity, 2; pellagra, 3; large hematoma of ovary, 1; large ovarian cyst, 1; chronic nephritis, 1; gallstones, 1; diseased gall-bladder, 1; pelvic abscess, 1; large multiple tumors fed by enormous highly atheromatous vessels, 3; fibroid of ovary, 1; procidentia, 1; large fibroid protruding through cervix, 1; necrotic fibroid, 1; calcareous degeneration, 1; syphilis and epilepsy, 1; fistula in ano, 1; diseased ovaries and tubes, 37.

We omit purposely a discussion of technique, except to say that experience has led us to be more and more careful to suspend the cervical stump (if left) by the round ligaments or by the gathered peritoneum of the broad ligaments. Bisection has been practised in some instances when it seemed to promise better protection to the ureters, or when the tumor could not be delivered without difficulty or danger or inaccessible hemorrhage.

Supravaginal amputation has been the usual procedure, the increased mortality of complete hysterectomy more than outweighing the immunity from cervical cancer acquired by the more radical operation. It has not been our practice to hollow out the cervical stump. Instead, the outer muscular layers have been sutured together anteroposteriorly in order to close the canal and prevent oozing.

In four cases necessitating the removal of both ovaries, one or a part of one ovary was transplanted. Two of these women have not been heard from. No. 110 had symptoms of artificial menopause for about five months after operation. They were less severe than those of the normal climacteric though she was seriously sick at the time with pulmonary tuberculosis. She had gained 60 pounds since the operation. In the case of No. 106 there were no symptoms resembling the menopause. For about one year she complained of tenderness in the middle of scar (the point of transplantation). We expect to soon report upon a more extensive series of cases in which ovarian transplantation was practised.

We believe that there is less likelihood of dangerous adhesions if care is taken to place the sigmoid in the pelvis before closing the abdomen, instead of allowing the small intestines to fill up the cavity, and to leave the omentum in its normal position.

With few exceptions the gall-bladder has been examined by palpation in all these operations. In only one case (No. 118) were gallstones discovered. In another case (130) a whitish adherent gall-bladder was found. These findings are out of keeping with the common teachings of internists, especially since cholelithiasis is a woman's disease and these one hundred and thirty-two women averaged middle age.

In two patients (Nos. 91 and 100) the bladder was opened accidentally, and in one patient (No. 108) the ureter was cut.

Thirty-nine patients required other work in addition to the removal of fibroids: appendectomy, 20; perineorrhaphy, appendectomy, 1; trachelorrhaphy, perineorrhaphy, and appendectomy, 1; perineorrhaphy and suspension, 1; perineorrhaphy and appendectomy, 1; trachelorrhaphy, suspension, and perineorrhaphy, 1; trachelorrhaphy and perineorrhaphy, 1; perineorrhaphy, 1; ventral suspension, 1; fistula-in-ano, 1; umbilical hernia repaired, 6.

The *mortality* in this series of cases is not such as, of itself, to claim favorable comment—nine patients having died—though it is, perhaps, not above that in the ordinary run of complicated and uncomplicated cases.

No. 9, æt. 44, died sixty hours after operation from paralytic ileus. This patient should not have been operated on in her then condition. Preliminary blood transfusion would have made her a better risk. She had known she had the tumor for fourteen years. During most of this time hemorrhage had been prominent, and for the last three years very profuse so that she was practically exsanguinated. Her pulse was 120 almost continuously after she came under our observation and the hemorrhage continued. The tumor was large and sloughing. It was removed quickly, but she did not rally.

No. 14, æt. 32, had a number of fibroids matted together with abdominal viscera. The operation was concluded in a comparatively short time with little evidence of shock, but with considerable trauma by reason of the adhesions. The patient died suddenly thirty hours after operation with characteristic symptoms of pulmonary embolism.

No. 20, æt. 48, was known to have albuminuria before operation. Continued hemorrhage demanded interference, and the patient died with the usual symptoms of urinary suppression.

No. 39, æt. 43, had a tedious operation on account of extensive and dangerous adhesions. Thirty-six hours after operation she was seized suddenly with tachycardia. Hemorrhage was positively excluded by a number of symptoms at the time and by the subsequent history. Her condition remained critical for three or four days. At the end of five days she seemed out of danger. On the eighth day the wound was carefully examined with the view of discovering infection. It was perfectly clean; the same afternoon she coughed, the wound opened and the intestines were somewhat soiled. No pus appeared. The tachycardia appeared again, and the patient died in thirty hours without any characteristic evidence of peritonitis. She had no gross cardiac lesion, though an undiscovered myocarditis may have explained her symptoms.

No. 61, æt. 35, supravaginal hysterectomy for multiple fibroids. The tumors occupied about equally the anterior and posterior uterine walls, pushing the bladder upward and filling Douglas' sac. The tumor was difficult to deliver on account of shape. There were no adhesions, and all raw surface was covered. Both ovaries were left. The appendix was apparently normal and was left. Five days later, with a practically normal temperature and pulse, death occurred suddenly from pulmonary embolism.

No. 83, æt. 57, had multiple intraligamentary fibroids. The cavity of the uterus was greatly enlarged and contained several submucous growths

projecting into it. There was extensive omental adhesions carrying enormous, highly atheromatous vessels (Fig. 3). The intestines were matted about the tumor. The bladder was displaced to the right. Patient died seven days after operation from post-operative pneumonia.

No. 85, æt. 44, had vaginal myomectomy. The polypoid growth protruded through the cervix and was as large as an orange. After operation she was referred for medical treatment for pellagra. Weakened from continuous severe hemorrhage before operation she died five days later. This patient cannot justly be considered in our operative mortality.

No. 91, æt. 40, had multiple fibroids for which supravaginal hysterectomy was performed. The growth was intraligamentous on both sides, and was removed by bisection. One large tumor occupied the uterine cavity and projected well into the vagina (Fig. 2). This tumor and the extensive adhesions within the abdomen prolonged the operation, and the patient died two or three hours later from shock.

No. 117 was 50 years old and had noticed the presence of the tumor for about fifteen years. There were enormous multiple fibroids which filled the abdomen and pelvis. One large tumor had dissected well behind the sigmoid; another lay beneath the liver and was connected to a pelvic tumor by a small pedicle—both of these tumors had undergone extensive calcareous degeneration. The intestines were matted about the growths. Enormous highly atheromatous vessels filled the omentum, from which they passed to the tumors. She died forty-eight hours later from suppression of urine.

SUITE 714 HERT BUILDING

A REPORT ON TWO CASES OF SYPHILIS OF THE LUNG.

By SOLOMON BAUCH, M.D.,

NEW YORK.

SENIOR PHYSICIAN TO THE TUBERCULOSIS DEPARTMENT OF THE MONTEFIORE HOSPITAL.

CASE I.—L. K., age 51, grocery clerk, single.

Family History: Father died at 78 of apoplexy and mother at 56 of pneumonia. One sister alive and well.

Previous personal history is negative, except for continuous general weakness, and especially sexual weakness. The reason for his celibacy was sexual impotency.

Present illness dates back to about three years ago when patient was confined to bed with fever, cough, and pain all over his chest for about one week. He made an uneventful recovery. About one year ago he began to cough, lost weight and complained of general weakness, night sweats, and pain in the right chest. These symptoms became so severe that he was compelled to give up his work. While he remained at home patient slightly improved. He never had hemoptysis.

Status Præsens.—Patient is fairly well nourished and developed. He is slightly dyspneic and cyanotic. There is no evidence of edema in any part of his body. He walks about with ease. There are no gross anatomical deformities.

Chest is barrel-shaped, expansion fair on both sides. There is a retraction on the right upper chest anteriorly. There is marked dullness over the right lung, especially at the apex and at the base. The breathing is amphoric in quality at the upper and the lower lobes, pleuritic râles over the middle and lower lobes; cavities at upper and lower lobes. There is hypertrophy of the left ventricle of the heart. The second aortic sound is accentuated. The radials are somewhat sclerosed, and the temporal vessels are tortuous.

Extremities.—There is no evidence of edema, scars, or paralysis. Reflexes normal.

Glands.—Epitrochlear on the right side are palpable; inguinal palpable; submaxillary palpable.

Fluoroscopy.—Marked dense bands of fibrous tissue all over the right side. Hilus glands enlarged on both sides. Left side clear all through. There are a great number of variously sized cavities and marked fibrous and pleural adhesions in the upper half. Pneumothorax in axillary portion of the upper half. Differentiation very difficult, due to the marked adhesive and fibroid process. The lower half shows a dense peribronchial infiltration, with marked density at axillary portion of the base, and with numerous enlarged bronchi. The quiet, evenly dense shadow at the lower axilla might be due to thickened pleura. Left lung is normal, except for the enlargement of the hilus gland. The mediastinum is displaced to the right. The diaphragm on the right side is high up and irregular. The ascending aorta is markedly widened. The heart is exceedingly small.

Patient is always running an afebrile course. Weight stationary.

Laboratory Notes.—Urine, negative. Sputum (twenty-four examinations for tubercle) negative, including antiformin. Four Wassermann examinations + + + each time. Guinea-pig injection with sputum proved negative. Complement fixation, negative.

Therapeutics.—Patient received five injections of salvarsan, mercurial injections and iodide administration for one year and a half, without any apparent improvement, neither in the general nor in the local conditions.

Summary.—(1) Patient's condition stationary. (2) The lung involvement is on the right, and mostly at the base and the roots. (3) Sputum negative. (4) Wassermann positive. (5) In spite of the excavations, the

Patient L. K. The radiogram shows that, in the right lung, there is involvement of the base, mostly near the hilus. The left lung is clear, except for the hilus. The aorta is markedly dilated.

patient feels comfortably well, is mostly afebrile, and does not lose in weight. (6) X-ray plate, as is seen, has the typical location of luetic infection.

We therefore infer that the above is a case of syphilis of the lung, and not tuberculosis.

CASE II.—I. M., age 28; married. Occupation, carpenter. Russian, in United States seven years.

Admitted to hospital September 19, 1913. Readmitted July 20, 1914. Diagnosis, incipient tuberculosis. Length of stay in hospital three months. Condition arrested. Weight on admission, 114 pounds; on discharge, 125 pounds. Cough moderate. Expectoration, one bottle daily. Sputum, frequent examinations for tubercle bacilli negative. Guinea-pig (injected several times) negative. Von Pirquet negative. Digestion fair. Hemoptysis prior to admission two or three times.

Family History.—Father died at 62, of cancer; mother at 31, cause unknown. Brothers and sisters—four brothers and four sisters—alive and well. Consort alive and well at 30. He has four children; one suffers of lues, and probably also of tuberculosis, and another one also shows symptoms of tuberculosis. All other members of the family are well. Patient is the fifth child. Married for sixteen years.

Tuberculosis in consort's family, negative for Tbc. He never lived or associated with consumptives. Was a carpenter all his life. The surroundings when at work were fair. Worked daily 10-11 hours. Mode of

life and habits poor. Present dwelling poor; previous dwelling poor. Spent his evenings at home.

Habits.—Tobacco, no. Liquor, no. No excess whatever. Appetite good. Was breast fed.

Disease of childhood, smallpox at 14. General condition in childhood good.

Present illness.—First presumable evidence of disease, cough and expectoration. In February, 1913, pain in chest. First demonstrable evidence of disease, slight hemoptysis in February, 1913. Patient caught a cold in February, 1913, and coughed and expectorated considerably. Had transitory pains in chest and back. Appetite was poor, spat up a mouthful of blood. Was examined by Board of Health, and told he had pulmonary tuberculosis. Was advised to discontinue work and go to the country. Remained at work until the middle of April, when, on account of loss of weight (from 138 to 120 pounds) and increasing weakness, patient left work and went to Sullivan County, remaining ten weeks, and gaining twenty-seven pounds. Expecterated a mouthful of blood in May. Felt well on return to city, and returned to work, but was forced to discontinue on account of general weakness.

Status Præsens.—Nutrition poor. Skin and mucosæ normal. Complexion dark. Extremities normal. Thorax, type rachitic. Spinal column slightly hypophotic. Laryngology, negative. Angulus ludovici large. Retraction marked above and below both clavicles, more on the left side. Cervical glands palpable. Dullness both apices, anteriorly and posteriorly, strip at left base with few fine râles.

Laboratory Notes.—Temperature (first time) afebrile. Urine (twenty-four hours) clear, amber, acid 1.019 negative (4 urines). Sputum, first time nine times, and second time thirteen, including several antiformin, negative.

Weight.—Gained six pounds first time from October 13 (119) to December (125), and five pounds from August 14 (121) to December (126).

X-ray Report.—Left lung—the entire left lung shows markedly diminished aeration as compared with the opposite side. This is apparently due to diffuse peribronchial infiltration, most marked at and around the hilus, and along the left border of the heart toward the base. The right lung fails to show any changes, except for a few small calcified glands around the hilus. Almost all the costal cartilages appeared calcified. Bulging of the right diaphragm. The ascending aorta appears dilated.

The patient had two children at a sanatorium, one of whom (a girl of twelve) developed interstitial keratitis. We made a Wassermann test, and the reaction was positive; we then took the blood serum from the father, which showed a reaction of + + + + each time out of four tests. The child improved on the mixed anti-syphilitic treatment, but the father did not heed our suggestions, and left the institution against our advice.

Summary.—The following facts afford sufficient proof for us to diagnose this case as syphilis of the lung rather than tuberculosis:

(1) The fact that the patient's lung condition remained the same, without the rapid destruction of lung tissue. (2) The fact that the patient's general condition was always stationary, without becoming emaciated. (3) The repeated negative sputum. (4) The repeated positive Wassermann. (5) The child's setting up interstitial keratitis, and improving on the mixed treatment. (6) The x-ray findings, showing that the roots are mainly involved, and that the ascending aorta is dilated.

The two cases reported above not only add material to the subject of syphilis of the lung, but they tend to stimulate the minds of those who have human interest at heart to investigate whether many more so-called cases of tuberculosis are not truly of syphilitic origin, and not to wait till gummatous ulcerations or excavations are found, when the anti-syphilitic treatment does them little good. It would be advisable, in the many cases in the sanatoria which show lung involvement and negative sputum, to take the blood for Wassermann, and, in case of doubt to begin antisyphilitic treatment.

We shall not discuss the disputes among the authorities regarding the frequency or rarity of the disease. They all agree as to the symptomatology

and pathology of the condition. We only refer the reader to an exhaustive article in the *American Journal of the Medical Sciences*, April, 1905, on "Syphilis of the Lungs" by Thomas A. Clayton.

I am indebted for the material of the reported cases to Dr. S. Wachsmann and Dr. Leo Kessel.

THE DIET IN DIABETES MELLITUS AS MODIFIED BY CONSIDERATIONS OF NITROGENOUS METABOLISM.

BY EDWARD E. CORNWALL, M.D.

BROOKLYN, NEW YORK

ATTENDING PHYSICIAN TO THE WILLIAMSBURG AND SOR-
WEGIAN HOSPITALS, CONSULTING PHYSICIAN TO THE
BETHANY DEACONESSES HOSPITAL.

It has long been known that in diabetes mellitus there exists an inability on the part of the body properly to store or utilize the normal amount of carbohydrate fuel, and the treatment generally has been to restrict carbohydrate in the diet and to substitute for it other food elements. Recently Naunyn and very lately Allen have emphasized the importance of giving periods of rest from all food in the treatment of this disease; and Allen in particular has elaborated the starvation feature of the treatment and demonstrated its value.

Besides the modifications of the diet above alluded to it has seemed to the writer that the diet in diabetes should be further modified so as to favor in every way and as much as possible the conditions of nitrogenous metabolism. To this point in the treatment of diabetes, which seemed to have been generally overlooked, he called attention in a discussion before the Medical Association of Greater New York on October 20, 1913. On that occasion he suggested that the diet in diabetes should be so arranged as to make as easy as possible the processes involved in nitrogenous metabolism, because insufficiency of nitrogenous metabolism, absolute or relative, was apt to be present in that disease along with the carbohydrate metabolic insufficiency and to react unfavorably on the latter. And he called attention to the fact that the prevailing methods of treating diabetes were devoted almost exclusively to restricting carbohydrates; that they failed very largely to regard or favor nitrogenous metabolism; and that they often imposed unnecessarily heavy burdens on nitrogenous metabolism by giving protein in excess and especially by giving it in forms whose metabolism is comparatively difficult. And he advanced the argument that the instability of the sugar factory, whose central establishment is located in the liver, is relatively increased by thus overworking the nitrogenous metabolic function; and that by giving a diet which limits and selects the articles of food containing protein so as to reduce materially the work of the liver in sifting and modifying the split protein products brought to it, and at the same time lessening the quantity of toxic protein fragments in the blood and the consequent vital depression of the tissues which their irritation might produce, a superior degree of carbohydrate tolerance could be secured. And he adduced in support of this argument the clinical observation that a large proportion of cases of diabetes occur in persons and families in which perversions or insufficiency of nitrogenous metabolism, as shown by lithemia, chronic nephritis, arthritis deformans, apoplexy, and cardiovascular disease, are prevalent.

In further support of this argument the following significant observations are cited:

Thompson and Waller found that the giving of meat extractives was followed by an increase of glycosuria.

Roper and Brown found that diabetics who had a tolerance for either oatmeal or meat separately did not have it for both together.

Von Noorden found a difference in effect on glycosuria of different proteins, that of meat being the most productive of glycosuria and that of wheat being the least. Von Noorden also found that under certain circumstances large quantities of carbohydrate in the form of oatmeal could be tolerated by diabetics if no meat was eaten at the same time.

The potato cure, like the oatmeal cure, excludes animal flesh.

Horowitz found that the ingestion of cultures of the lactic acid bacillus diminished glycosuria.

Allen found that short periods of starvation in which there was deprivation of protein as well as carbohydrate, with gradual resumption of the protein, produced good results.

All of the foregoing observations apparently support the writer's argument and none of them contradicts it. This argument, moreover, seems *a priori* reasonable, viewed in the light of what we know of the physiology of the liver and of metabolism in general.

Let us briefly review our knowledge of the physiology of the liver, with special reference to its relations to carbohydrate and nitrogenous metabolism.

The carbohydrate metabolic function of the liver has to do with the storage and distribution of sugar, and also, to a certain extent, with the cleavage of a carbohydrate radicle from split protein products and the changing of fat into sugar. This carbohydrate metabolic function, which von Noorden calls the sugar factory of the liver, is under control of influences which come from the outside, notably the internal secretions of the pancreas and adrenal glands. The former, there is reason to believe, facilitates the storage of glucose as glycogen and restrains its outgo, while the latter facilitates the conversion of the glycogen back to glucose and its distribution to the blood. Both of these internal secretions are themselves influenced from the outside; that of the pancreas being influenced particularly by the internal secretion of the thyroid, which is inhibitory in its action, and that of the adrenals being apparently under direct nervous control. Relative deficiency of the internal secretion of the pancreas or relative excess of the adrenal secretion naturally result in hyperglycemia. There are other factors in the case, but the ones mentioned are probably among the most important, or, at least, they appear to be so in the present imperfect state of our knowledge of this obscure and complicated subject. A factor which logically might possess significance in this connection is the condition of the liver itself.

The nitrogenous metabolic function of the liver, although perhaps not so clearly defined and exclusive as its carbohydrate metabolic function, appears to be relatively of not inferior magnitude and importance. The liver is the principal organ for the preparation for utilization of absorbed protein material just as it is the principal organ for the preparation for utilization of absorbed carbohydrate material.

The intraenteral digestion of protein results in the splitting of the protein molecule into amino acids, which are the utilizable split protein products, and into other fragments which are apparently not

utilizable but useless or injurious. The digestive enzymes perform this splitting process in the best and most regular manner, but bacteria, notably the saprophytic or putrefactive bacteria, also do some of it; and the fragments of the protein molecule which the latter split off belong largely to the useless or injurious classes. The desirable amino acids and the useless and injurious protein fragments (not only those split off in the alimentary canal but also those, like the purins, which are directly introduced with the food) are carried by the portal vein to the liver. The action of the liver on these split proteins consists essentially in further splitting or modification. The amino acids are sifted out and passed on into the general circulation for constructive use by the tissues; that is, a portion of them, for if they are in excess of the body needs that excess, we have reason to believe, is immediately split up into urea, a carbohydrate radicle, and other substances. The protein chips which are useless or injurious are modified so as to become less injurious and passed on for elimination. This is a crude and superficial statement of the hepatic phase of the extremely complex and poorly understood process of protein metabolism, but it may serve for the purpose of this brief paper.

The following observations seem to have a significant bearing on the nitrogenous metabolic function of the liver.

It has been found that blood drawn directly from the portal vein contains twice as much ammonia as blood drawn directly from the inferior vena cava.

Increase in ammonia nitrogen in the urine has been found in certain diseases and functional disorders of the liver.

Dogs with an Eck's fistula (which turns most of the portal blood directly into the inferior vena cava so that it does not pass through the liver) which were fed on a meat diet, developed convulsions and died, while those which were fed on a cereal diet continued apparently well.

Starvation experiments have been made which tend to show that the nitrogen in the urine which represents actual tissue metabolism is creatinin nitrogen.

Matthews, in his recently published text-book on physiological chemistry, says that the place where the ethereal sulphates, which are products of the putrefaction of protein, are paired with sulphuric acid to form the conjugated sulphates for the purpose of rendering them less toxic, is in the liver.

The foregoing observations give definite though scanty indications of the scope of the nitrogenous metabolic function of the liver. They indicate that the liver is the principal refinery of split protein products in the body, and that the character and extent of its work, as well as the consequences of its functional insufficiency, depend largely on the quantity and kind of the split proteins which are brought to it.

This conception of the liver as a refinery of split protein products as well as a sugar factory does not in itself compel an interdependence between the two, although such an interdependence seems likely on the basis of both occupying the same plant, which means receiving the same blood supply with all that implies. Another reason for this interdependence, and one which lies more deeply, may perhaps be found in the disturbances of the controllers of metabolism, the organs of internal secretion, which result from imperfect performance of its nitrogenous metabolic function by the overworked or de-

fective liver. In addition to the disturbances due to hyperglycemia and allied conditions, these glands are also liable to be poisoned as a result of the failure of the liver to modify properly the injurious split proteins which pass through it. And in this connection abnormal sensitiveness of organs or tissues, congenital or acquired, to deleterious split proteins, is entitled to at least speculative consideration.

In arranging diabetic dietaries according to the principles suggested in the foregoing discussion, it is necessary (in addition to the indicated restriction of carbohydrate, the supplying of proper amounts of needed salts and vitamins, and the exercise of such selection in regard to all articles of food as will favor digestion and the hygiene of the alimentary canal) to regulate consciously and definitely the protein ration both as to quantity and quality.

Reduction of the *quantity* of protein below the ordinarily accepted health ration, and even extreme reduction temporarily, has been particularly advocated by Allen, who reduces the protein along with the carbohydrate and fat in his "starvation treatment" of diabetes; but the Allen treatment does not, apparently, take into account the indications suggested in the preceding discussion for regulating the quality of the protein given.

The regulation of the *quality* of the protein has for its object the protection of the body from injurious split proteins, and is affected mainly by excluding or restricting the articles which contain free purins and other undesirable split proteins, and those whose protein is especially susceptible to the action of the saprophytic or putrefactive bacteria in the alimentary canal. This means excluding from the dietary or limiting in quantity the protein articles of animal origin, with the exception of milk and its products, and certain of the vegetables which contain purins in notable quantity.

The regulation of the diet so as to safeguard against digestive disturbances and to favor otherwise the hygiene of the alimentary tract, refers not only to selection of articles with reference to their intrinsic digestibility but also to their relationship to individual peculiarities. Cooked cabbage, for example, should not be allowed to many patients whose digestion it regularly disturbs and delays; nor some other articles of food, intrinsically acceptable but often objectionable in the individual case, which are mentioned dogmatically in most diabetic diet lists. The question of fats calls for individual study and adaptation, and also the question of salts.

In the practical application of the principles above discussed, the writer has found it convenient to rely to a considerable extent on the proteins of milk, especially in the forms of cream cheese and cottage cheese, and those of the cereals; using the proteins of eggs and animal flesh mostly in the diets with the larger protein, rations, and then only in minor proportions of the ration.

The following cases were treated according to the principles above discussed.

CASE I.—Woman aged 60. Suffered from headaches and constipation when young. Three years ago underwent an operation for ventral fixation of the uterus. Since then has noticed increased frequency of urination. Lately has suffered from intense pruritus vulvæ. August 6, 1914, passed 72 grams of glucose. Was given a diet composed entirely of cereal, green vegetables, a little fruit, and milk products, which supplied daily about 120 grams of carbohydrate, 50 grams of protein, and fat to bring the fuel value of the ration

to nearly 1,300 calories. August 10, 1914, passed 45 grams of glucose. Diet now given supplied daily about 80 grams of carbohydrate, 50 grams of protein, and had a fuel value of about 1,600 calories. It was composed of the same articles as the preceding with addition of one ounce of bacon daily. August 13, 1914, passed 36 grams of glucose. Diet now given supplied daily 125 grams of carbohydrate, a little more than 50 grams of protein, and had a fuel value of about 1,800 calories. August 24, 1914, passed 4 grams of glucose. Diet now given practically same as before, with addition of two ounces of animal flesh or two eggs three times a week. September 8, 1914, passed 1 gram of glucose. November 6, 1914, no glucose was found in the urine. The patient now felt perfectly well; her weight, which was 168 pounds at the beginning of treatment, was 161 pounds. She continued well, with sugar-free urine, on practically the same diet as that given on August 24, 1914, until the summer of 1915, when, after indiscretions in eating during the summer vacation, the sugar reappeared in the urine. August 5, 1915, she passed 30 grams of glucose. She was given the same treatment as before, and by November 4, 1915, the urine was sugar-free, and has stayed so to the present time, February 27, 1916.

CASE II.—Woman aged 58. Has had sugar in her urine for at least five years past. Was given practically the same treatment as in Case I. December 28, 1914, passed 193 grams of glucose. January 3, 1915, passed 56 grams of glucose. January 9, 1915, passed 38 grams of glucose. January 15, 1915, passed 30 grams of glucose. January 31, 1915, passed 30 grams of glucose. February 9, 1915, passed 25 grams of glucose. March 7, 1915, passed 14 grams of glucose. During the above period the quantity of urine passed daily was reduced from 4,300 c.c. to 1,400 c.c. It was not found practicable to reduce the sugar in this case below the small amount last mentioned. The patient remains comfortable on a fairly liberal diet, though restricted in regard to the articles which make for difficult nitrogenous metabolism.

CASE III.—Woman aged 41. Gives a family history of arthritis deformans, and is obese. In September, 1912, she developed polyuria and pruritus vulvæ, and showed a glycosuria of 5 per cent. After a month of the easy nitrogenous diet above described, with moderate restriction of carbohydrate, the sugar disappeared from the urine. A year later, after indiscretions in eating, the glycosuria reappeared to the extent of 4 per cent., but disappeared nine days after return to the prescribed diet.

CASE IV.—Man aged 41. Has been a large eater of meat. Sugar in small amounts has been discovered in his urine at different times during the past year. December 14, 1914, passed 30 grams of glucose. Was put on the easy nitrogenous diet, with moderate restriction of carbohydrate, and seven days later his urine was sugar-free. He has kept to this diet to the present time, and no sugar has been found in his urine.

CASE V.—Woman aged 39. Sugar has been found in her urine off and on during the past five years. She is very obese. July 17, 1915, passed 38 grams of glucose. She was put on the easy nitrogenous diet with moderate restriction of carbohydrates. July 24, 1915, passed 7 grams of glucose. She was not seen by the writer for nearly six months following. January 20, 1916, passed 50 grams of glucose. She was treated in the same way as before. January 30, 1916, passed 30 grams of glucose. February 6, 1916, passed 16 grams of glucose. February 12, 1916, no glucose was found in the urine.

These few case reports serve to illustrate the point which the writer desires to make, viz., that advantage can be secured in the treatment of diabetes mellitus by regulating the quality as well as the quantity of protein so as to make as easy as possible the processes involved in protein metabolism.

Appended is an index table of a graduated series of dietetic prescriptions devised by the writer in accordance with the principles above discussed, in which are stated separately the amounts of protein derived from the two classes of articles (viz., from milk, cereals, fruits, and vegetables, and from animal tissues and eggs), along with the car-

bohydrate content and fuel value of each prescription. These prescriptions serve as standards which can easily be modified to meet the requirements of individualization.

INDEX TABLE OF DIABETIC DIETS

Prescription Number	Carbohydrate Grams	Protein,* Grams	Calories
1	9	4	300
2	18	9	600
3	20	23	860
3a	20	33+6	1240

*The numbers in the protein column after the plus sign tell the grams of protein derived from animal flesh and eggs; the other numbers in the same column tell the grams of protein derived from articles of the vegetable kingdom and milk and its products

DR. JOHN HALL—SHAKESPEARE'S SON-IN-LAW.*

By WALTER LINDLEY, M.D.,
LOS ANGELES, CAL.

THE tercentenary of the death of William Shakespeare occurs April 23, 1916, the tercentenary of his birth having been on April 23, 1864. While memorial pageants on this tercentenary are being held throughout the civilized world, except where there is actual warfare, yet for many years each twenty-third of April has witnessed Shakespearean birthday celebrations in many places, and particularly in the town of his birth, Stratford on Avon.

It was my privilege to participate in this annual occasion in his natal town April 23, 1909. A procession composed of two thousand people formed in front of Shakespeare's birthplace. Our ambassador, the late Whitelaw Reid, and the Mayor of Stratford on Avon led us. Each person carried a posy of daffodils, narcissus, and other spring flowers. The walk began at 10 A. M., our objective point being the grave of Shakespeare in Holy Trinity Church, a distance of about one mile. It was in truth a journey from the cradle to the grave. We paused, when about half way, at the Latin School where the bard was a student, and here the present pupils of that school joined us. Soon we were in the sacred churchyard, marching four abreast under the archway formed by an avenue of great old elms, into the beautiful church, passing the font where Shakespeare was

*Read before the Los Angeles County Medical Association, April 6, 1916.

baptized, to our seats. After a brief service of song and prayer and an inspiring address by Ambassador Reid we all, one by one, stepped to the chancel and dropped our little floral tribute on the poet's grave.

On the stone over the grave is written:

"Good friend for Jesus sake forbear
To digg the dust enclosed here;
Blest be ye man ty spares thes stones,
And curst be he ty moves my bones."

Here, also, are the graves of Shakespeare's wife, Anne Hathaway; their daughter Susanna, and her husband, Dr. John Hall.

That Shakespeare and his family were given the most prominent place of burial in this noble church; that the home of his mother, the childhood home of his wife, and the house where he was born were all good substantial attractive houses—all go to prove that Shakespeare and his family were the most prominent citizens—outside of the nobility—in Stratford on Avon.

Books have been written treating on Shakespeare's extended knowledge of medicine and allied subjects. It is in "Romeo and Juliet" that Ben-volio says:

"Take thou some new infection to the eye,
And the rank poison of the old will die."

Thus forestalling Hahneman in his "Similia Similibus Curantur" and at the same time showing a vision of and faith in antitoxins.

Where can a more appealing picture of insomnia be found than in "King Henry IV?" Here the king says:

"How many thousands of my poorest subjects
Are at this hour asleep, sleep, gentle sleep,
Nature's soft nurse, how have I frighted thee.
That thou no more wilt weigh my eye-lids down
And steep my senses in forgetfulness?
Why, rather, sleep, liest thou in smoky cribs,
Upon uneasy pallets stretching thee,
And hush'd with buzzing night-flies to thy slumber,
Than in the perfumed chambers of the great,
Under the canopies of costly state,
And lulled with sounds of sweetest melody?
O thou dull god, why liest thou with the vile
In loathsome beds; and leav'st the kingly couch?

Wilt thou upon the high and giddy mast
Seal up the ship-boy's eyes and rock his brains
In cradle of the rude imperious surge?

Canst thou, O partial sleep! give thy repose
To the wet sea boy in an hour so rude;
And in the calmest and most stillest night,
With all appliances and means to boot,
Deny it to a king! Then, happy low, lie down!
Uneasy lies the head that wears a crown."

It is in "The Winter's Tale" that Antigonus says:

"I have three daughters, the eldest is eleven,
The second, and the third, nine; and some five;
If this prove true, they'll pay for't by mine honor,
I'll geld them all; fourteen they shall not see,
To bring false generations."

In this Shakespeare places fourteen as the age of beginning menstruation and indicates that oophorectomy was considered a reasonable operation over three hundred years ago.

Nowhere can the alienist find a more agonizing appeal for help than in the well-known lines from "Macbeth," and that appeal is almost as hopeless to-day as it was then:

Macbeth:
"Canst thou not minister to a mind diseased;
Pluck from the memory a rooted sorrow;
Raze out the written troubles of the brain;

And, with some sweet oblivious antidote,
 Cleanse the stuff'd bosom of that perilous stuff,
 Which weighs upon the heart?"

It is in "Pericles," written after Dr. Hall became Shakespeare's son-in-law, that the physician Cerimon opens the chest containing the body of Thasia and says:

"Look how fresh she looks!

Make fire within:

Fetch hither all the boxes in my closet,
 Death may usurp on nature many hours,
 And yet the fire of life kindle again
 The o'erpressed spirits. I heard of an Egyptian
 That had nine hours lien dead,
 Who was by good appliances recovered.
 Well said, well said; the fire and the cloths,
 The rough and woful music that we have,
 Cause it to sound beseech you,
 The vial once more: how thou stirr'st, thou block!
 The music there! I pray you give her air.
 Gentlemen,
 This queen will live; nature awake; a warmth
 Breathes out of her: She hath not been entranc'd
 Above five hours: see how she 'gins to blow
 Into life's flower again."

Thus we might go on reading by the hundred quotations showing Shakespeare's intelligent familiarity with every branch of medicine.

How did a man, not a physician, secure such a vast fund of knowledge in a profession to understand the elemental principles of which requires years of study?

First, his was probably the most comprehensive mind of all time; second, intimate association with physicians, among whom was his son-in-law, Dr. John Hall, an eminent member of the profession. Dr. Hall was but twelve years younger than his father-in-law, who lived either as a neighbor or in his family for the last nine years of his life.

Shakespeare was eighteen years old when he married Anne Hathaway, who was his senior by eight years. May 26, 1583—five months after their marriage—Susanna was born. On February 1, 1585, twins—Hamnet and Judith—were born.

Thus before he was twenty-one Shakespeare was the father of three children. The son Hamnet died before he was twelve years old; the daughter Judith married and bore children, but they all died during childhood. Susanna married Dr. John Hall on June 5, 1607, she being twenty-four and the doctor thirty-one.

One of the writers of that day says Dr. Hall "had a large and gainful practice." He attended the families of Lord Say, the Earl of Shrewsbury, Earl of Northampton, then President of Wales, and, in fact, all of the leading families of that part of England.

Dr. John Bird, Linacre professor in the Medical College, London, speaking of Dr. Hall, and of the book he wrote entitled "Select Observations on English Bodies of Eminent Persons in Desperate Diseases," says: "The learned author lived in our times, and in the county of Warwick, where he practised many years, and in great fame for his skill, far and near. Those who seemed highly to esteem him, and whom, by God's blessing, he wrought these cures upon, you shall find to be, among others, persons noble, rich, and learned. And this I take to be a great sign of his ability, that such who spare not for cost, and they who have more than ordinary understanding—nay, such as hated him for his religion, often made use of him."

Dr. Hall died in 1635 and eight years later (1643) his widow, still in the beautiful property known as New Place, entertained for three days Queen Hen-

rietta Maria, wife of Charles I, and her retinue. The queen was on her progress to meet the king, and proceed with him to Oxford. Shakespeare's daughter, a physician's widow, had as her house guest the Queen of England. This again gives an idea of the eminence of Shakespeare's family.

The Halls had one child, Elizabeth, the only grandchild of Shakespeare that reached adult age. She was born in 1607 and was nine years old when Shakespeare died. One can reasonably look backward three hundred years and see the King of Poets, who was noted for his loveliness and usually spoken of by his contemporaries as "Sweet Shakespeare," strolling through the extensive gardens of his favorite daughter, hand in hand with his little grandchild. Thus was spent the evening of his life.

Elizabeth, in 1626, married Thomas Nash, who died in 1647 and was buried with the Shakespeare family in the chancel of Holy Trinity Church. After being a widow two years this doctor's daughter, then forty-two years old, married Sir John Bernard, an eminent nobleman, who had been knighted by Charles II. She never had a child and at her death in 1670 there was an utter extinction of the progeny of William Shakespeare, which thus endured only fifty-four years.

Joseph Hunter, nearly a century ago, said: "It is rather a striking fact in the history of the human race, that, when there are men preeminently great, the issue, if any, generally becomes soon extinct." Chaucer, Sidney, Shakespeare, Milton, Dryden, Pope, Bacon, Locke, and Newton have no one left to claim them as ancestors. How easy we Americans could make a similar list: Charles Sumner, Wendell Phillips, Walt Whitman, Edgar A. Poe, and George Washington, while Abraham Lincoln's only grand-son died several years ago.

Returning to the book of which Dr. Hall is author: It was in 1644, nine years after the doctor's death, when Oliver Cromwell's troops occupied Stratford on Avon, that James Cooke, surgeon in the army and author of a work entitled "The Marrow of Surgery," called on the widow. Mrs. Hall received him pleasantly, and after she had allowed him to look through her late husband's library she sold Dr. Cooke some notebooks that Dr. Hall had evidently prepared for publication.

These notebooks were a selected record in Latin of several hundred notable cases that he had attended. Dr. Cooke translated, edited, and issued this work. Three editions were issued: in 1657, 1679, and 1683 respectively. The first edition is now worth \$250; second, \$100; third, \$20. It is very interesting to look through this little work.

On page sixteen, Observation XIX, is the case of "Mrs. Hall of Stratford, my wife" (Shakespeare's daughter), "being miserably tormented with the cholic, was cured as followeth:

R.—

Diaphen,

Diacatholic, each one ounce;

Pulv. Holland, two ounces;

Ol. Rut., one ounce.

Lactæ q.s. Ft. clyster.

This, injected, gave two stools, yet the pain continued, being but little mitigated; therefore, I appointed to inject a pint of sack [a weak wine] made hot. This presently brought forth a great deal of wind and freed her from all pain. With one of these clysters I delivered the Earl of Northampton from a grievous cholick."

Michael Drayton was a contemporary and intimate associate of Shakespeare. His poetry, particularly his sonnets, is valued to-day. Observation XXII is as follows: "Mr. Drayton, an excellent poet, labouring of a Tertian, was cured by the following:

R.—

The Emetick Infusion, one ounce;
Syrup of Violets, a spoonful.

Mix them. This given, wrought very well both upward and downward.

"Observation XXXVI, Elizabeth Hall, my only daughter [Shakespeare's granddaughter] was vexed with tortura oris, or the convulsion of the mouth, and was happily cured as followeth (I first exhibited these pills):

R.—Pil Coch and Aurear, each one drachm.

Ft. Pil 10. She took five the first day, which gave her seven stools; the next day with the other five she had five stools." He then goes on recounting his daughter's case, and in conclusion says: Thus was she delivered from death, and deadly diseases, and was well for many years. To God be praised."

This little book gives us quaint reading, but we must not forget that all along in the development of medicine there are records the reading of which would make us smile.

In spite of this ancient style of Dr. Hall he was a scholar and a painstaking general practitioner. He was proficient in both Latin and French, and it is inferred that he also was quite a traveler.

This time of Shakespeare, the Elizabethan period, the last half of the sixteenth century and the opening years of the seventeenth, formed the seething years of an intellectual new birth. The world had not seen such intellectual activity since the days of Æschylus, Sophocles, and Euripides, four hundred years before the Christian era.

This day of Shakespeare witnessed the circumnavigation of the globe by Sir Francis Drake, the explorations of Henry Hudson, Martin Frobisher, Sir John Franklin, and William Baffin; the colonization by Sir Walter Raleigh, whose death occurred in 1618, two years after that of the poet. It was the time of Christopher Marlowe, Ben Jonson, and Beaumont and Fletcher, while John Milton, the poet, who ranks second only to our bard, was eight years old when Shakespeare died. It was also during Shakespeare's day that the world was given that ideal model of English, the St. James translation of the Bible.

We of the medical profession should not fail to remember that the scientific students were as active as poets, dramatists, and explorers; for while this is a Shakespearean tercentenary, 1616 was the year in which, in a course of lectures delivered in St. Bartholomew's Hospital in London, William Harvey first announced his discovery of the circulation of the blood.

The tercentenary of William Harvey's discovery would fully justify a far more general celebration than it is receiving.

In conclusion Dr. John Hall, the subject of our sketch, was not a great man. He held the position in his day that the leading practitioner in Pasadena, Long Beach, or Santa Monica hold to-day a strong, busy, useful personality. The fact that his little book passed through three editions in twenty-five years, that the leading members of the profession spoke highly of him, and that Roman Catholic, High Churchman, and no-churchman em-

ployed him, although he was a staunch Puritan, give proof conclusive that he was a strong and forceful character and a credit to our profession.

1414 SOUTH HOPE STREET.

THE SALT WATER EAR.

BY HUGH B. BLACKWELL, M.D.,

NEW YORK.

FOR the past ten years the writer has been impressed by the large number of acute infections of the external auditory canal, middle ear, and mastoid bone, as well as by the acute exacerbations of chronic suppurative otitis media caused by sea-bathing in the vicinity of New York, frequently necessitating operative treatment, and sometimes resulting in serious intracranial complications.

During the months of July, August, and September, a large proportion of the operations performed in the otological service of the New York Eye and Ear Infirmary and in the Manhattan Eye, Ear, and Throat Hospital can be directly attributed to this cause. In view of the annual occurrence of these seasonal ear infections, a few remarks on their prophylaxis, etiology, and treatment may be timely.

Physicians should warn all patients coming under any of the following classifications against sea-bathing without first submitting to an aural examination: (1) Those with a history of having had supuration from one or both ears; (2) those with discharging ears; (3) the deaf; (4) individuals who complain of itching in the external auditory canals.

An intranasal examination should be made in cases of profuse discharge from the nose or throat, also if there is any difficulty in nasal breathing; the nose should be rendered as clean and as free as possible.

In this connection it is well to state that in the majority of instances the ear infection takes place by way of the Eustachian tube. The modus operandi is probably as follows: While bathing, small quantities of salt water accumulate in the pharynx and nasopharynx, producing slight strangling and involuntary swallowing. This act opens the Eustachian tube and forces water into the channel and, in some instances, into the middle ear as well. Frequently the swimmer, in attempting to clear his nose of water by means of an expiratory blast, forces the fluid into the tympanic cavity per tubam. This is especially apt to occur in cases of nasal obstruction, as the air is unable to escape freely from the nose. The necessity, therefore, for correcting a nasal discharge is obvious, as the pathogenic organisms contained therein might cause a middle-ear abscess, if introduced into that cavity. The safest way to free the nose is to hold the mouth slightly open and blow through both nostrils gently and simultaneously. Many bathers who are afflicted with some form of nasal catarrh are in the habit of snuffing sea water up the nose under the impression that they are employing nature's remedy and, therefore, a sovereign cure. It is a dangerous practice from an otitic standpoint.

In making an aural examination one should look specifically for the following conditions: (1) Acute, subacute, or chronic suppuration of the middle ear; (2) dry perforation of the membrana tympani; (3) partial or complete destruction of the drum-head caused by previous suppuration, resulting in its replacement by connective tissue; (4) eczema of the canals.

Should any of these conditions be present, the patient should be instructed to place a well-fitting plug of lamb's wool into the external auditory canal before entering the water. Absorbent cotton is useless for this purpose, and even the non-absorbent variety is unsatisfactory. A rubber bathing cap, fitted over the head and ears, will serve to hold the wool in position. The patient should be cautioned against diving and be told to keep the head out of water as much as possible. Immediately on leaving the bath the plug of wool should be removed from the canal, and the concha wiped dry. The canal can be thoroughly dried by tightly twisting a bit of absorbent cotton about the square end of a match, thereby protecting its corners and edges, and inserting it carefully within the canal for about half an inch, then rotating it gently. With a little practice this can be done without danger. The capillary attraction of the fibrils of cotton soon frees the canal of any moisture that may be present. The Frank rubber suction stopple, if well fitting and properly applied, serves the purpose of the wool plug. The same precautions should be followed when they are removed. Should examination reveal a normal drum and canal, it would, of course, be unnecessary to protect them by means of wool or stopple.

Cerumen, if found in excess, should be removed from the canals, as the absorption of water would cause it to swell and possibly produce a temporary deafness.

Crops of otitic furuncles are frequently observed in persons accustomed to taking daily surf baths. This condition is probably caused by the excessive dryness of the skin of the canal, due to frequent submersions and resulting in subsequent infection of the unprotected hair follicles. Under these circumstances, a good preventive measure consists in placing a few drops of glycerin or a small portion of vaseline in the canal. This will protect the epithelial lining.

Inflammation of the middle ear and mastoid produced by sea bathing is frequently complicated by the development of furuncles in the external auditory canal. The degree of swelling from this cause may at times be so great as to exclude a view of the drum and, in addition, produce a postauricular edema, and thus serve to still further mask the presence of a mastoid inflammation.

A detailed description of all the symptoms, points of diagnosis, and treatment of these conditions is beyond the scope of this paper. It is sufficient to say that ordinarily they call for the exercise of the best judgment and skill on the part of a specially trained physician.

The catarrhal inflammation of the middle ear, which usually produces the sensation of water in the ear, stuffiness, tinnitus, deafness, etc., frequently develops immediately after leaving the water, but while it may be a source of much discomfort to the patient it is not attended by any definite pain. The treatment consists in hot irrigations of saline to the drum and topical applications to the tube; and, in some instances, gentle inflation of the tympanum and free catharsis. Should an earache develop and the membrana tympani lose its landmarks, luster, and finally bulge, an immediate myringotomy under general anesthesia is very strongly indicated.

Furuncles in the canal are, in the writer's opinion, best treated by hot irrigations in the early stage, combined with wet dressing. When the

swelling points, an incision should be made so that the pus may be evacuated.

Finally, patients with chronic discharge from the middle ear, as indicated by the foul odor of the pus and the presence of granulations in the fundus of the canal, who, as a result of sea-bathing develop a diminution, suppression, or increase of the discharge, associated with earache, headache, insomnia, or mastoid tenderness, should be carefully observed and treated, as these conditions are apt to be serious, and frequently require operative procedure upon the mastoid for their relief.

118 WEST FIFTY-EIGHTH STREET

Medicolegal Notes.

Physician's Liability to Company's Employee.—In an action for malpractice against a firm of physicians and surgeons who operated a hospital, it appeared that the plaintiff's employer had an arrangement with the defendants by which the employer deducted a certain sum each month from the pay of each employee, and turned over the sums so deducted to the defendants, who agreed for such compensation to care for and treat all injured employees which the employer should send to them. The plaintiff was injured and was taken to the defendants' hospital and treated by them under this arrangement. It was held that the relation of patient and physician existed between the plaintiff and the defendants, and that the latter owed the plaintiff the duty to exercise ordinary care and skill in treating him.—*Vrita v. Dolan*, Minnesota Supreme Court, 155 N. W. 1077.

Malpractice of Homeopath—Expert Testimony of Allopath.—In an action for malpractice by a physician of the homeopathic school, alleging that he neglected to see the plaintiff's daughter with such frequency as the case demanded, to give her proper medicine and skillful treatment, and to do anything for her relief and cure when it appeared that she was dangerously ill, it was held that testimony of a physician of the allopathic school, who admitted that he knew nothing of the homeopathic method, after the recital of the conditions and symptoms of the deceased to the time of her death, including the treatment given by the defendant, as to what the deceased was probably suffering from was admissible, as such testimony, followed by inquiry of a homeopathist as to what would have been appropriate as a remedy, might prove that improper treatment was given; but as to materia medica, therapeutics, and the principles and practice of medicine he was incompetent to testify, in view of Iowa Code, sec. 2576, providing that candidates for examination in any school of medicine shall be given the same set of questions covering pathology, etc., but prescribing for a different set of questions in materia medica, etc., corresponding to the school in which the applicant desires to practice.—*Van Sickle v. Doolittle*, Iowa Supreme Court, 155 N. W. 1007.

Injury to Neck—Comparison of X-Ray Pictures.—In a railway mail clerk's action for injury to his neck, alleged to have fractured the transverse process of the third cervical vertebra, when the door of the car shut, on the train being more or less suddenly checked, the plaintiff's medical expert, whose experience as an x-ray specialist was limited, offered two x-ray plates of the plaintiff's neck and explained them to show a fracture. The trial court refused to allow an x-ray specialist for the defendant company to exhibit to the jury an x-ray picture taken by him, showing a man's neck in normal condition to prove that the plaintiff did not have such a fracture, with the explanation that the plaintiff's fracture did not support the interpretation of his expert, on the ground that to permit a comparison of the plaintiff's neck with other necks would lead to confusion and irrelevancy. On appeal it was held that this refusal was erroneous. The plaintiff's case and the result, the court said, depended much upon the true interpretation of the x-ray pictures offered by the defendant's expert. The x-ray process is comparatively new, and is more or less occult, certainly to the lay mind. The plaintiff was properly given a free hand in developing the proof of his alleged injuries by means of the x-ray pictures and an expert explanation of them; and similar freedom should have been accorded the defendant in testing before the jury the correctness of that explanation.—*Virginian Ry. Co. v. Bell*, Virginia Supreme Court, 87 S. E. 570.

New York, May 20, 1916.

THE PROPHYLACTIC USE OF TETANUS ANTITOXIN.

CONFIDENCE in the efficiency of tetanus antitoxin when properly used as a prophylactic measure against the development of tetanus, is well-nigh universal among immunologists. In a certain percentage of cases, however, the prophylactic action has been slight or absent, and in a few instances unfavorable results have followed, so that there is a group of clinicians and others who are more or less opposed to the use of the serum and who claim that confidence in it is not justified. The fallacy of this claim is shown in an article by Robertson recently published (*Am. Jour. Med. Sci.*, 1916, cli, 668).

In the majority of instances unfavorable results occur in consequence of certain well understood conditions. The patient may be unduly susceptible to the toxin of the disease, or he may react abnormally to the serum which contains the antitoxin. The serum may have been administered in too small a dose or so long after the infection that cure is not possible, or the quality of the product may be such as to prevent its effective action. It is probable that little can be expected from the use of the serum in those persons who are so susceptible that the toxin is absorbed with exceeding rapidity. The occurrence of serum sickness is of relatively little importance, while serious anaphylaxis is quite rare; nevertheless, improvements in the methods of preparing the serum have reduced the number of cases in which these complications occur, and it is reasonable to believe that further improvements will reduce it still more. The ideal method, the use of human serum as a vehicle for the antitoxin, is as yet impractical as a general procedure, though it has been done in a few isolated instances. The production of an active immunity by vaccination with tetanus toxin would be a desirable method were it not so unsafe, since the administration of toxin is apt to be a dangerous procedure. One great advantage of an active immunity is that it lasts for several months or even years while the passive immunity conferred by the injection of an alien serum lasts for only about three weeks, while a second dose will extend that period by only from five to eight days. The factors which may be most readily controlled are the time and the method of administration.

The importance of early immunization is shown by some experiments upon mice. The investigator inoculated the tails of these animals with tetanus cultures, and after varying intervals cut off the infected portion, thus removing the source of toxin production. It was found that one hour after inoculation such an operation was too late to save the animal from a fatal attack. Statistical studies upon man have shown the same results—the earlier after the receipt of an injury the antitoxin is given the smaller the number of cases which develop and the lower the mortality. The mode of administration is usually the subcutaneous or intravenous injection. Under certain circumstances, notably in war, it is not possible to administer the serum in this manner very promptly after the injury. Calmette recommended dry powdered antitoxin to be applied to the wound, but practically this has proved efficacious in the prevention only of tetanus neonatorum. Robertson suggests that the antitoxin be soaked up in sterile absorbent cotton and then dried and preserved for use. The cotton can be standardized, and before use is to be moistened with some clean fluid. He found that it remained active for at least six weeks and that the results were excellent. Such a preparation would be a valuable addition to the first-aid packet carried by the soldier. It is intended, of course, not to supplant injections of antitoxin, but for use when the latter are not available, for the purpose of saving valuable time. If the wound remains unhealed, it can be used for the repetition of the dose without the danger of anaphylaxis.

A study of the use of antitoxin in the present war has shown that the subcutaneous injection of twenty units immediately after the injury will, in the great majority of cases, prevent the development of tetanus. The remedy is not perfect; indeed, there are probably no perfect remedies, and one must expect to have a certain percentage of failures. Nevertheless it is an exceedingly valuable one, and one whose value will probably be improved as a result of further researches, and all can agree with Kocher in his statement: "I should strongly resent it and call him to account if a doctor, in treating a relative of mine who had received a wound which was infected with street dirt, did not administer a prophylactic injection of tetanus antitoxin."

STEREOSCOPIC ROENTGENOGRAPHY IN THE DIAGNOSIS OF FRACTURES.

IN fractures of the shafts of the long bones, x-ray plates taken in the usual right-angled planes (anteroposterior and lateral) are generally all that are required for a sufficiently correct interpretation of the relative position of the fragments. Occasionally, however, in fractures of the shafts, and frequently in fractures into and near certain joints, where satisfactory lateral views are to be obtained with great difficulty or not at all, the stereoscopic method is wellnigh invaluable.

In connection with a series of articles on "War Fractures" in the March, 1916, number of the *Practitioner*, Capt. Francis Hernaman-Johnson, M.D., R.A.M.C., briefly discusses the uses and limi-

tations of this method. He says that there is a tendency in some quarters to regard the stereoscope, when adapted to radiography, as merely an ingenious toy, while in others it is looked upon as a valid substitute for the method of right-angled planes; and that stereoscopy is sometimes mentioned as a substitute for localization methods in the case of bullets or other foreign bodies. He believes that the method has a well-defined place in radiographic work and says it can neither be dispensed with nor employed to the exclusion of other well-known procedures.

He divides the uses of the stereoscope in connection with fractures into (a) essential and (b) supplementary. Under the first heading he calls attention to the fact that an exact diagnosis of certain bone injuries can be reached only by the aid of the stereoscope; and states that it is obvious that such a state of affairs must exist fairly often in injuries of the shoulder, spine, pelvis, and hip when it is remembered that lateral views of these regions are, for the most part, unobtainable. He feels that the "solid effect" produced by the fusion of stereoscopic radiographs is here the only means of checking the oftentimes misleading appearances seen in an ordinary x-ray projection of such parts, and concludes that the regions enumerated should, therefore, be taken in stereoscopic pairs as a matter of routine wherever time and materials permit. Sometimes, too, even in situations where plates at right-angled planes are easily obtainable, exact diagnosis radiographically is impossible without the aid of stereoscopy. This is well shown by a case which he reports where there had been a gunshot injury in the neighborhood of the elbow resulting in multiple fracture. There was a fracture of the internal condyle which was well shown in the ordinary anteroposterior plate. The lateral view, however, showing a rather large fragment of bone in front of the joint, was very confusing, and, after a number of lateral views had been taken, some experts at interpreting plates considered that there was a fracture of the radius, while others were equally positive that the fracture involved the ulna. A stereoscopic plate showed that the apparently solid fragment was in reality composed of two, one derived from the ulna and one from the radius. Such experiences as this led him to declare that while in skiagraphy of the skull and limbs anteroposterior and lateral single views are, in most cases, sufficient, when a negative opinion has been given on such views and the subsequent clinical course of the case is such as to give rise to continued suspicion of fracture or subluxation, the x-ray examination should be repeated on the lines indicated, namely, stereoscopically. He finds that the elbow, the ankle, the carpus and the tarsus are the parts where re-examinations are most often needed.

As to the supplementary uses, these are concerned with obtaining a general view, in relief, of the position of the fragments of a fracture which is to be operated upon, or with "seeing for oneself" the exact relationship of a bullet that is about to be extracted; but he finds such uses of stereoscopy generally more favored by surgeons than by expert radiologists "who are aware that no real idea of

distances can be so obtained, and that the apparent relationships shown are highly misleading and confusing unless a very rigid method is followed in the taking and interpretation of the stereogram." While it is usually possible to say whether a bullet is at one or other side of a bone or buried within it, and to determine the relative position of fragments in a similar general way, the stereoscope must be regarded not as an instrument of precision but merely as a useful adjunct in the localization of metallic fragments in fracture due to gunshot injuries. It is nevertheless in some cases of fracture not merely an assistance but the only method by which a certain diagnosis can be arrived at.

CENTENNIAL ANNIVERSARY OF THE HAMBURG AERZTLICHER VEREIN.

ONE hundred years ago Hamburg, as well as the other German cities, was emancipated from enemy control, and then and all over what is now the German Empire the native activities were manifested in divers ways. Local medical societies sprang into existence, and on January 2, 1816, one was organized in Hamburg with a membership of 60 physicians and 14 apothecaries. In 1834 the latter profession organized an independent society. At the outset there was no program, but the meeting was given up to extemporaneous reports and discussions, followed by a supper at the tavern in which the meeting was held. Soon rooms for their use were hired, gradually increasing in number to accommodate books and museum specimens. These quarters also represented the inception of the Hamburg Vaccination Institute, and from an early period vaccination sessions were held weekly. Young members performed the inoculations and took charge of the supply of lymph. Voigt, who contributes these details to the *Deutsche medizinische Wochenschrift* for January 27, was himself vaccinated in the 60's with nine punctures in each arm. In 1872 this private foundation was replaced by a State institute. A large endowment fund for maintaining the former must have been set free by this step. From the outset a book department had been associated with other society activities; it suffered a total loss by fire in 1842, but nevertheless has grown to be one of the greatest medical libraries in Germany. The pathological museum was eventually transferred to the Hamburg-Eppendorf Hospital. Two other societies have split off from the main body—the Obstetrical Society in 1860 and much more recently the Biological Society. The permanent headquarters of the society have been and are still in the so-called Patriotic House of Hamburg.

A NEW WAR PESTILENCE.

THE nosological status of war maladies of epidemic incidence is notably uncertain, and this applies also to affections which develop when bodies of men assemble on peaceful occasions, for example in harvesting time, when a spreading disease may run the gamut of diagnosis until finally its nature is recognized beyond doubt. At the January session of the Hamburg Medical Society (*Berliner klinische Wochenschrift*, January 31) Rumpel describes an epidemic which attacked over 420 men in a Russian prison camp. The disease began with violent gastroenteric symptoms, rapidly followed by an ulceropurulent stomatitis, in which false mem-

branes sometimes formed. In certain of the cases an exanthem appeared. But a third of those exposed escaped the disease. There were evidences here and there of grave infection but not a single death occurred. The buccal symptoms *per se* suggested a Plaut-Vincent infection, and the micro-organisms of the latter were found, although possibly only as saprophytes. The principal view was that the foot and mouth disease had been contracted from infected horses, but this was disproved by inoculation experiments. In fact there was no proof that the disease had been transmitted at all. Scurvy was thought of as well as a mass mercurial intoxication but both these notions were quickly dismissed. At present the only plausible view is that of an unknown food poisoning. A similar disease has appeared in the French military hospitals and also elsewhere in Germany. Both milk and meat have been accused.

THE NEW UNIVERSITY OF WARSAW

THIS institution was originally the youngest of the old Polish universities, having been founded in 1816. A medical faculty does not seem to have existed until 1857. From 1870 to 1882 the university became Russianized. Considerable good work has been done by the university under Russian domination, although Polish students have for years flocked in great numbers to German, Austrian, Swiss, French, and even to some of the purely Russian universities. Since the German conquest of Poland in 1915 the University of Warsaw and in fact educational institutions in general have been reorganized, with a Polish faculty and official recognition of the Polish language. Over 1100 students are now in attendance, of which nearly one-half are medical. Dr. von Brudzinski, the new rector of the University, describes the institution at length in the *Berliner klinische Wochenschrift* for February 28. The new administration is confronted with great difficulties, as the old buildings were rendered unfit for use by the evacuating Russians. A faculty for the teaching of the various physical sciences has been assembled, but there is no mention of chairs for medical and surgical teaching or of clinical facilities. Even histology and comparative anatomy are not taught at present, although there are professorships for physiology and physiological chemistry. Much of the difficulty of organization arises from the fact that the various buildings for clinics are too antiquated for modern requirements. For several years at least, assuming that the Germans remain in possession that length of time, only elementary studies can be pursued here, and the medical students must betake themselves elsewhere for technical training. We must therefore regard this institution as more of a political than an efficiency move, one which is intended to win the friendliness and cooperation of the Poles.

News of the Week

New York City Death Rate.—The mortality in New York City during the week ending May 6 was lower than that of the corresponding week of last year and also than that of the previous week of this year. The number of deaths was 1,580, giving a death rate of 14.71 per 1,000, while during the corresponding week of 1915 the deaths numbered 1,609 and the rate was 15.35. The death rate for

the first nineteen weeks of the year was 15.40, as compared with 15.64 for the corresponding period of last year. The mortality for the week was decreased in measles, scarlet fever; typhoid fever, cancer, influenza, lobar pneumonia, diseases of the nervous system, and violence; and increased in diphtheria and croup, whooping cough, diarrheal diseases, heart disease, bronchopneumonia, pulmonary tuberculosis, and Bright's disease. The lowest rate for the week was noted in the Borough of Queens, where only 98 deaths were reported, giving a rate of 13.95 per 1,000.

Deaths in Chicago.—During the week ending May 6 there were reported in Chicago 693 deaths, giving a death rate of 14.5 per 1,000, as compared with 699 deaths and a rate of 14.6 for the preceding week, and 665 deaths and a rate of 14.2 for the corresponding week of last year. The increase occurred chiefly in the number of deaths due to pneumonia and influenza.

Baby Week in New York.—With the slogan "Better Parents, Better Babies, Better City" as its motto, New York successfully celebrated Baby Week from May 6 to 12. Saturday and Sunday were devoted to meetings in the synagogues and churches; Monday was Brothers' and Sisters' Day and appropriate exercises were held in the public schools; Tuesday was Visiting Day, and an inspection of all the child-agencies in the city was made; Wednesday was Fathers' Day, when special meetings were held; Thursday was prize day, when prizes were awarded to the best babies; and Friday was Neighborhood Day.

Civil Service Examinations.—The United States Civil Service Commission announces an open competitive examination for the position of assistant epidemiologist (male) in the Public Health Service, at a salary ranging from \$2,000 to \$2,500. The duties of the position will be the making of epidemiologic and sanitary surveys to determine the prevalence and causation of disease, the conducting of laboratory studies in relation thereto, and the recommendation of measures to prevent and control outbreaks of disease. It is desired to secure persons thoroughly competent in the various branches of sanitary bacteriology and especially in isolating the typhoid bacillus from infected persons and materials. Graduation from a medical school or college of recognized standing, or graduation in sanitary engineering from a college or university of recognized standing, at least three years' experience in epidemiologic work under Federal, State, or local authorities, and experience in laboratory technique, are prerequisites for consideration for the position. Further details may be obtained on application to the United States Civil Service Commission, Washington, D. C.

On June 7 the United States Civil Service Commission will hold an examination for medical interne, open to both men and women, for the purpose of filling a vacancy in this position in the Government Hospital for the Insane, Washington, D. C., at \$900 per annum. The position is tenable for one year, during which time a post-graduate course in mental and neurological diagnosis is given, an examination is held, and promotions to the next grade, junior assistant physician, are made. The Government Hospital for the Insane has over 3,000 patients and about 800 employees; in addition to the general medical practice the scientific opportunities in neurology and psychia-

try are unsurpassed. Applicants must be graduates of a reputable medical college, or senior students expecting to graduate within six months from the date of the examination; they must be unmarried, and twenty years of age or over. Further details may be obtained on application to the Commission at Washington.

Physicians' Summer School.—Short courses in clinical medicine and psychology, for recently graduated physicians who desire to perfect themselves in a knowledge of physical, mental, and nervous diseases of children, will be offered this summer at the Rome State Custodial Asylum, Rome, N. Y. Each course will cover a period of ten days, during which time the students will have an opportunity to observe and study special groups of defective children, the work being made intensely practical. The course will be given twice, from June 6 to 16, and from June 19 to 29, and accommodation will be provided for from twelve to twenty men in each group. There will be no charge for the course, and board and lodging will be furnished free, as is usual in general hospitals in the case of clinical assistants and medical internes. All communications in regard to the course and applications for admission should be addressed to the Rome State Custodial Asylum, Rome, N. Y.

New Hospital Bureau.—The National Hospital Bureau, recently incorporated, has opened its quarters at 8 West Fortieth Street, New York, where it will maintain an information and advisory service for the purpose of promoting and encouraging the building, equipment, and management of efficient hospitals. A model hospital is shown on the sixteenth floor of the building, and visitors are cordially invited to inspect the exhibit.

Gifts to Hospitals.—By the will of the late Mr. Charles W. Harkness of New York, the Presbyterian Hospital of this city receives the sum of \$100,000 to be added to its endowment fund and the sum of \$250,000 to be added to the Harkness Fund for scientific and educational work. The Harkness Fund was established a few years ago by Mr. Harkness' brother, Edward S. Harkness, for the purpose of promoting research in the hospital in connection with medical education.

Mr. Charles A. Wimpfheimer of this city has given \$150,000 to Mount Sinai Hospital for the endowment of a department of surgery of the stomach.

Dr. George W. Crile, professor of surgery at the Western Reserve University, Cleveland, Ohio, received the honorary degree of doctor of letters from Wooster College on May 12.

American Association of Anesthetists.—The fourth annual meeting of this association will be held in Detroit, Mich., on June 12, 1916, under the presidency of Dr. Willis D. Gatch of Indianapolis, Ind. An interesting program, consisting of fifteen papers and including an address by the president and reports by Dr. George W. Crile of Cleveland, Ohio, and Dr. Joseph C. Bloodgood of Baltimore, Md., has been prepared. The scientific session will be followed by a banquet at the Hotel Tuller at 7 o'clock.

Obituary Notes.—**Dr. ERNEST C. MORRIS** of Hephzibah, Ga., a graduate of the University of Georgia, College of Medicine, Augusta, in 1899, and a member of the Medical Association of Georgia, the Richmond County Medical Society, the Medical Society of the State of New York, and the American Medical Association, died on April 26, aged 37 years.

Dr. THOMAS J. WILLS of Washington, Ga., a graduate of the Atlanta Medical College in 1887, and a member of the American Medical Association, the Medical Association of Georgia, and the Wilkes County Medical Society, died suddenly at his home, on April 13, aged 54 years.

Dr. GEORGE W. DERRICK of Norwood, Mass., a graduate of the medical school, Tufts College, Boston, in 1903, died at the Brooks Hospital, Brookline, from blood poisoning, on April 16, aged 39 years.

Dr. WILLIAM M. BULLARD of Brooklyn, N. Y., a graduate of the University of Göttingen, Prussia, in 1867, died suddenly at his home on May 12, aged 75 years.

Dr. TRAVERSE ROCKE MAXFIELD of Brooklyn, N. Y., a graduate of the Michigan College of Medicine, Detroit, in 1884, and a member of the Medical Society of the State of New York, the Kings County Medical Society and the Brooklyn Medical Society, died at his home, on April 23, aged 54 years. Dr. Maxfield was for eighteen years a member of the Brooklyn Board of Health.

Dr. MILTON M. SMITH of Tuskegee, Ala., a graduate of the Louisville Medical College in 1890, and a member of the Medical Association of the State of Alabama, and the Colbert County Medical Society, died at his home, after a short illness, on April 24, aged 68 years.

Dr. HENRY A. MOODY of Mobile, Ala., a graduate of the Medical Department of the University of Louisville, Ky., in 1866, and a member of the American Medical Association, the Medical Association of the State of Alabama, and the Mobile County Medical Society, died at his home, after a brief illness, on April 16, aged 74 years. Dr. Moody was professor of therapeutics, materia medica, and pharmacognosy in the University of Alabama, School of Medicine, Mobile.

Dr. JOHN A. HUNTER died in Philadelphia on April 27 at the age of 78 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1866. He was visiting physician to Moyamensing Prison.

Dr. WILLIAM STANFORD STEVENS of Boston, Mass., a graduate of the Harvard University Medical School in 1883, and a member of the American Medical Association, died at his home on April 29, aged 57 years.

Dr. HARRY E. MYGATT of Berlin, N. H., a graduate of Dartmouth Medical School, Hanover, in 1896, and a member of the New Hampshire Medical Society and the Coos County Medical Society, died at his home recently, aged 44 years.

Dr. WILLIAM H. MCKENZIE of Newark, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1892, visiting physician to St. Barnabas' Hospital, Newark, and a member of the Medical Society of New Jersey and the Essex County Medical Society, died suddenly of apoplexy at a meeting of the medical board of St. Barnabas' Hospital, at which he had been elected president, on May 3, aged 49 years.

Dr. NATHAN R. SIMMONS of Lexington, Ky., a graduate of the Long Island College Hospital, Brooklyn, in 1864, and a member of the American Medical Association, the Kentucky State Medical Association, and the Fayette County Medical Society, died in Louisville, on April 21, aged 74 years.

Dr. CHARLES W. ENOS of Denver, Colo., a graduate of the Homeopathic Medical College of Missouri, St. Louis, in 1874, died at the Park Avenue Hospital, Denver, on April 20, aged 67 years. Dr. Enos was

the son of a physician, and one of ten children, of whom six were also physicians.

Dr. SIMEON HUNT of East Providence, R. I., a graduate of Dartmouth Medical School, Hanover, in 1865, and a member of the Rhode Island State Medical Society and the Providence District Medical Society, died at his home, after a short illness, on April 5, aged 79 years.

Dr. JAMES T. OWEN of Cloverport, Ky., a graduate of the medical department of the University of Louisville in 1867, died at his home, after a lingering illness, on April 12, aged 77 years.

Dr. SAMUEL W. STEVENSON of Mooresville, S. C., a graduate of the Washington University School of Medicine, Baltimore, in 1873, died at his home, after a long illness, on April 15, aged 72 years.

Dr. JOHN F. MOORE of Worcester, Mass., a graduate of the Baltimore Medical College in 1907, and a member of the staff of St. Vincent Hospital and the Memorial Hospital, died at his home, on April 15, aged 35 years.

Dr. ALBERT MCMICHAEL of Detroit, Mich., a graduate of the Pennsylvania Medical College, Gettysburg, in 1898, died at his home on April 29, aged 56 years.

Dr. ANTHONY PECK of Norwich, Conn., a graduate of the New York University Medical College in 1875, died at his home on April 3, after an illness of several months, aged 58 years. Dr. Peck was oculist and aurist to the William W. Backus Hospital, and was a member of the Connecticut State Medical Society and the New London County Medical Society.

Dr. DORRAN B. COXE of Chico, Cal., a graduate of Dartmouth Medical School, Hanover, in 1888, and a member of the Rhode Island Medical Society, the Medical Society of the State of California, and the San Bernardino County Medical Society, died at his home, on April 2, after a year's illness, aged 71 years.

Dr. JOHN F. HANIFIN of Holyoke, Mass., a graduate of the College of Physicians and Surgeons, Baltimore, in 1911, and a member of the Massachusetts and Hampden District Medical Societies, died recently at Saranac Lake, N. Y., aged 30 years.

Dr. CHARLES W. PECK of Brandon, Vt., a graduate of the Long Island College Hospital, Brooklyn, in 1866, and a member of the American Medical Association, the Vermont State Medical Association, and the Rutland County Medical Society, died at his home on April 21, aged 75 years.

Dr. CHARLES A. TEAGUE of Graniteville, S. C., a graduate of the New York University Medical College in 1890, died on April 25, in Columbia, after an operation, aged 52 years.

Dr. HUGH E. QUINN of Bangor, Me., a graduate of the Medical School of Maine, Portland, in 1909, and a member of the Maine Medical Association and the Penobscot County Medical Society, died at his home on April 29, aged 37 years.

Dr. WILLIAM H. HOYT of Wenham, Mass., a graduate of the New York University Medical College in 1886, died at his home on May 3, aged 54 years.

Dr. JOHN ERLE KENNEY of Chelsea, Mass., a graduate of the College of Medicine, University of Vermont, Burlington, in 1882, and a member of the Massachusetts Medical Society and the District Society, died at his home on May 3, aged 55 years.

Dr. JESSE E. HUNT of Kansas City, Mo., a graduate of the Western Reserve University, School of Medicine, Cleveland, in 1902, and a member of the

Missouri State Medical Association and the Jackson County Medical Society, died at his home, of diphtheria, on April 29, aged 38 years. Dr. Hunt was assistant professor of pediatrics in the University of Kansas School of Medicine.

Dr. JOSEPH R. WEBSTER of Lexington, Mass., a graduate of Harvard University Medical School in 1859, and a member of the Massachusetts Medical Society and the District Society, died at his home on May 9.

Dr. CHARLES A. WHEATON of St. Paul, Minn., a graduate of Harvard University Medical School in 1877, and emeritus professor of surgery in the University of Minnesota, died at St. Joseph's Hospital on April 29, aged 63 years.

Dr. ISAAC C. MCCOY of Fort Worth, Tex., a graduate of the University of Georgia, College of Medicine, Augusta, in 1870, died suddenly at his home on April 29, aged 68 years.

Dr. FRANCIS W. CAMPBELL of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1909, a member of the Brooklyn Medical Society, visiting anesthetist to St. Catherine's Hospital, and gynecologist to St. Catherine's Dispensary, died at his home on May 9, aged 32 years.

Obituary.

EDWARD LEAMING, M.D.,
NEW YORK.

DR. EDWARD LEAMING, attending radiologist to Roosevelt Hospital, and formerly instructor in photomicrography at the College of Physicians and Surgeons, died at his home on May 11, aged 54 years. He was the son of the late Dr. James R. Leaming, one of New York's best-known practitioners in the 70's of the last century. He was graduated from Columbia University in 1884, and from the College of Physicians and Surgeons in 1892, and also studied at the University of Edinburgh. He was a member of the American Medical Association, the New York State and County Medical Societies, the American Roentgen Ray Society, the New York Roentgen Ray Society, and the New York Gastro-Enterological Society. Dr. Leaming early won distinction as an amateur photographer, and when laboratory teaching and research in pathology and bacteriology had secured an important place in the new outlooks in medicine in this country, he realized the significance of the new field for the development of new and special phases of photography. Becoming associated with the Department of Pathology at the College of Physicians and Surgeons in New York, he organized the section of Photography and Microphotography, and for years, with uncommon skill and boundless patience, devoted himself to the preparation of illustrations of researches for special publications and numerous text-books. The continuing value of many of the latter, for example the Text-book of Pathology by Delafield and Prudden, is due in a large measure to the reproduction of Dr. Leaming's accurate and excellent photographs. At a later period he organized, and for some time directed, the Section of Photography and Illustration of the Rockefeller Institute for Medical Research. He brought to his work a wide range of interest and knowledge in many phases of science and art, and his technical skill, his great experience, his ready helpfulness, and his kindly spirit will be keenly missed by his many colleagues and friends.

THE HARVEIAN LECTURE—GENERAL DISEASES SEEN AT AN EYE HOSPITAL—OPTIC ATROPHY—DEFECT IN OCULAR MOVEMENTS—MYASTHENIA GRAVIS—DIPLOPIA—THYROID SECRETION.

LONDON, April 20, 1916.

THE extraordinarily varied medical interests which converge at any eye hospital were discussed by Dr. James Taylor in his Harveian lecture. At the outset he confessed that he had long wished to do more than he had done to impress on his confrères the enormous importance of ocular and visual signs and symptoms as indications of general disease. His unique opportunities at Moorfields of seeing cases illustrating this certainly renders him to some extent a debtor to his brethren, for it is only working at an eye hospital that enables any one to realize how many patients apply there for relief to some eye trouble which is found to be an indication of a general condition. Going over the notes of his hospital cases for the last five years Dr. Taylor dealt with them in groups, as: optic atrophy, defect of movements, myasthenia gravis, and other forms of ocular palsy, albuminuric and glycosuric retinitis, Graves' disease, hemiopia, retinal embolism, and thrombosis and optic neuritis. The largest group was of optic atrophy, which brought him 233 cases; in over 200 of these there were definite signs of tabes or general paralysis of the insane; sometimes only the Argyll-Robertson pupil; in one case on one side only; sometimes only absence of knee-jerks and lightning pains; sometimes both these conditions; occasionally gastric crises. Ataxy occurs only rarely in tabes with optic atrophy, a fact generally well known and confirmed by these cases, for it was only complained of in two out of the 200, and in only one of them was it very marked. There were signs indicative of general paralysis in three or four, but mental symptoms pointing to general paralysis not uncommonly appear years after the patients have been quite blind.

In a few cases the optic atrophy was the result of retrobulbar neuritis and in a number of these indications of disseminated sclerosis were present. In other cases there is evidence of lesion at the optic chiasma and usually also indications of interference with the visual fields. In many patients, on applying to the hospital, there was complete blindness of one eye and well-marked blindness of the temporal field in the other. A few of the cases are toxic, brought on by tobacco, often with alcohol as well. Recovery in such may occur, if the toxic agent can be quite excluded and the blindness is not too long established, but in some the recovery is not complete and the condition remains, though not necessarily progressive. In the cases named after Leber there is a state of family optic atrophy, the impairment of vision being gradual and slow, but in some of these it is extraordinarily rapid.

Defect in ocular movements formed the next largest group of Dr. Taylor's cases. One might expect diplopia to be complained of in all these, but that was not so, for in a certain number of third nerve paralysis cases, whether complete or partial ptosis was the first sign and when there is complete ptosis, either before or simultaneously with affection of other ocular movements controlled by the third nerve, there will, of course, not be diplopia

In some of the cases there were definite signs of tabes (in many good reason to suspect syphilis), but in one or two classes of third nerve cases this plays no part, *e. g.* migraine ophthalmoplégique—a condition in which there is paralysis of an ocular nerve, usually the third, occasionally the sixth, occurring in association with unilateral headache. This is a recurring condition, but after each attack of headache with ocular paralysis recovery from the paralysis is less and less complete, till finally there is complete paralysis of the affected nerve, when not infrequently the headache ceases. Dr. Taylor had had eight such cases, in seven of which the third nerve was the one affected. In none of them had there been any visual phenomena, such as occur in ordinary migraine. Third nerve paralysis may also be present in lesions of the crux, and in such cases is usually associated with paralysis of the limbs of the opposite side. There are cases in which only the sixth nerve is affected. It is said this may result from exposure to cold, but skepticism of this is common, and Dr. Taylor was satisfied that they were really an early sign of a graver affection—in one case disseminated sclerosis, in another tabes, in another third nerve paralysis.

Diplopia may also be due to myasthenia gravis, a disease which has lately received much attention, and deserves still more. It is in connection with ocular conditions that it is most interesting. It also occurs in Graves' disease, and more frequently than is generally recognized. Occasionally it is so marked that patients apply for relief on account of it. In one of his 27 cases Dr. Taylor reports upward movement of the eyes beyond the horizontal plane was quite absent, and this was not a case in which the proptosis was at all extreme. He had only once seen optic atrophy in Graves' disease, and in that he was satisfied it was a mere coincidence. He has little doubt that the phenomena are due to excessive thyroid secretion. He has seen all the symptoms and signs (except the enlarged thyroid) develop in a patient who took large quantities of thyroid to reduce a not-excessive corpulency. He thought fright or other emotional disturbances seem to have some relationship to the onset of the symptoms, and mentions incidentally that the same may be said of chorea. In the majority of cases a cure may be anticipated, but in some the result is sad. One of the most terrible disasters is sloughing of the cornea, which sometimes results in complete destruction of the eyes. Yet the outlook is good as a rule. Of 31 cases referred to by Dr. Taylor not one became worse, several were completely cured, and in most the disease became quiescent. He always gave belladonna, and from the manner in which patients returned for treatment and from the discomfort they reported they felt if without it, he cannot but think it a most helpful drug in these cases.

A URINARY TEST FOR SYPHILIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Through some oversight in reading the proof of the article "A Urinary Test for Syphilis and Its Comparison with the Wassermann Reaction," I neglected to state the strength of Sol. I and have received several inquiries relating to the same. I have had the best result with a 1 per cent. solution of resublimed iodine in chloroform.

4. The Pituitary Body and Renal Function. Rehl Motzfeldt.

2. **Hallux Valgus.**—Charles F. Painter, in discussing hallux valgus deals with the etiology of the trouble and the most serious objection to that method of operative treatment which the majority of surgeons regard as highly satisfactory. He thinks that there is little doubt the deformity is owing to ill fitting shoes, and points out that most shoes, particularly women's shoes—and it is among women that the deformity is most common—narrow from a point about opposite the first metatarsophalangeal articulation forward to the tip of the great toe. An x-ray examination and other facts noted, the writer thinks, show pretty conclusively that hallux valgus is not an exostosis of the metatarsal head of its articulating phalanx. If it is not this then it is merely a lateral deviation of the great toe at the outset, accompanied by stretching of the inner capsular attachments and later on by structural alterations of the articulating surfaces no longer in use, dependent upon lack of function. If these premises are correct as to etiology, and anatomico-pathological changes are as they have been stated and their cause is properly interpreted, their treatment should divide itself into two phases: First, where the deformity can be manually overcome, an attempt should be made to correct it by mechanical means, employing night splints to adduct the toe and a toe post in the shoe for day use. Manual stretching and proper shoes are also needed. The second phase requires operative treatment. If there is no exostosis then none of the operations contemplating the shaving off of a lateral sliver of bone from the metatarsal and phalanx are logical surgical procedures. The presence of an intermetatarsum is so rare that its removal as a cause of hallux valgus is to be remembered only as an occasional necessity. The operation that makes the strongest bid for first place is the old Hüter operation. The removal of the head of the metatarsal and preservation of the phalanx satisfies the demands of the probable anatomical cause, the fact that the metatarsal may be too long. This operation shortens it and permits conformity to the ready-made last. It equalizes pressure in the metatarso-phalangeal joints by squaring up the unopposed articulating surfaces. This procedure when accompanied by resection of the bursa, when enlarged, meets all the anatomical and pathological conditions presented by the situation and has only one objection raised against it, viz., that the chief buttress of the anterior arch is weakened by the operation; occasionally this may be true, though in the majority of instances the functional results obtained after this operation are excellent. After about four weeks' convalescence a patient with the Hüter operation can generally walk with a fair degree of comfort and will be permanently relieved. The disturbance of the support of the anterior arch by a bone-operation upon the first metatarsal head, which has constituted the one serious objection to Hüter's method and has led to the suggestion of some other procedures, may be obviated by the employment of a post-operative splint. There is probably no surgical procedure practised which brings more comfort than that which relieves one who has suffered for long years from the discomforts of hallux valgus.

3. **The Choice of a Climate in Cases of Bright's Disease.**—Guy Hindsdale, after pointing out that in a general way the impression seems to be that damp and cold climates are unfavorable and dry climates are

beneficial for Bright's disease or nephritis. While this is probably true, he goes on to describe the results of data on the subject collected by him during the past ten years, so that it may be definitely shown just what localities might be advised and why they are beneficial. A chart is shown, by the courtesy of the University of Chicago Press, which illustrates the relative humidity by months in fifteen cities of the United States, arranged by Professors Cox and Armington. Hindsdale also shows tables demonstrating the deaths from nephritis and acute Bright's disease in the principal cities of the country and the death rate from nephritis and Bright's disease in States. He concludes as follows: Bright's disease and nephritis are diseases clearly amenable to climatic treatment. Apparently the first requisite is that the air and soil shall be warm, sunny, reasonably dry and free from malaria and disagreeable atmospheric changes. It is a disease attended by extensive degenerative changes in the renal and circulatory organs, and hence it is highly necessary to insure an abundant and undisturbed action of the skin. The locality should be conducive to an out-of-door life the year round. This is the well-known advantage of the climate of Southern California, where the little rain that falls never does any one any harm. Our best course is to advise a warm climate first—one having moderate elevation and only a moderate rainfall, with small diurnal variations in temperature, the humidity being, perhaps, secondary in importance to temperature and wind. The fact that other localities in the extreme Northwest, such as the States of Washington and Montana, as well as Colorado, Minnesota, Wisconsin, Michigan and Utah, have such diverse climates, and, nevertheless, fall on the favored group, should not determine their choice as health resorts for renal cases, but would indicate some advantage in the character of the population and that the sum total of the elements of climate in these localities is conducive to a hardy race.

1. **The Treatment of Cardiac Syphilis.**—James M. Anders points out that the fact has long been recognized that a more systematic treatment of syphilis would lessen the incidence of cardiovascular affections. Numerous investigators have demonstrated that syphilis is responsible for a large proportion of heart affections, and perhaps one of the principal reasons why treatment should be carried out at the earliest possible period after infection lies in the hazard and danger from the administration of salvarsan in cases in which severe forms of cardiovascular syphilis develop subsequently. A sane view of the prophylaxis of cardiac involvement in syphilis demands inclusion of the treatment of its secondary manifestations. In the writer's opinion, when aortic insufficiency, myocarditis, a certain group of cases of angina pectoris, aortic aneurisms arise in the acute and secondary stages of syphilis, they are most successfully treated by the alternate use of mercury and salvarsan. The iodides should not be employed in these stages, but are valuable adjuncts quite late in the disease, or after the active syphilitic process has been checked. The most successful method is by the vigorous administration, intramuscularly, of

mercuric salicylate pushed to the limit of tolerance to be followed by salvarsan, which is also to be given intramuscularly. After the lapse of a few days the mercury must be resumed, and respecting cases that do not manifest the most active symptoms he is in agreement with Brooke and Carroll in stating that the protiodide administered *per os* may at times prove entirely satisfactory in its effects. The Wassermann test should invariably be made, and the only criterion of sufficiency of specific treatment is a negative Wassermann reaction. As for treatment in the tertiary stage, the majority of cases of cardiac syphilis which the writer has treated either in hospital or private practice, have been late cases, typical instances for the most part of aortic regurgitation in decompensation, and equally typical ones of myocardial degeneration independent of aortic incompetence. Assuming the Wassermann reaction to be present, how shall the syphilitic element be attacked in these late cases? There are two small classes of cases in which the use of salvarsan is, in the mind of the writer, quite justifiable. (1) In myocarditis and aortic insufficiency in which the actual condition of the myocardium is indeterminable, but obviously not degenerated to a marked extent; and (2) cases occurring in patients who urgently demand that something be done to afford relief from their sufferings. In well marked cases of syphilitic myocarditis and in aortic incompetency due to the same cause, it is his custom to give mercury a prolonged trial by inunction, and the failing by the hypodermic method. If this does not yield a favorable result, *i.e.* a negative Wassermann reaction, then salvarsan is used intramuscularly, at first, however, in small doses. In this group of cases the injections of salvarsan are to be followed by a period of absolute physical rest. Unless a negative Wassermann reaction occurs when salvarsan is administered in the manner stated above, a follow-up course of mercury should be accorded a fair trial, and it may now give a permanent result. The iodides are indicated in the treatment of cardiac syphilis after the active process has been checked or has ceased, in order to effect absorption and replacement of tissue, and it is advisable to outline them so long as progressive improvement is manifest. As a result of personal experience the writer has become thoroughly convinced that the majority of late cases of tertiary cardiac syphilis do not carry a favorable prognosis as to cure, but some degree of amelioration of the symptoms, and prolongation of life in comparative comfort may be expected in the majority of cases.

6. Compensation and Insurance in Eye Injuries.—Charles B. Meding draws attention to the fact that commonly all injured persons are first seen and attended by general physicians, and he knows of no branch of medicine in which they are less fitted to serve. If this is true of that service, it is doubly so of their statements as to effects of injury. Yet since they have attended, their statement is received and considered together with that of all others mentioned by patient. In several cases final results were only apparent after compensation had been awarded. In the matter of insurance so far as it covers the expense of medical treatment we are personally interested. There are two sides to the question, and experience makes the writer alive to the company's side as well as his own. There is no doubt a tendency or temptation to overcharge a corporation. We should remember that the majority of these patients are clinical cases. Of themselves they could not afford private treatment. Now that they are insured our clinics are entitled to the money awarded, but should the charge, therefore, be our best private-practice fee or greater? We should agree on definite fees

for definite operations. As to the moneys received, the writer believes there should be a diversion between the institution and the surgeon who treats the case. The bills should be sent and collected by the institution and the division should be proportionate with values of work and board.

7. Reflex Vesical Irritation.—J. N. Upshur, in discussing this subject, emphasizes the point that any lesion of the cervix, because of its richer nervous endowment, is more apt to be the cause of reflex vesical irritation than are lesions of the cavity on body of the uterus. There is another class of cases which is emotional; the subjects are women who are run down, or school-girls in whom the nervous system has been overtaxed by close application and they have become chlorotic and hysterical; or women suffering from neurasthenia, the result of abuse of the sexual relation. Change of air and scene and active ferruginous tonics are the remedies indicated in such cases. Finally, much might have been said of treatment which has been left unsaid. But the whole field is covered by the exhortation to endeavor painstakingly to locate and remove the cause. Get firmly fixed in your mind that in all obstinate and intractable cases there is an appreciable cause somewhere. There may be no lesion of the bladder, but there is the condition, near or remote, responsible, a reflex from some pelvic disorder or gastric derangement modifying the composition of the urine.

2. Endocrinopathic Inheritance.—Walter Timm discusses some cases of transmitted abnormalities on characteristics which he deems to be due to disturbed function of the endocrine glands, and goes on to say that it may be interesting to attempt an explanation of this transmission based on the Mendelian laws of heredity. Of course a great deal must be assumed in such an attempt which cannot be submitted to proof. Such an attempt must also necessarily deal with the simplest factors to which we can possibly reduce, if such reduction is at all possible, the complicated interrelations of the internal glandular system. Such a reduction, the writer believes, might be best expressed in terms of two factors, both of which are end results of disharmony among the endocrine glands. One of these factors relates to the normal control of growth and the other to the normal control of metabolism in the organism. An absence of such a normal coefficient of growth we may assume to result in various structural abnormalities of the individual, on the side either of overgrowth or undergrowth, or even vicious growth. Absence of a normal metabolic factor might be said to result in disarrangements of the secretions and excretions producing underweight or overweight, and increased or diminished oxidation of the tissues, with the incidental hyperglycemia or hypoglycemia. It is admittedly difficult to demarcate sharply the field where growth and metabolism merge into one another, and for our present insufficient and fragment-

any knowledge only the gross clinical evidences of either type are possible of recognition. The writer then analyzes by means of Mendel's laws of heredity certain cases which presented abnormalities probably due to disturbed function of the endocrine glands. He concludes that this growth-controlling factor is subject to various modifiers and coefficients, producing in one individual, through absence, a giant stature, in another dwarf stature, and in a third absolute lapses in bony continuity, may be reasonably assumed. The actual unit character of growth in Mendel's giant peas was not really, as he first assumed, growth in height, but internodal growth. It simply happened that excessive internodal growth corresponded to increased tallness in his plants. Increased internodal growth might just as well have produced tortuous stems of no greater height than the dwarf peas. Therefore we have a reason for the non-conformity of transmission of gigantism to Mendelian laws as heretofore investigated, gigantism being simply only one form of abnormal growth and not the unit character in itself. The importance of investigating such inheritance is that it may enable us to forecast, within some limits of probability, the characteristics of the offspring of certain marriages and to advise the prospective parents of such probability. It forces on us the necessity of closer study and investigation into the nature and treatment of endocrine disturbances. An interesting observation also in the series cited by the writer was that all the abnormal-growth zygotes were male while all the abnormal-metabolic ones were female. It would seem that abnormal growth is dominant in the male and recessive in the female, while abnormal metabolism may be dominant in the female and recessive in the male. But the observations were far too few to warrant such general conclusions, and many more families and individuals will have to be studied to obtain sufficient data.

3. Industrial Anilin Poisoning in the United States.

—Rey Vincent Luce and Alice Hamilton deal with the question of anilin poisoning in the United States at considerable length and draw the following conclusions: Commercial anilin, a well-known industrial poison in Germany and in Great Britain. It is just beginning to be known in the United States, where it has already been the cause of numerous cases of poisoning among men engaged in the manufacture of rubber goods, in reclaiming rubber from scrap, in making anilin from benzine, and in using certain washes for press rollers. It is a blood poison, causing the formation of methemoglobin with the consequent "internal suffocation." Poisoning may take place through the skin or lungs. Usually in industrial cases both portals of entry play a part. Exposure to the fumes need not be excessive or long continued to bring about serious symptoms in the susceptible. Young men are more susceptible than the old or middle aged, blonds than dark-haired men, heavy drinkers than the temperate. Hot, humid weather, heated rooms and poor ventilation are important factors in the production of acute anilin poisoning. Early recognition of anilin poisoning is of prime importance so that the sufferer may be withdrawn from the danger of further exposure to the poison. Men working in anilin constantly seem to acquire a certain amount of tolerance to it; nevertheless if the exposure is increased beyond the point of tolerance there is apparently a cumulative effect, and symptoms of chronic poisoning result. After symptoms of poisoning have once manifested themselves the patient is usually hypersensitive to the fumes. The treatment consists in fresh air, oxygen, and heart stimulants, especially camphorated oil. Prevention of subsequent exposure is imperative.

5. Vitamin Solution of the Pellagra Problem.—Edward

Jenner Wood states that there is no doubt in the minds of a large number of the students of pellagra that the deficiency theory of Dr. Joseph Goldberger is correct. The writer bases his report on the correctness of this theory. He points out that up to recent years, in the South especially, corn was simply crushed between two stones and the power was that of the stream near-by. The only thing removed was the coarse particles of outer skin or husk. This method of milling has been largely replaced by steam or electric milling. By this process the corn is subjected to heat in order to loosen the outer coarse husk. The attention of the writer and coworkers is directed to this portion of the industry to determine how much heat is employed. In the modern mill in which these observations were made the heat is a negligible quantity, but it must be remembered that 120° C. is sufficient to destroy any vitamin that may be contained. This part of the work, therefore, cannot be too strongly emphasized. After the heating process the grain is passed into a "degerminator," which removes the germ. This is done because the germ contains such a large amount of fat that rancidity would soon occur if it were left in the meal. Besides this the germ would give to the meal a yellow color which by modern standards is counted undesirable. The offal, which contains the germ, husks, and bran, some flour and flinty portions of the grain, constitutes about 30 per cent. of the entire weight of the grain. It is known as "corn chops" and is fed to the cattle. The remaining endosperm, after the removal of the offal, is finely ground, and the product is known as granulated cornmeal. The writer refers to it as milled meal. These observations lead him to believe that it is probably not only that pellagra is a deficiency disease but also that the deficiency can be definitely placed to the modern method of corn milling. It would appear, therefore, that the eating of the whole grain in corn countries will stop the ravages of pellagra. Deterioration of corn is productive of pellagra because the germ is the portion of the grain most subject to the action of molds and animal parasites.

1. **Acute Poliomyelitis.**—Frederick E. Batten points out that acute poliomyelitis has during the past decade spread in epidemic form over the face of the globe, and considerable advances have been made in our knowledge of the disease. During the year 1913 an epidemic of poliomyelitis occurred in Barrow-in-Furness which was investigated by Dr. H. A. MacEwen, who noted that it was restricted to young children. It is known that Barrow-in-Furness suffered from a severe epidemic of poliomyelitis investigated by Dr. R. P. Garrow in 1910. So the disease when it occurred again in 1913 fell upon a locality in which the susceptibles had been picked out by the former epidemic, and the population, except for those who had come into existence since 1910, had a natural or acquired immunity. It would seem that the susceptible material of a population is fairly soon exhausted. The clinical features of poliomyelitis may be most varied, according to the part or parts of the nervous system affected. The grouping on an anatomical basis suggested by Wickman is that which is most help-

ful to the clinical description of the disease. The groups are as follows: (1) The spinal form. (2) The bulbar, pontine, and mid-brain form. (3) The cerebral form. (4) The cerebellar form. (5) The neuritic form. (6) The meningitic form. (7) The abortive form. The meningitic form is one of the most interesting groups of poliomyelitis, and one which frequently leads to an error in diagnosis. The meningitis is indicated by the presence of lymphocytic cells in the cerebrospinal fluid. Some of these cases show on pathological examination characteristic poliomyelitic changes in the brain. Second attacks of poliomyelitis are very rare. The literature contains some three or more instances of such, but none of them are very convincing nor will they bear critical investigation. The diagnostic value of the examination of the cerebrospinal fluid was discussed. A high lymphocytic count is present in the cerebrospinal fluid, in infection by tubercle, syphilis, mumps, measles, infective conditions of the sinuses, and ear diseases, and also in a group of cases with acute meningeal symptoms described and investigated by Gordon. Monkeys inoculated with an emulsion from the spinal cord and from the parotid glands from these cases were unaffected, the presumption being that the cases were not cases of poliomyelitis. Recognizing that poliomyelitis is an acute specific fever having an incubation period of four to twelve days, the patient should be isolated. As the virus is known to exist in the nasal and buccal mucous membrane it is essential to pay careful attention to the discharge therefrom. There is no doubt that rest is the most important factor in treatment; the too early movement may in some cases restart the disease which has become quiescent. The principles by which physiological rest can be secured to the muscles were considered, and the conclusion arrived at was that the paralyzed muscles must be put in the "zero position," a position defined by Mackenzie as the position in which the individual muscle itself is relaxed and both its own action and that of its opponents prevented. Various methods have been adopted for keeping the affected muscles at rest. Most of them tend to immobilize the patients for many months. It is important while keeping the completely paralyzed muscles in a normal zero position and at rest to encourage other muscles, which may have been more or less affected, to resume their normal function. This is accomplished by re-education. The erect position and walking are the best forms of re-education for the trunk muscles. In re-educating a severely paralyzed muscle it is important in the early stages to place the limb in such a position that the load on the muscle is at its minimum and only a very small force is required to overcome the effects of gravity. A bath is an excellent place to practise the re-education of badly paralyzed muscles, for the weight of the limb is supported and ranges of movement are possible which without the support of the water are impossible. Walking exercises and the erect position are the best forms for the re-education of the trunk and abdominal muscles. When once the legs are splinted it is possible to get the patient into the erect position; and such allows of the physiological use of the back trunk and pelvic muscles. Such walking exercises are carried out by the use of a walking machine which supports the patient both physically and morally, for it is important to give the patient the feeling of complete security. The adoption of the practice of placing the limb in a position of rest at an early stage of the disease will not only facilitate recovery but prevent the greater proportion of deformities now seen as the result of poliomyelitis.

2. Auscultation in the Diagnosis of the Vascular Injuries Accompanying Gunshot Wounds.—George Makins lays stress on the routine employment of the stetho-

scope for the detection of traumatic openings in the walls of the blood vessels. Observation of the point at which the bruit is loudest and highest pitched will serve to localize the exact position of the lesion. The examination of a large service of arterial wounds has shown that in a very considerable proportion of the cases the local murmur, whether systolic if purely arterial in origin, or of the "machinery type" in arteriovenous lesions, is conducted to the heart. Such bruits, although temporary, may persist for several weeks. The method of conduction would seem to vary according to the position of the vascular injury and the distance of the local lesion from the heart. When the murmur is conducted upward from the lower extremity it appears to be conveyed by the column of blood in the vessels. In the arteriovenous injuries this is not surprising, because the roar of the continuous murmur is always transmitted the more widely in a central direction. When, however, the bruit is due to a purely arterial lesion the circumstance is less likely to have been suspected, because in the majority of instances the pure systolic bruit is more freely transmitted along the limb in the peripheral direction. In spite of this fact, however, a systolic bruit, even though not of a very loud character, may often be readily audible at the cardiac apex. The pure systolic murmurs are heard at the apex alone, but in one case of arteriovenous aneurysm of the thigh the double murmur was conveyed also to the base of the heart. The writer has dwelt upon the question of the cardiac bruits not because the presence of a conducted murmur can be of general use in diagnosis, in view of the fact that such an occurrence is not a necessary accompaniment of an arterial lesion. Still, the detection of an apical systolic murmur in a young, healthy subject with an injury to the thigh might draw attention to the fact that a grave arterial lesion was present in the limb, and lead to its detection when the absence of local pulsation, together with the presence of free pulsation of the peripheral vessels had led to the question of a serious vascular injury being placed aside.

5. The Treatment of Hemorrhoids by Injection.—F. Swinford Edwards brought the subject before the profession in a paper published in the *Lancet* in the year 1888. He was led to try injection in the treatment of hemorrhoids as a substitute for operation by reports from certain American surgeons, among whom was Van Buren, professor of surgery in the Bellevue Hospital. Edwards's method is as follows. The piles having been protruded, possibly with the aid of an enema, the patient is placed in the knee-elbow position with the buttocks opposite a good light. The parts are then sponged over with an antiseptic, as lysol and water, and an injection of 20 per cent of carbolic acid in equal parts of glycerin and water made through a sterilized needle. From 3 to 6 minims of the solution is injected into the center of each pile in turn. In large piles he often injects 5 minims in two places. The piles are then smeared with vaseline or sulphate of iron ointment and returned as soon as possible, for the injection always causes the hemorrhoids to swell; therefore the longer they remain outside the more difficult are they to return. He advises no action of the bowels for forty-eight hours, and should prolapse occur in the meantime immediate replacement is essential. The great advantages of the injection treatment are: (1) No confinement in bed excepting for a few hours when possible; (2) no anesthetic and therefore no post-anesthetic vomiting; (3) no pain; (4) no enforced absence from business; (5) no risk from the little operation itself, and no risk of stricture or incontinence following, and (6) finally there is an immediate and steadily increasing betterment.

1. On "Colds" and the Influence of the Atmosphere on the Nasal Mucous Membrane.—Leonard Hill states that "colds" are most common when the humidity of the atmosphere is great and the temperature variable but on the whole cool; when raw winds with thawing snow, or strong winds blow charged with cold rain, and the ground is wet and cold. Acute rhinitis or coryza, the common cold, may be caused by bacterial infection—by dust, for example, cycling in the dust of motor cars; by a chemical irritant, for example sulphuric acid from furnaces; the poison cloud of chlorine suffocates by causing the outflow of fluid in the air passages; by the pollen of certain grasses. There is also a class of people who suffer from a nervous derangement of the nasal membrane, from vasomotor rhinitis or paroxysmal rhinorrhea, as it is called. The nasal reflexes of such people are unduly excitable. Sudden changes of atmosphere, a draught, may provoke in these an acute paroxysm. Open fires and properly flued modern gas fires give us radiant heat and a warm floor within the range of this heat. We can toast the feet at these, and much of the hot air goes up the chimney. The so-called radiators, gas or steam, and artificial lights, together with the heat and moisture from the bodies of people, make warm and humid the upper strata of rooms and afford the conditions bad for the nose. Suppose the nasal membrane has become swollen, congested, and covered with thick secretion in these bad conditions and the subjects go outside again into the cold air; then the membrane at once becomes pale, owing to the vasoconstriction; but for some little time it remains swollen and boggy, pitting on the touch of the probe. The writer believes that these conditions of the nasal membrane have a great deal to do with the "catching of colds." In crowded rooms infection takes place from mucous spray, sneezed, coughed, or sputtered out in speaking. The inhaled bacteria will be caught by the swollen mucous membrane covered with thick secretion. In cold, outside air not only is the membrane kept taut but the flow of blood through it is rapid, for the inhaled air has to be warmed up and moisture rapidly evaporated from the membrane so as to saturate this air at body temperature. Thus more lymph comes out into the membrane from the blood vessels, and this contains the immunizing substances. The offensive bacteria are washed away or destroyed and thus kept out. On the other hand, in the condition where the membrane is covered with thick secretion, congested and boggy, there is a medium more suitable for the bacteria to settle and grow upon, for it is boggy and stagnant, not flooded with fresh lymph, particularly when vasoconstriction takes place on passing from an over-hot, moist atmosphere into the wintry outside air. The washing away of bacteria by the outflow of secretion must be one of the most important methods of defence. In the alimentary canal poisonous concentrations of substances, for example sugar, are diluted and kept away from the living membrane by the secretion of mucus. In the respiratory tract fluid is poured out to dilute and wash away a chemical irritant, such as chlorine. Now the rate of evaporation from the nasal

membrane must be of first importance in promoting the outflow of lymph through it and the factors which determine this are worth considering. The writer enters into explanation of the manner in which these factors act, and concludes that when out of doors a man has much more arterial blood flow through his nasal membrane than when indoors in heated atmospheres. He further suggests that now the open-air treatment of wounds is extolled, the surgeon's attention may perhaps be directed to the problems of evaporation from temperature of and blood flow through wounds, in so far as these may be influenced not only by dressing but by the relative dryness, temperature, and movement of the atmosphere.

6. A Preliminary Note on the Nature and Treatment of Concussion.—T. E. Harwood notes the fact that in the treatment of neurasthenic conditions arising in the course of the war one point has attracted little attention. Almost every patient will be found to have more or less difficulty with reading. This is usually taken for granted and passed over as a mere incident. In reality it gives a clue to the most efficient treatment of such cases from whatever cause arising. The living body may be compared to an electrical system, which may break down owing to faults either in the circuit or in the battery. Neurasthenia is compared by the writer to a lowered efficiency of the battery of the system, and two lines of treatment are advocated—the one to increase the efficiency of the battery, say by suggestion; the other to give the battery less to do, say by putting the patient to bed. It is absurd, thinks the writer, to ascribe neurasthenic conditions to errors of refraction, but refractive errors are basic errors, and their accurate correction breaks a vicious circle. The earlier the refraction is corrected the easier it is to do, the more likely the correction is to be effectual, and the more willing the patient is to wear the glasses. The nature of the error does not matter in the least, everything depends upon the accuracy of the correction. The object to be aimed at is to leave a minimum, and as far as possible equal, amount of error for each eye to correct. An over-correction does no good and may do a great deal of harm. If the astigmatism is not fully corrected the probable result will be the conversion of, say, a compound hypermetropic astigmatism into an artificial compound myopia or mixed astigmatism. It is useless to attempt the work without an unlimited supply of patience. With simple astigmatism the results are almost certain. Mixed or compound cases are much more difficult. Whether the patient is complaining of his eyes or not makes no difference. Giddiness is far more diagnostic of ciliary paresis than is headache. It is no great compliment to Weir Mitchell to adopt his system of rest cure, which with suggestion, is the usual line of treatment in these cases, and to ignore his pioneer work on the paramount importance of eyestrain.

8. Heart Block in Jaundice.—R. D. Rudolf describes a case of heart block in jaundice, the first seen by him. He agrees with Dr. J. Davenport Windle, who described a case of jaundice in the *British Medical Journal*, January 22, 1916, and does not accept the commonly made statement that the heart tends to beat slow in jaundice. The writer has noticed this for years in civil hospital practice, and since coming to France, where many cases of jaundice are seen, the point has been brought home to him more than ever. But Dr. Windle goes on to say that in his knowledge heart block has never been demonstrated, and for this reason the writer records this case. It was a case of partial heart block, and, strange to say, was at once relieved completely, and as far as the observations of the medical attendants went, permanently, by a single dose of atropine. The case was, of course,

not one of simple catarrhal jaundice, but was probably one of organic disease of the liver. The writer had no evidence that the heart block did not exist before the jaundice, except that the patient assured us that he was very fit and quite up to all his work as an officer at the front. The fact that the block was partially relieved by gentle exercise and completely and as far as we were able to watch the case, permanently, by a single dose of atropine would all point to the probability of the delay in transmission of stimuli through the auriculo-ventricular bundle, being due rather to vagal origin than to any organic disease there. The patient had not been taking digitalis for days before the tracings were taken.

Results of Protective Inoculation Against Tetanus.—Kümmell, speaking from nineteen months of experience with war tetanus, states that early in the war surgeons were optimistic in regard to preventing infection. Wounds healed kindly under conservative procedures. Very soon, however, it became only too apparent that active measures must replace passive ones, at least as far as injuries of the skull and extremities were concerned, because of the sudden cumulation of lockjaw, and gas gangrene and gas phlegmon. We are concerned here with the first named, the mortality of which, originally 100 per cent, fell after a time slowly to 50 per cent. All therapy instituted after the development of the disease was valueless and preventive inoculation became the sole reliance, as practised in all suspicious wounds. Kümmell's figures in this field are epoch making. In one base hospital 483 wounded were inoculated and but one developed (fatal) tetanus. In another the number of inoculated was 372 with no case of tetanus. A colleague, Gasch, reports no case of tetanus in 700 inoculated wounded. Adding these figures, we obtain 1555 cases with but one of tetanus. Otherwise stated, there was practically no tetanus in a certain body of troops wounded chiefly with cannon projectiles (shells and shrapnel). Severe wounds with ordinary bullets were included in the material. The ideal is, of course, that all wounded be inoculated. Strict immunization has now been practised from ten to eleven months, and the question arises "How much tetanus would have developed had immunization not been performed?" Queries directed to colleagues who did not practice immunization show in a relatively small material a large proportion of cases. Included are certain cases in which immunization may or may not have been practised and a few in which it did not prevent the disease. In inoculated cases much must depend on the time, dosage, etc.; also on degree of local disinfection. The material controlled by the author shows a remarkable correspondence with American figures for Fourth of July tetanus (in 1914 over 1500 immunized cases with three cases of tetanus, all fatal). All recent cases of tetanus developing despite preventive inoculation are being controlled as far as possible in regard to time, dose and make of antitoxin. Thus far the death rate of such cases is heavy, and stands in direct relation to the interval between wound and inoculation. Protection may be so brief that a second immunizing injection should perhaps be made in case absorption of the germs may have been delayed or favored by wound conditions. Delayed interventions, say a week or more after injury, even if slight, require a new injection. Everything points to the truth of the claim that war tetanus is practically preventable.

Causal Relationship between Angina and Articular Rheumatism.—Brodski states that this sequence, long known, has of late received much corroboration. Of

1200 cases treated in a marine hospital during seventeen months one half (610) had tonsillitis and exactly 10 per cent of these patients developed rheumatism either at the same time or one, two or more days later; sometimes as a true sequel after the tonsils had recovered. The author saw few cardiac complications in his material. Of considerable interest because noted by others was tenesmus and dysuria with the passage of much uratic sediment in the elderly, and enuresis in the young marines. The connection of these phenomena with tonsillitis was in part speculative. A number of cases of anginal nephritis are mentioned, but this association is more commonly seen in hot climates. In the author's material exposure to cold and wet seemed to be one of the chief efficient causes, and this could perhaps have set up the rheumatism and nephritis without the mediation of an angina. Of great importance for selection is the state of the tonsils in young recruits. The examination should be thorough, not merely visual, and any surgical condition should be relieved before the men are recommended. As far as possible the tonsillar mucosa should be spared as representing a bacteria-proof filter.

Treatment of Epidemic Meningitis with Ethylhydrocuprein.—Friedemann refers to the considerable rôle of cerebrospinal meningitis in war morbidity, and its high mortality, even under serum treatment. A chemotherapeutic remedy must still be the ideal, for various reasons, in a bacterial disease; hence the striving for substances of bacteriostatic character which shall be readily available for wholesale use, and despite apparent failure with methylene blue, urotropin and the like we must test new remedies in the hope of finding substances of salvarsan efficiency. Ethylhydrocuprein can prevail over the pneumococcus infection in mice and the author because of its ready applicability through the cerebrospinal fluid elected to test it in meningitis, with the added reason that *in vitro* this substance is decidedly antiseptic to the meningococcus. The remedy was exhibited in eight cases of severe, apparently malignant meningitis. Every patient recovered, a result which might possibly have come about of itself in so small a number of cases, but the chance that all of the cases were of the benign type is infinitesimal. Some months before the author had treated a series of sixteen cases of the same disease with serum and had lost eight of them. The remedy was usually injected once into the cord, while also pushed internally; but two, three and even five injections respectively were used in some cases.

The Diphtheria Toxin Skin Reaction.—Henry Koplik and Lester J. Unger comment on the advantages gained by a prompt recognition of individual susceptibility or immunity to diphtheria and present a method of applying the test which they claim is simpler than that recently devised by Park and Zingher and less likely to be attended by an anaphylactic pseudo-reaction. The technique of their method is as follows: After an area of skin on the forearm has been cleansed with alcohol, the latter is encircled by the thumb and index finger, and the skin held tense between them. The needle is dipped into the bottle of pure undiluted diphtheria toxin and then immediately inserted *intradermally*. The needle is an ordinary hypodermic bent at a distance of one-quarter inch from its point so as to make an angle of about 170°. From the place of bending to the distal end it is shielded so that only the unshielded one-quarter inch can be inserted into the skin. In all the cases tested by the original Schick technique and by this technique the results have coincided precisely. — *Journal of the American Medical Association*.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Tenth Triennial Session, Held in Washington, May 9 and 10, 1916.

(Special Report to the MEDICAL RECORD.)

First Day—Tuesday, May 9.

PRESIDENT, DR. WILLIAM S. THAYER OF BALTIMORE.

Diagnosis and General Treatment of Syphilis.—Dr. JOHN A. FORDYCE of New York presented this communication. He said that the future of the syphilitic individual depended upon the early diagnosis of his infection and the intensity with which treatment was carried out in the first six months. In the accomplishment of this purpose the modern aids to diagnosis had rendered great service. The dark field illumination furnished a valuable corroboration of all suspicious genital sores and assisted in determining the nature of extragenital lesions which might simulate chancre. It should be employed in every case of chancroid to confirm or rule out the possible coincident infection with the *Treponema pallidum*. The Wassermann test filled a large field of usefulness not only as a diagnostic medium, but as a guide as to the effect of treatment and a criterion of cure. It was of special value in all conditions of obscure etiology referable to the cardiovascular system, cerebrospinal system, or viscera in which syphilis might be a factor, and in cases with an indefinite clinical picture, such as neurasthenia, febrile attacks, rheumatic pains, etc. Its interpretation was of great importance and required on the part of the practitioner as much training and experience as did the interpretation of the physical signs. The examination of the spinal fluid enabled one to determine the activity of the luetic process in the brain or cord, to distinguish the various pathological types affecting the central nervous system and in many cases to differentiate between these and non-syphilitic affections. Recent investigations had shown that an analysis of the spinal fluid was not complete unless the Lange gold test was performed in addition to the Wassermann reaction and the cytological and chemical examination. Its chief usefulness lay in distinguishing true paresis from types of cerebrospinal syphilis which simulated it, and in diagnosing incipient cases before the clinical syndrome was established. In primary syphilis where the spirochetes were demonstrated and the Wassermann reaction was negative it was possible to cure syphilis by salvarsan alone. It could not be determined beforehand how many doses would be required, and it was, therefore, better to err on the side of safety and to give at least eight or ten doses, and follow this with mercury for six months. In secondary syphilis where the early rash was present and the Wassermann positive it was better to precede the salvarsan with several injections of a mercurial salt, preferably a soluble one. After the salvarsan was begun the combined treatment was continued. Salvarsan might be recommended in courses of five to six, or six to eight, injections, in doses of 0.3 gm. to 0.5 gm. for men and 0.25 to 0.4 gm. for women, at intervals of one or two weeks, depending upon the tolerance of the patient. Two or three such courses were given with rest periods of six weeks. The mercurial injections were given every day if a soluble salt was used, or once a week if an insoluble one. Dr. Fordyce said his preference was for the bichloride of mercury in course of 20 to 30 injections given daily every other day. Of the insoluble preparations, gray oil in the form of mercurial cream, of which five minims represented one grain in series of 10 to 12 injections, or salicylate of mercury (40 per cent.) one to three grains gradually increased, 10 to 12 injections constituting a course. Each series was followed by a rest period of six weeks and then the procedure repeated. Wassermann tests were made periodically, but treatment was not interrupted in spite of a negative reaction until the adequate amount of medication had been given. The dermatologist and syphilologist should keep in mind the possibility of the involvement of the nervous system in secondary syphilis and a complete status should be made when the patient came under observation so that this record could be compared with a subsequent development. The most frequent early signs of changes in the nervous system were irregularity of the pupils, persistent headache, and optic neuritis or auditory disturbance. In latent syphilis with a positive Wassermann reaction an in-

vestigation should be made of the cardiovascular and of the nervous systems or of previous involvement of any of the viscera, as, for instance, syphilitic hepatitis. In cardiovascular syphilis the prolonged use of mercury in connection with potassium iodide was probably of more value than the haphazard use of occasional doses of salvarsan. This point was most important. In bone and periosteal lesions attended by severe pain there was no drug in the pharmacopœia that produced so rapid an effect in relieving the pain and reducing the neoplasm. The criteria of cure were a negative Wassermann reaction for at least a year, continuing so after a provocative injection of salvarsan, and a normal spinal fluid, with certain exceptions.

Treatment of Syphilis of the Central Nervous System.

—Dr. HOMER F. SWIFT of New York presented this communication. He said that in order to discuss the treatment of syphilis of the central nervous system it was essential to orient oneself in the various problems that this disease presented. It was well known that the majority of patients in the secondary stage suffered from an infection of the central nervous system. As only a small proportion of these patients showed nervous involvement in later years, it was evident that in many cases the infection must undergo spontaneous resolution, which was due in part to treatment and in part to the tissue immunity which developed as a result of prolonged contact between the infectious agent and the host. If the patient received intensive treatment, but not sufficient to kill all the spirochetes, the development of this immunity might be inhibitive and the few remaining spirochetes develop with greater intensity. If this relapse occurred in the central nervous system we would have symptoms of a severe meningitis. Before starting treatment in any case it was well to try to recognize the character of the involvement, for subsequent therapy was determined by the type of manifestation. The present classification of syphilis of the central nervous system comprised (1) interstitial types, (2) parenchymatous types, and (3) endarteritis syphilitica. In both the interstitial and parenchymatous forms the common lesion was a perivascularitis which varied from a simple mantling of the vessels to a collection of cells in the form of a milium gumma, or, when combined with a similar process in the meninges, to large gumma formation. In the interstitial forms the disturbance of function was due to either actual destruction of the nervous elements or to pressure from the exudate. In tabes it did not seem reasonable to consider that the degeneration followed an infiltration of the dorsal roots which was secondary to a low grade meningitis. In paresis, in addition to the perivascularitis and localized meningitis, they had seen degeneration of the brain due to the actual presence of spirochetes in the cortical substance as an element in the development of parenchymatous syphilis. The infiltration occurred more slowly, and the symptoms were less pronounced until they were well developed. In both tabes and cerebrospinal syphilis they were dealing with diseases of similar nature and the variation seemed to depend upon the difference in the rapidity of development as well as upon the localization of the inflammatory process. In paresis we appeared to be dealing with a disease not strictly comparable to the two just described. The difference in the type of curve, in the gold reaction, and the difference in response to treatment, were striking features. The best prevention of syphilis of the nervous system was prophylaxis of syphilis; next in importance was the proper treatment of syphilis in its early stages. No patient should be released from treatment until his cerebrospinal fluid had been normal in so far as pleocytosis and Wassermann reaction were concerned. At times there seemed to be a slight excess of globulin which could not be eradicated. It was important to emphasize the value of constant methods of making the various tests of the fluid. Of special value was the titration method of Hauptmann in testing the fluid with the Wassermann reaction. The problem of the treatment of syphilis of the central nervous system was complicated by the peculiarities of the subarachnoid space, which was directly continuous with the perivascular, perineural, and perineuronal spaces. Anti-bacterial immune bodies, vital stains, and most drugs were not excreted into the cerebrospinal fluid. Even drugs which acted on the central nervous system when given by mouth or subcutaneously acted in much weakened concentration when injected subdurally. In many cases general treatment affected the course of syphilis in the cerebrospinal axis favorably; this was especially marked in the early forms of the disease. The tendency of cerebrospinal

syphilis to relapse had been long known; even marked improvement in most cases of cerebrospinal syphilis was often not followed by a parallel improvement in the cerebrospinal fluid. The desirability of subarachnoid therapy was evident. After reviewing the various methods of subarachnoid therapy, the essayist said that the use of serum of patients, withdrawn after intravenous salvarsan injection, had been criticized chiefly because of the small amount of salvarsan it contained. By an analysis of a number of sera it had been shown that the amount of serum injected contained from 0.1 to 0.2 mg. This autosalvarsanized serum was definitely spirocheticidal, the salvarsan being present in a colloidal combination which was less easily dialyzed than was salvarsan. Moreover, some of the beneficial effects might be due to the introduction of the serum, for by the injection of serum alone seven out of eight cases showed a diminution in the strength of the Wassermann reaction in the spinal fluid; in three of them it became negative with 1 c.c. In all, twelve cases were treated; in six of them the Wassermann reaction became negative. This proved that there was distinct benefit from the intraspinal injections of serum. The writer said the explanations of these effects were probably theoretical, but so were the objections to the treatment. The injection of autosalvarsanized serum was followed by fewer permanent unpleasant effects than from the intraspinal injection of any other antisyphilitic remedy. In some patients the pain was so severe that the treatment had to be discontinued, but such instances were the exception. Most patients were willing to continue treatment. The treatments were better borne if not given oftener than once in two weeks. No form of treatment should be pushed if the patient became more and more depressed. In the general treatment of syphilis of the central nervous system, if the patient showed signs of involvement of the cerebral meninges, or brain salvarsan should be preceded by a short course of mercury to prevent the occurrence of a Herxheimer reaction in the region of vital centers. If one suspected the presence of gumma a vigorous course of iodide was of value. In the meningitis of the secondary period the response to alternate courses of mercury and iodide and of salvarsan were usually prompt and permanent. In the tertiary form of the disease, alternate course of mercury and iodide and of salvarsan were usually followed by decided improvement. The fluid should be examined before and after each course. If it became normal after a few months' treatment the prognosis was good. In tabes, because of the apparent sensitiveness to mercury, it was better to start the treatment with small doses of salvarsan intravenously, gradually increasing, and giving an injection once a week for six or eight doses. If at the end of this course the Wassermann reaction was weaker, then a course of mercury might be tried, followed by another course of salvarsan. If the reaction did not change appreciably intraspinal therapy was of value. Our aim should be to bring the fluid to normal and to keep it there. This could be done in the majority of cases; 75 per cent. of their cases had a negative reaction with 1 c.c. of fluid, one-half of them had a negative reaction with 2 c.c. Fourteen have remained negative with 2 c.c. Only four had shown slight relapses. Relapses in the fluid were usually accompanied by clinical relapses. In the presence of rapidly advancing tabes or of optic atrophy it was desirable to introduce intraspinal therapy in addition to general treatment from the beginning. Compared with the results in other forms of lues of the central nervous system, the treatment of paralytica dementia had been disappointing, although the number of remissions and the amount of improvement under salvarsan and serum intraspinally was many times greater than in the untreated cases. In the treatment of syphilis of the nervous system we should pay attention not only to the syphilis, but to other conditions which might be present.

Syphilis and Society.—Dr. HUGH CABOT of Boston read this paper, in which he said that since the other papers in the discussion had concerned themselves with what syphilis did for society it might perhaps not be improper to consider what society did or might do for syphilis. It must be admitted that syphilis was the most serious of the contagious diseases which had not yet been subjected to control. It might further be admitted that it was essentially a controllable disease, that in its early stage it was entirely curable, and that at all stages it was controllable as concerned its contagious nature, and that, finally, it seemed likely that if society should fail to control syphilis, syphilis was not likely to fail to control society. Upon this basis Dr.

Cabot proceeded to consider what society had done in attempting to control syphilis and what society might properly be expected to do in the immediate future. In discussing the reporting to public health authorities as a measure of control, he pointed out the fact that eleven States had enacted laws or State Board Regulations looking to the reporting of cases of venereal disease in general and of syphilis in particular. Some cities also had such regulations. He distinguished between true and false reporting, stating that true reporting required that the case be notified to the health authorities by the name and address precisely as were the cases of other contagious diseases including tuberculosis. False reporting was reporting by number or by some *quasi* secret method and was evidently an attempt to deal with these conditions in a manner not thought applicable to other forms of contagious disease. On the question of the value of reporting there were three main types of opinion: The opinion of the public health officer, the opinion of the practising physician and the opinion of the enthusiastic layman (generally women). Broadly speaking, the opinion of the public health officer had generally been in favor of reporting, though they realized the difficulties which stood in its way and were prepared to temporize with half-way measures. Such measures could only be justified on the ground that they represented a step toward true reporting and were intended to get the public accustomed to the appearance of these diseases in the weekly or monthly reports and to later support the attempt to make these diseases truly reportable. To this it might properly be objected that reporting by number not only had no statistical value, but was positively misleading. The opinion of the practising physician and particularly of those physicians who dealt with syphilis on a large scale had been almost unanimously opposed to reporting. They reasoned that if physicians were required to report these cases by name they would in a short time, if they were honest, have no patients to report. This would have the exceedingly undesirable effect of throwing this disease into the care of the dishonest physician, the quack, and the charlatan, and far from acting as a method of controlling the disease it would not only make it less controllable, but more severe in its manifestations. Very generally lay opinion had supported suggestions to make this disease reportable, and much existing legislation had come either from this source or from the advocacy of public health officers with an amiable disregard of the gross improbability that such legislation would serve any useful purpose and the almost absolute certainty that it would only encumber the statute books with laws that were unenforceable and served no other purpose than to bring the law into well-merited contempt. Dr. Cabot concluded that reporting had been worthless as a method of assisting in the control of this particular variety of contagious disease. Any law that was to achieve success must be of practical benefit to the patient, a fact which must have been commonly overlooked by the advocates of reportability. Dr. Cabot then proceeded to discuss the status of legislation making syphilis a bar to marriage and showed that most of these laws as such were largely worthless. He cited the law of Wisconsin and pointed out that if the law meant what it said it would require of physicians an amount of time, knowledge, and scientific equipment entirely out of proportion to the fee required by the law. This difficulty the Attorney General was asked to untangle and he did so in an opinion rendered to the effect that if there were clinical and laboratory tests such as the Wassermann test, which required special study and special apparatus for this application and which only a very small percentage of the licensed physicians of scientific attainment could apply, he was convinced that the law did not intend to require and, therefore, did not require such tests. That legislation of this sort interpreted by such judicial opinion and backed by public health authority could exist in a civilized country to-day was the most discouraging feature of the attempt to control syphilis. In regard to the issuing of marriage certificates under any machinery now required by the law, in the opinion of the essayist, any benefit that might result was more than counterbalanced by the harm. It must be obvious to any observer familiar with the intricacies of the diagnosis of syphilis that it was extremely difficult to deny the presence of the disease at any given time, particularly if the antecedents and previous history of the patient were unknown. The probability of error became almost overwhelming if there was any lack of co-opera-

tion between the physician and the patient. It was of the first importance that existing medical opinion as to what constituted freedom from danger of infection for the purposes of marriage should be authoritatively stated. In view of the wide divergence of opinion on this subject this Congress could do an important service in formulating expert opinion in concrete form and he therefore suggested to the properly constituted authorities of this Congress that, if in their opinion it was advisable, a committee be appointed to make a report on this subject. Dr. Cabot then took up the subject of what society did for the individual in the way of diagnosis and treatment of syphilis, and pointed out that society had been exceedingly backward in making proper provision for this condition and even at the present time only the very beginnings of proper arrangements were to be found. The Scandinavian countries had undertaken the wholesale treatment of venereal disease, and, though much difference of opinion existed as to the details, he had heard of none in regard to the principle. Here lay the most fruitful field of effort. The State, the municipality and the university or corporation hospital must be prepared to deal with syphilis upon a large scale not only in regard to diagnosis, but in regard to treatment and subsequent supervision. It had been assumed that treatment should be free or practically free, and that the whole burden of the expense must come from the tax payer who had naturally shied at the prospect. Here seemed to lie the error. There was no reason why society should fear to step in and separate the patient from the private physician. Diagnosis and treatment for all should be offered at a sliding scale of fees proportionate to the ability of the patient to pay. A full-time salaried staff should be put in charge and these salaries should be sufficient to attract first class professional ability. The greatest difficulty which was likely to arise in the course of this attempt would be the lack of control of the patient which such an institution would have. It would, therefore, be desirable to have legislation empowering certain institutions as deputies of the State to compel the attendance of patients during such periods as seemed desirable. Such legislation would not seriously invade the rights of the individual and would, therefore, not meet with violent opposition.

Dr. ISADORE DYER of New Orleans said that in weighing the question of syphilis in its relation to society, meaning the social economy of all the people, two points stood out, the lack of the control of syphilis and the effect this had upon those who had not voluntarily contributed to its spread, namely, those who had acquired syphilis innocently and those who had escaped it. It could be stated as a very safe hypothesis that if every case of syphilis with a chancre or with an early eruption could be promptly hospitalized and treated under compulsion, the disease could be controlled far better than through any system of legislation regulating the reporting of cases or determining the eligibility for such marriage. If enough of those who dealt with syphilis could reach this point of view, it was rather certain that the hospitals would help, for in the large majority of hospitals approached on this subject the very emphatic opinion was derived that the authorities considered the hospitalization of all syphilitics desirable. If syphilis was to be controlled the viewpoint of hospitals must be changed. All general hospitals should have special provisions for the indoor care of incipient or acute cases of syphilis and all men who treated syphilis in public practice should enforce the indoor care of such patients with the object of getting such patients under prompt control and thereby minimizing the spread of the disease. Legislation should be directed at enforcing the hospitalization of all cases of acute syphilis coming under public charge. Educational movement should encourage the public to recognize syphilis among the communicable diseases and amenable to isolation just as were scarlet fever, measles, and other contagious diseases. Discovery and wide use of the newer arsenical preparations in the treatment of syphilis had placed in the hands of the medical profession a group of powerful remedies with rather exact relations to the disease. There had not been time enough to fix the value of these preparations, and yet the majority of medical men had grown to depend upon them in the treatment of disease. Former ignorance and timidity in treating syphilis had given place to a degree of rashness in the use of these remedies which had not been wholly justified. The medical schools were not teaching syphilis properly. All the more

reason that the student and the physician should have the chance to study the disease at first hand among cases assembled in hospital wards under the direction of men qualified to teach the subject. It was too early to argue for special hospitals for syphilis, for the public was not educated to see this necessity. This might come as the outgrowth of a more liberal provision in the general hospital. Dr. Dyer suggested that if the medical authority in each State were given the right to supply health certificates, covering particularly the disease which disqualified for marriage, then it would become an easy matter for a State board of health through its medical and laboratory forces, to dispense such certificates after a thorough review of the applicant, including all laboratory tests essential to proper examination. Such a plan would possess the advantage of providing a central bureau of record, and would make for a more systematic knowledge of the incidence of such diseases, and of syphilis especially.

Dr. HUGH T. PATRICK of Chicago said he entirely agreed with the previous speakers with reference to the treatment of syphilis, that its successful treatment depended upon early treatment, understanding treatment, and individual treatment. The question before them was when treatment fulfilled these requirements. Excluding paresis and tabes, he advocated the administration of mercury and later iodide, provided enough mercury was given. What enough meant would have to be determined by the results, and not by any stated doses. Then salvarsan might be given. One reason that they got results in many cases by the newer methods of treatment where they did not by the older methods was that the amounts of mercury had been inadequate. In the vast majority of men one could give two high inunctions of mercury daily. When mercury was given in this way the teeth and gums must be scrubbed three times a day. For this purpose chlorate of potassium rubbed (not pounded) with oil of cloves might be added. It might be emphasized that mercury and salvarsan were effected in combating the constitutional disease and potassium iodide which was a spirocheticide was effective in combatting local lesions. The speaker also condemned the attempts at the treatment of syphilis with cacodylate of soda and said that he believed that many were treated for tabes and paresis who did not have these diseases, and that the Lange gold test was not an infallible test for paresis.

Dr. ABNER POST recalled that the subject before the Congress in 1891 was also syphilis and this was the only subject to have been brought up before the Congress twice. He compared methods of treatment at that time with those of the present and spoke of the burden that syphilis placed on society, not only from the standpoint of public expenses, but the many private and individual burdens for which it was responsible. He also spoke at some length of the stigma attached to the word syphilis. This was so great that physicians in private practice did not have the courage to give it as a cause of death. This was one reason why one found so many more deaths from syphilis on the records of almshouses and institutions than in the records of the general population.

Dr. WILLIAM G. SPILLER of Philadelphia said he was not an advocate of the intraspinal treatment of syphilis of the central nervous system. He believed that very brilliant results could be obtained in the early stages of syphilis of the central nervous system by extraspinal methods of treatment.

Dr. GEORGE WALKER of Baltimore said one thing that should be brought out was how much syphilis there was in the community. He had examined 1080 patients at Johns Hopkins Dispensary, exclusive of the genitourinary department, and found 10.8 per cent. with positive Wassermann reactions; 1027 prostitutes with 67 per cent. with positive Wassermann reactions; 480 feeble-minded, expecting to find a large percentage of positive Wassermann reactions, but found less than 3 per cent. positive. In examining sixty of the lowest grade imbeciles he found only one with a positive Wassermann. In a jail with 600 inmates he found 24 per cent. positive, and in the Spring Grove Asylum for both males and females 11 per cent. were positive. In a boy's school where there was a good class of boys he did not find a single positive reaction, while in one of a lower grade he found two positive. He examined sixty-three men in a factory and found one or two with positive Wassermann reactions. He then described provisions made for the care of syphilis at the Johns Hopkins Dispensary and thought many cases of syphilis were better handled by a dispensary than

by hospital and that there was no reason why they should be kept in the hospital the entire time.

Dr. HAVEN EMERSON of New York spoke of the lack of co-operation of the profession with the health departments in reference to dealing with venereal diseases. They had been making considerable progress in the reporting of these diseases in New York. When the regulation requiring the reporting of venereal diseases went into effect there were at first only about fifty cases reported a week; now about 300 were reported weekly, and the figures were approaching 350. He emphasized the fact that that board of health might stand ready to care for patients with these diseases, but that the medical profession at least in New York, was opposed to such a step, and he did not see that much could be done in the direction of State or municipal care of syphilitic patients until the attitude of physicians changed and they were willing to sacrifice their financial interests to the public welfare. The New York Department of Health had made some Wassermann tests in its routine examination of push-cart peddlers among 1000 of whom 8 per cent. were found to have a positive Wassermann reaction. In the examination of 20,000 food handlers they had found 111 who gave a positive reaction, while among 20,000 food handlers examined by private physicians only seven were reported as having a positive Wassermann.

President's Address.—Dr. WILLIAM S. THAYER of Baltimore made this address and chose as his topic "Teaching and Practice." He said that the relations between teaching and practice in hospital and in university had of late been the subject of vigorous controversy in this as in other countries. With all the divergences of opinion the goal aimed at was almost universally the same. It was their desire that the hospital, the school of medicine and the teaching staff should be so organized that the ultimate service to humanity might be the largest; that we might gain greater knowledge of disease; that we might acquire more efficient means, public and private, of recognition, prevention, and alleviation of the innumerable ills to which the human race and its inarticulate companions and servants were heirs that we might become more efficient in the care of our patients; that we might train better physicians. These were the main ends of the study of medicine. In the early days, the study of medicine in this country was begun in the office of the practising physician. By and by there developed schools of medicine in which the teachers were successful practitioners. The first of these schools were associated with hospitals, and although the body of teachers was not large, yet John Morgan in his famous address on medical schools, early pointed out the necessity that special branches of medicine should be taught by men who had given their greater attention to these branches in practice. The professors of medicine and of surgery who bore the brunt of the teaching and directed their department were usually busy men much sought for by the public in their community; and the teaching in the old days consisted largely of didactic lectures, with but limited demonstrations. In such a school of medicine the clinical instruction of a single medical department or unit could be, and often was carried out in a variety of hospitals—those hospitals with which the professors of medicine had the good fortune to be connected. The only association between the university and the hospitals was, in many instances, an amicable agreement on the part of the latter to allow instruction in the out-patient departments, through public clinics in amphitheater and operating room, and to a certain limited extent in the wards. There were no university laboratories connected with the hospital. The hospital was, indeed, a close and valuable accessory, but yet an accessory to the department of medicine. To-day the hospital must be considered not as an accessory to the department of medicine, but as its vital center. One could scarcely conceive of a school of medicine wholly independent of its hospital. The laboratories for the study of the chemical and anatomical and physiological phenomena of disease could not well exist at a center removed from the hospital, or under the control of individuals other than those directly associated with the hospital management. On the other hand, the hospital in many instances had come to depend largely on the co-operation of the university in the performing of some of its most essential functions. Professors, assistants, undergraduate students all went to form a corps of hospital servants invaluable to the institution. In a word, the relations between hospital and school of medicine were so close and intricate to-day that a discussion of the

organization of a medical or surgical clinic, or of a department of pathological anatomy, presupposed the assumption that hospital and university men under one management or in such close affiliation as to form a single working body.

But to return again to the organization and constitution of a single department of medicine as compared with that of thirty years ago. The changes in the method of teaching clinical medicine had been great. Demonstrative clinical lectures remained an important element of medical teaching. But the place of the didactic lecture had largely been taken by practical instruction before small groups at the bedside. This involved a considerable increase in the teaching staff and increased greatly the amount of time which the teacher must give to his work. Thirty years ago the professor of medicine might have been expected to give two or three hours a week to his classes. To-day he could hardly be expected to devote less than six or eight hours to personal teaching. The problems of the teaching of physical diagnosis in its restricted sense were not so different from those of thirty years ago; but to-day it was generally recognized that the university should offer the student far more individual practical training than he used to receive. In the old days three men were entrusted with the teaching of a class of ninety; to-day the work would be distributed among six or eight at least. Thirty years ago there was no such thing as a clinical laboratory, and clinical microscopy and chemistry were not taught in the medical department. Indeed, there were no special medical laboratories. To-day a modern medical clinic must, in the first place, control a clinical laboratory presided over by men who were called upon to give a considerable portion of their time to the training of the student in a large variety of methods of examination of secreta, excreta, and body fluids; and this laboratory should also be a center for scientific research. It was easy for one man to preside over the entire department of medicine thirty years ago and to conduct his practice as well. It was extremely difficult, if not impossible, for a practitioner to preside over the clinical laboratory to-day, and at the same time to do justice to his responsibilities as a physician.

To reconsider the problems which confronted the director of a department of medicine to-day. The teacher of thirty years ago followed a relatively simple routine. The chief of a modern medical clinic found himself at the head of a complicated machine, involving the appointment of a large number of salaried assistants, the manipulation of a considerable budget, the coordination of a large staff of trained workers in clinical, chemical, physical, bacteriological, serological, and physiological departments, and the organization of a system of group teaching to which he must himself devote a very considerable amount of his time. It was evident that the director of such a department should be a man who had had a rather broad training, who should have had a basis of chemical instruction such as was impossible thirty years ago, and should have spent a sufficient amount of time in work in each of the branches represented by the sub-departments of his clinic to enable him at least to comprehend the significance of the work which was there being done, and to carry out real supervision. Thirty years ago the professor of medicine was properly he who had obtained the greatest reputation as practitioner or consultant. This reputation was often not attained before the age of fifty, and was gained through the active practice of the art. Such a man, who with years, might or might not have attained financial ease, might suitably in those days be called upon, at a nominal salary, to direct a department and to give the two or three hours a week which were the sum total of the time exacted by the teaching duties of the professor. But to-day it would be extremely difficult, if not impossible, for a man with a considerable consulting practice to organize and direct a medical clinic, and in addition to do the amount of personal teaching which would be necessary. The practitioner, even if he were purely a consultant, was not master of his own time. He might limit his consultations to special hours, but he could not cut off the increasing calls which appealed to his sympathy and came at any moment. And even if he saw ever so few patients, he could not control the complicating side-questions to which relations with any one ill human being were too apt to give rise. To accept such a position would necessitate the abandonment of a large part of that physician's practice; this would mean the loss of the main source of his income, unless he were a man of inde-

pendent means. If then the professor of medicine in a modern university was to be chosen from the ranks of those men who had acquired great experience through professional success, it would be necessary either that the university should pay a very considerable salary or that the professor should be a man of independent means.

One of the questions which had been most actively discussed of recent years was whether a man who had obtained his clinical experience largely or purely in hospitals was properly fitted to teach students the essentials of the practice of medicine. A distinguished student of the problems of medical education had been quoted as saying essentially: "Diseases are the same in the rich and in the poor, in human beings, and in animals. To the clinician the ward is his laboratory, and the study of disease in the patient in the ward is, in all essentials, the same as the study of disease in the animal in a laboratory. The only difference between the study of disease in hospital and outside is that in the hospital the patient may better be observed. It is a mistake to say that it is necessary for a professor of medicine to have had experience in private practice when the same experience may be obtained more intelligently and in a much more concentrated form in the hospital." This conception which had, by some, been regarded as characteristic of the point of view of those who had favored the establishment of professorships of medicine on the so-called "full time" basis, had been looked upon as fallacious and dangerous by many of the opponents of certain modern tendencies in medical education. "No man," they said, "is fit to teach students the art of the practice of medicine who has not himself passed through the experiences of the practitioner. Practice in a hospital ward is one thing; practice in the home of the patient, another. He who has been accustomed to rely on the trained nurse and on the many appliances and instruments of precision which a well-appointed hospital affords can have little conception of the difficulties which he will encounter in private practice. He whose only experience has been with the trusting, unresisting patient in the general wards, will find himself at sea when treating the whimsical, critical, prejudiced, opinionated invalid in private life. He who has been accustomed largely to study serious diseases in the wards of the hospital will have small sympathy with, and little understanding of, the trivial complaints of the supersensitive and nervous members of the more well-to-do classes. The conditions that he is called upon to treat are to be remedied in great part by minor regulations of habits and manner of life. His main duties consist in ministering to the minds of his patients—in kindly counsel and encouragement, in advice tending toward the alleviation of a thousand petty ills which he who knows that they will pass with time—does not even consider in himself, which the less sensitive patient in the ward barely notices. How can one who has never had this experience teach students the art of practice? Is it not folly to take away the teaching of medicine from the experienced practitioner and to give it to one who has had a training which might almost be called academic? Must we not regard this idea as the dream of the layman and of the laboratory student who with all his scientific attainments, is yet wofully ignorant of the conditions of the doctor's life and of his duties? The speaker admitted that there was much truth in these objections. The medical experience suitable to qualify a physician as a consultant or a teacher of medicine could not well be obtained wholly in the free wards of a hospital. There was a great difference between the mental workings of the patient in the free ward and those of the average individual with whom one was thrown in private practice. But fortunately in many hospitals to-day the great development of private wards offer abundant opportunity for the acquisition of just this experience. The man who desired to fit himself for a position as teacher of medicine or consultant should spend a considerable period of time in practice among the class of patients which was to be found in the large private departments of many of the hospitals. Such an experience gained in the hospital would afford him in concentrated manner just what he might obtain otherwise through a much longer period of time in private practice.

Recognizing the magnitude of the problems associated with the organization of a large medical clinic, it had been felt that such a department could best be presided over by men who were able to give their whole energies to the university in organization, in teaching, in the conduct and direction of research. And, notably,

at that institution with which the speaker had been connected for more than twenty-five years, several of the clinical departments had been reorganized upon a university plan. Through the generosity of the General Education Board, the institution had been enabled to establish a staff of university professors and salaried assistants who took charge of these clinics for hospital and university. These men, freed from the calls of outside practice, were able to give their entire time to the service of the department in the care of patients, the promotion and conduct of research, and in the teaching of medicine. And, as was well known, the members of this staff had agreed to abstain from the practice of their profession for their own emolument. The discussion associated with this experiment had been very active, centering largely upon the last-mentioned circumstance—the withdrawal or abstention of the university professors and assistants from private practice. Those who had objected to this procedure had regarded the idea as unwise and even unfair to the physician himself, to the hospital, to the students, and to the public. With regard to the professor himself, it had been pointed out that there could be little relation between the salary which the university could or should pay to the professor of surgery or medicine and the gross income of the successful surgeon or consultant in a large city. It had been asserted that the opportunities brought by a considerable income for wide associations with the world at large were broadening to the character of the man and were indirectly of value to the institution with which he was connected; that furthermore it must be a very serious question to the physician himself whether he was justified in planning deliberately a manner of life which could never lead to wealth or real financial freedom, when there might be open to him an opportunity to give to his family and those dependent on him the advantages which came with a large income. But the salaries of university professors, whether in clinical or scientific branches, should be materially—very materially—larger than they had been in the past, if these men were not expected by outside activities to add to their incomes. If the salary were adequate there would always be efficient men whose ambition it would be to occupy chairs of medicine and surgery, even though they realize fully that the chances of the acquisition of a large income were small. So far as the student went, the danger that under the direction of a salaried professor, he might be given a training more purely academic and insufficiently practical seemed small. In the first place, it had already been pointed out that the professor of medicine would doubtless be a man who had had a considerable clinical experience with patients in all classes of life, whose training had been by no means purely academic, and although some of his associates would perhaps be men who have not yet acquired the ripened experience which should be that of the head of the department, yet no one for a moment fancied that *all* the instruction in medicine and surgery would be given by the nucleus of teachers wholly dependent on their salaries. In every large clinic, and in every large hospital affiliated with a university, a considerable part of the instruction in general medicine and surgery, as well as in specialties, must be entrusted to men with or without salaries, who were more or less actively engaged in practice.

The objection so often raised that there was danger that a professor of medicine or surgery who abstained from outside consulting practice might be removed from touch with the profession was comprehensible, but not serious. If the director of the department was one who did a considerable amount of clinical work, he would still keep in active touch with the medical profession even though his consultations were held only at the hospital. In any event, the work of the department itself, set forth by him and by his associates and assistants in public clinics, in medical societies, and in journals, should keep him well before the eyes of the medical world.

One of the most important functions of a modern medical or surgical clinic was that it should afford opportunities for the ambitious student with scientific aspirations to pursue that course of study and acquire that experience which would fit him for a university career. Every year there were graduated from our schools of medicine men with the ideals, aspirations, and abilities of the true student, who, because of financial disability, were obliged to enter directly into active practice. With the organization of the modern medical clinic, there should be a considerable number of assistantships commanding salaries which should make it

possible for many of the really good men to pursue their chosen career. And it was highly desirable that such salaries should be sufficient and so graded that these men might continue their work through long years should they prove themselves of suitable character and ability. There was one point in connection with the reorganization of the clinic upon a university basis which seems to him of real importance—the desirability of ample provision for voluntary assistantships. But where could one find the director of a medical clinic who was not longing for the services of more young men, recent graduates with scientific aspirations, to assist him in the study of a variety of different problems? As it was to-day, only those men who could obtain salaried positions upon the staff or were of independent means could afford to give the time required for such studies. But many a student, upon his graduation, and during the several years that followed, would be more than willing to accept a position as voluntary assistant if he might be given a room and his lodging in the hospital. Every modern medical or surgical clinic should have a number of such positions open to such men as the professor might select. There could be no better investment for the hospital. Research assistants should be considered as essential to the welfare of the hospital to-day as were the regular internes.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, N. Y., May 16, 17, 18, 1916.

(Special Report to the MEDICAL RECORD.)

GENERAL MEETING.

Tuesday, May 16.

THE PRESIDENT, DR. D. W. STANTON GLEASON OF NEWBURGH, IN THE CHAIR.

Invocation.—The Rev. H. P. Le F. GRABAUOF of Saratoga Springs made the invocation.

Address of Welcome.—DR. ALBERT WARREN FERRIS of Saratoga Springs made this address. He said, in part: "Last year we met at Buffalo, and contemplated that great wonder of the modern world, Niagara Falls, the perfect type of everlasting, irresistible force; force which may be transmitted as far as you please and be delivered in the form of heat, or of light, or of electricity. To-day we invite you to contemplate the no less mysterious combination of dynamic agencies in our mineral waters for drinking or bathing, due to their natural and inimitable chemical ingredients, and their great supersaturation with carbonic acid gas. It is altogether fitting that this society of ours should meet at Saratoga Springs more fully to comprehend the great plans of the State of New York for the development of the natural mineral water resources here and the provision from year to year, as funds permit, of adequate equipment for their utilization. Critical and intelligent invalids from the eastern part of the country, who heretofore have frequented the resorts of France, Germany, Austria, and England, in search of bath treatment, now look to you for advice, and to New York State's provision at Saratoga Springs for the healing waters, which nowhere east of the Rocky Mountains can be found in such abundance and with such great supersaturation of carbonic acid gas. We physicians fully recognize that ours is the opportunity and that parallel with opportunity lies duty."

Dr. ABRAHAM JACOBI of New York, in response to an invitation from the president, said that if they would refer to some very old books they might learn that he had been president of the Medical Society of the State of New York in 1882. That was a time of rebellion, and perhaps they did not know that that was the time when the old code of ethics was abolished and they were given the code of ethics that made it possible for them to re-enter the American Medical Association. He said he also wanted to remind them that it was good to look back and to see what was behind them and to examine the forward strides that had been made by the medical profession that had made it what it was to-day. He said there was one thing they could all do to help forward the progress of the medical profession, and that was to come to the meetings. If one could not do anything else he could come to these meetings. This much he proposed to do himself, next year, ten years, and perhaps twenty-five years from now.

Address of Welcome.—The Honorable WILLIAM S. OSTRANDER, Surrogate of the County of Saratoga, made a brief address of welcome. He said he once heard a man say that a certain acquaintance was a very learned man, he could tell the simplest thing in a way that no one could understand it; that had always been his idea of the medical profession. He then spoke of the great progress of the medical profession which was the envy of all other professions, described the attractions of Saratoga Springs, and extended a hearty welcome to all the members and guests of the Society.

Oration on Medicine.—Dr. HAVEN EMERSON, president of the Department of Health, New York City, gave this oration, taking as his subject "Will the Private Practitioner Determine the Future of Public Health Work?" He said the very reason for their chosen guest's absence, the wholly admirable excuse of Professor Strong's inability to fulfill his engagement to address them, gave special point to the subject which he offered for their consideration. Professor Strong had gone to make available for all and sundry sufferers from violence and disease among the combatants in France, the services which the practitioners of medicine and surgery were offering daily throughout this State as individuals. Co-operation for a common end was replacing competition for personal gains. He said that the accident of opportunity had put him at a desk where two currents of correspondences, two floods of complaint and comment met. The citizens of New York City sent 46,267 complaints a year which fell roughly into the complaints of the layman that he was neglected and unprotected against his fellow citizen, and the protests of the practitioner of medicine that his privacy was invaded and his living stolen from him. It was his plan and hope to show them that the causes for both complaints might be abated by personal efforts among themselves, without recourse to recrimination or to the legislature. It might be accepted as axiomatic that public health work could progress only so far and so fast as the family physician was ready to go. If he had disapproved of the use of the diagnostic throat cultures, diphtheria would not have been reduced. When he found the examination of sputum and the Widal test of value to his patient, he acknowledged the right of the State to inquire as to the identity, residence, occupation, etc., of his patient for the community's sake. If the practitioner of medicine had not been heart and soul in the attack upon excessive infant mortality, the appeals of the public agent would have fallen on deaf ears. The laity no longer objected to, but welcomed, the visit of the public agent of health, the physician, and the nurse to school, to home, and to factory. The protests were not of officious interference and intrusion but against insufficient inspection and protection. In 1914, Dr. Goldwater called for the assistance of an Advisory Council; this now numbered 240 members. Of these, 72 were physicians, each one a representative of some professional group, an expert in the field in which the department had interests and where the public need would be best met by expert advice and support. The other members were drawn either from social groups whose major interests and whose occupations touched official medicine at many points, such as nurses, social workers, administrators of charities, etc., or from the industries which operated largely under the control of the Department of Health, such as the milk, oyster, food, chemical and drug trades. There were enlisted also members of the technical engineering professions whose knowledge of sanitation was an invaluable aid to the purely medically trained man. In addition to the help and direction of the Health Department, provided by the Advisory Council, important contributions to the health interests of the State and City of New York had been made by the active and effective Committee on Public Health of the New York Academy of Medicine, and within the last few years also by the Committee on Public Health of the County Societies of New York and Kings. He said he would give his answer to the inquiry of the title. The practitioner of medicine was now directing the present policies of public health work. In August, 1915, notice was given that handlers of food employed in kitchens and dining rooms of hotels and restaurants must be examined to discover the presence of infectious diseases in communicable form. It was fully explained that the particular object of the examination was to discover cases of typhoid carriers, active cases of pulmonary tuberculosis, and syphilis and gonorrhea in the active stages. The department maintained a corps of men and women physicians to examine those who were too poor to obtain private services,

and to inquire into the industrial conditions of this small army of 90,000 cooks and waiters working in New York City. One thousand one hundred and sixteen (1116) private physicians had participated in the examination of food handlers under authorization of the department, and they had made and reported to the department 20,550 examinations. During this period, 20 department physicians had examined 20,351. The diagnostic facilities of the department laboratories were available to the private as well as for the department examiners. The results were as follows: The 1116 private physicians discovered 1 case of pulmonary tuberculosis, 7 cases of syphilis, 5 cases of gonorrhea, but no case of typhoid carrier among 20,550. The 20 physicians of the Department of Health discovered 20 of tuberculosis, 111 cases of syphilis, 22 cases of gonorrhea, and 6 cases of typhoid carriers. If the same rate of incidence had prevailed among the food handlers examined by physicians in their own employ as was found among their fellow-workers examined by the Department of Health, there would have been approximately 26 instead of 1 case of tuberculosis reported, 143 instead of 7 cases of syphilis reported, 26 instead of 5 cases of gonorrhea reported, and 7 instead of no cases of typhoid carrier reported. There was much food for thought in these results. The Health Departments could and doubtless would turn over to physicians a larger and larger share of work as fast as the practitioners showed their willingness to join in the partnership of prevention. This most desirable incorporation awaited only the action of the organized medical profession. They were all enlisted in the same army, the army of sanitation, the army for social protection and reconstruction.

The Geology and Hydrostatics of Saratoga Springs.—DR. ALBERT WARREN FERRIS of Saratoga Springs made this address and gave a lantern slide exhibition showing the geological formation found in this region and also many views of the various springs and the country in this vicinity. He stated that there were three theories to account for these springs. The first that they were basins of water formed in the earth; the second that the rain permeated the earth and reached a lower strata; the third that they were sea water imprisoned in earlier geological times. The first of these theories was manifestly incorrect, since it would not account for the vast quantities of water discharged. The second that they were the result of surface water was not altogether correct, because the spring water was so highly charged with carbonic gas and minerals. The third was wrong because if sea water had been thus imprisoned the salts in it would have been crystallized under the great pressure. There was a volcanic formation in this region, and gases from former eruptions had been imprisoned in the earth and rocks. The water falling on the surface percolated through the shales and crevices of rocks and absorbed these gases. It then passed over mineral deposits and according to the character of these absorbed minerals such as potassium salts, iron, lithium, strontium, barium, calcium and others. The majority of the springs were found at a depth of 300 to 600 feet, but one had been reached at a depth of 1009 feet. The waters were thrust to the surface both because the gas absorbed made them lighter and because of the pressure. When the water lay beneath the surface of the upper ground water it sometimes reached the surface by striking a fault. The geological strata from the surface downward in this region were first drift shale, Canajoharie slate, Amsterdam limestone, and then dolomite and Potsdam and under the Potsdam the older Cambrian strata. The water obtained from the springs came from the dolomite. There were in all about 140 springs. The amount of water discharged varied considerably, but one spring gave 2400 gallons daily.

The Relation of the State to Saratoga Springs Reservation.—His Excellency CHARLES S. WHITMAN, Governor of the State of New York, spoke on this subject by invitation. He said in part that the general public was interested in the medical profession and the work they were doing. He wished to take this opportunity to call attention to the last report of the State Board of Health which showed that for the year 1915 the lowest death rate occurred in the history of the State; this was due not alone to the Health Department, but was an achievement in which they had all had a part. In 1915 there had been a saving of 4000 lives as compared with the previous three year period. The general death rate was the lowest in the history of the State; the infant death rate was the lowest in the history of the State; the death rates from tuberculosis, from measles,

from scarlet fever, diphtheria and whooping cough were the lowest in the history of the State. They were very proud of the Department of Public Health of the State of New York. While Dr. Biggs was to be felicitated on the record just read, and his was the most wonderful Health Department in the United States, they all knew that much was due to the devoted skill and conscientious work of the physicians all over the State. He felt conscious of the responsibility of the governing power of the State to do everything in its power to uphold and assist the hospitals and public health work of the State. He realized that the public health was a matter of the most vital concern to anyone who took the office of Governor of this State. As to the work to be done at Saratoga Springs, he wished to make it plain that much depended upon the attitude of the members of this association and on the physicians throughout the State. If these springs were to be developed as had been those of Europe to a point of world-wide fame it must be done here as it had been done in Europe by physicians. Americans had been flocking to Europe to the spas to receive the benefits of the spas, but it was stated on the authority of those who had made the investigations that the waters of Saratoga contained more healing powers than the spas of Europe, that by these healing powers men might receive life extension through health conservation. While he hesitated to mention what might seem like taking advantage of the wretched conditions in Europe, if Saratoga Springs were developed now and Americans who could not go to Europe could find rest and health here by the use of these waters their value might be established for all time. It must be emphasized that if these springs were to be brought to a place of equality with those of Europe it must be done through the help of physicians. He said that there was a sentiment to the effect that medical men should not indulge in political activities. He felt that the medical profession had taken something less than an active interest in political affairs and that they had shown too much faith in "absent treatment." The state needed the advantages of their teaching and scientific investigations. They had been seeking to reduce infant mortality, for the inspection of school children, for the reduction of working hours, they had been fighting slums and working to banish preventable disease. The physician was becoming the overparent of the people. The government was placing a new emphasis on health matters, and because of this the physicians should be alert and take an intelligent interest in public affairs to the end that "the wise thing might be done wisely and the unwise thing left undone." There was no automatic device for good government, and it was the duty of every citizen to do his part. We were now facing a time, it seemed, when a decisive stand would have to be taken, when we should have to answer the problem whether American institutions could hold their own. The children of the present would have to be prepared for citizenship. He stood for social preparedness as well as for military preparedness; he believed we should take the water out of blood, the chalk out of milk, and disease out of life. Physicians should take the leadership in this battle for social preparedness; they should take a keen interest in the political life of the day. Many had come forward and given their services to the State without reward or request for reward, and he hoped this generosity would be characteristic of all throughout the State. In taking the Hippocratic oath the physician had assumed an obligation to the State as well as to the individual patient. The State had transferred Saratoga Reservation to the Conservation Commission, which had charge of the water courses, oyster beds, and other natural resources of the State, and the Saratoga Conservation Commission had been abolished. Special tribute should be paid to George Foster Peabody, who had done so much to develop Saratoga. The government would now extend the benefits of this resort freely to the people. Their development depended not only upon the will of the people, but in no small degree on the medical profession.

The Therapeutic Importance of a Scientifically Conducted Health Resort.—DR. WALTER B. JAMES of New York presented this paper. He said health resorts, like psychotherapeutics, had in this country been discovered by the general public. The patient asked for this form of treatment and the physician accepted it with more or less reluctance. We had formerly depended upon European literature and European schools and hospitals to keep abreast of the times in medicine. Now the time had come when the facilities in this direction

were as great in this country as in Europe. But there was one department where we must still turn to Europe, and that was with reference to the study of the complex agencies of hydrotherapy, mechanical therapeutics, environment and diet. A few advances had been made in diet, but we had no experience in the combinations of the above-named agents such as they had in Europe at Nauheim, Vichy, Carlsbad, Kissingen, etc. The value of the treatment at these places was no longer a matter of debate. The great number of Americans and Europeans who had obtained relief there was proof of their value. Many remedies had been used in the past empirically, before we knew the chemistry and physiology involved in their action. Quinine was used in malaria long before the parasite of the disease was demonstrated. The influence of climate and environment combined with the thousand minor details was recognized in the treatment of tuberculosis. While it could not be said that any one of these factors determined the success or failure of the treatment, when they were wisely correlated they determined the difference between success and failure, between health and disease. There were other diseases in which this combination of diet, rest, fresh air, climate, and these waters were of value. It was not the baths alone, or any one of the other factors, but the combination of all. In the use of the waters science must be our guide. The science of medicine should no longer be dominated by empiricism. The attitude of the world had changed and they no longer regarded disease as a punishment sent by God, but as an evidence of man's carelessness or ignorance. The large infant mortality of former times illustrated this. As an instance Dr. James cited Queen Anne, who, after giving birth to seventeen or eighteen children, left no heir to the throne, all having died in early life. To-day this would have been considered a subject for judicial investigation, perhaps punishment. Much had been accomplished in the reduction of infant mortality, but when it came to the diseases of middle life little serious work had been done. Such conditions as chronic heart disease, high blood pressure, arteriosclerosis, and chronic Bright's disease, all testified to the need of more careful study of these diseases. They had been attributed to the nervous tension of modern life, but a study of history showed that "dyspepsia" was common 2,000 years ago, practically as common as it was to-day. It was in such disorders that the well regulated treatment at Saratoga would prove valuable. The same treatment was not suited to all, but must be used discriminately, and must be developed on a scientific basis. The Nauheim treatment for heart disease required a wisely regulated diet, annual manipulations, and various other features, a life carefully regulated in every particular. The patient must adhere to the scientific plan of treatment laid out for him. A single concrete example might serve as an illustration. If one had a case of kidney trouble with chloride retention, the diet for this patient should be very poor in salts or salt free, and in such a case the waters of Hatshorn Springs, which were rich in salts, would defeat the purpose of the treatment. Now chloride retention could be recognized only by the most careful laboratory and dietary methods. This meant that to be efficient a spa must be equipped with every modern laboratory and clinical appliance for diagnostic purposes, for they had in hydrotherapy a two edged sword. After speaking of the careful detail employed at Nauheim, he said no Nauheim bath was given without the prescription of a physician. For the proper administration of such treatment they would have to go to the Old World for instruction and guidance; they would have to learn how at the same time to cure, amuse, and recuperate. The speaker then described the life at Vichy. He said first that this had been conducted as a co-operative corporation; the shares were very high in price and paid 16 per cent. dividends showing the financial possibilities that a similar development here might hold out. They had every kind of electric and mechanical therapeutic appliance and all laboratory and hospital facilities. When a patient went to one of the hotels he was carefully examined and a diet was carefully made out and sent to the kitchen and the chef and head waiter devised a proper menu, showing such remarkable skill that after the patient had been there for three or four weeks he scarcely realized that he had been on a diet. In closing, Dr. James commented on the remarkable spectacle of a State turning over such a resort to the people, said there was nothing like it in this country unless it was Hot Springs,

Ark., and that bringing to fruition the promise it held rested in the hands of the medical profession.

HOUSE OF DELEGATES.

In Memoriam.—Dr. W. STANTON GLEASON presented the following memorial to Dr. Wisner R. Townsend, who died March 12, 1916, and who had been Secretary of the Medical Society of New York for ten consecutive years: "Paramount to rules and orders, and rising high above business considerations is the tribute we owe to the memory of our late Secretary, the man and the physician, Dr. Wisner R. Townsend. Encomiums are meaningless to you, his friends, for it was the little unremembered acts of devotion that bound him to you. His winsome personality and adaptability placed him in close touch with our entire membership. Out of the depths of our appreciation we place this laurel wreath of affection to his memory in the archives of this Society."

Report of the President.—Dr. W. STANTON GLEASON presented this report. He said that having gone a decade beyond their centenary it was well in retrospect to briefly estimate their status as an organized body, whether it were for progress or inertia, whether they were advancing consistently with the present era of science and development, or whether they were following the unchanging grooves of precedent. He felt that their scientific development had been positive and that a great interest had been stimulated through a division of the society into sections. The best minds of the State reflected their influence through the high standard of work accomplished. Their official body had been carefully and judiciously selected, and it had been their desire to keep in the line of progress. The opportunities offered during his tenure of office had shown him that contentment and a rapidly broadening interest in high grade scientific work were largely the governing factors in the District Branch and County meetings. Sectional unrest was periodically manifested, but recourse could always be had to the House of Delegates, which was and should be arbiter on all matters of expediency. After expressing his appreciation of the work of the officers and committees of the society during the year Dr. Gleason spoke at some length on legislation affecting the medical profession. He called special attention to the fact that in the tentative plans drawn up for enactment by Congress no attempt had been made to provide the increased military force with adequate medical attendance. We must be prepared before the emergency arose and physicians were the best judges in the final selection of medical men to care for the health and lives of the soldiers of our country. At the December meeting of the council a committee had been appointed to further the Society's interests in this important matter. He said further that in the State Legislature many bills had been introduced attacking the fundamentals of regular medicine. The intelligent effective work of the Committee on Legislation was worthy our highest praise. The indifference and lack of information on important medical legislation of many of the members of the society was a serious drawback to the Legislative Committee, for they needed the intelligent and balanced support of every physician to prove to law makers their honesty of purpose and the justice of their claims.

In speaking of the Compulsory Health Insurance Bill, Dr. Gleason said that this was one of the most important proposals ever brought before the State. It was the duty of every physician to familiarize himself with this proposed enactment, recognizing the fact that health insurance sooner or later was inevitable. Dr. Gleason then said that the interpretation of the principles of ethics of the medical profession should be legally given over to the Medical Society of the State of New York, and that the form of this legal recognition should include the right of the Medical Society of the State of New York to bring charges of unprofessional conduct or breach of ethics, to hear such charges, and to fix the penalty. It should then be binding upon the Board of Regents to impose such penalty as the Medical Society of the State of New York should fix, without further hearing or hearings upon the matter.

This report was adopted and the recommendation referred to a committee for consideration.

Report of the Secretary.—Dr. FLOYD M. CRANDALL of New York presented this report. After paying tribute to the masterly manner in which Dr. Townsend had conducted the business of the Society, he reported on

the membership of the Society. On January 21, 1907, the membership of the Society was 5,857. To-day there was an increase of over 2,000. During these nine years 4,610 new members had been admitted, and there had been 820 deaths, 451 resignations, and 18 expulsions. The membership of the Society was increasing more rapidly than were the accessions to the profession.

Report of the Council.—In addition to a few minor changes to the by-laws the following amendment was offered: "A Committee on Medical Economics and Medical Education shall be appointed which shall consist of five members, including the chairman. It shall investigate all matters affecting the economic status of physicians, and shall report annually to the House of Delegates such recommendations as may, in its judgment, seem proper."

The Report of the Committee on Publication Appointed by the Council.—This committee reported that the regular monthly issue of the journal was each month from 8,750 to 9,000 copies. In spite of a gross increase of over 4,000 copies the cost to the State Society for the year was \$2,803 less than in 1914. This committee also reported that all monies due the society had been collected and that there were no doubtful debts to be charged off at the end of the year. The directory had been published at a total saving in 1915 over 1914 of \$4,167.

Report of Committees on Prize Essays.—This committee reported that no essay had been presented for the Lucien Howe Prize for 1916.

Report of the Treasurer.—Dr. ALEXANDER LAMBERT presented this report. He referred to the saving in the publication of the Journal and Directory and stated that the excess of income for the last ten years was \$6,240.01.

Report of the Committee on Public Health.—Dr. JOSHUA M. VAN COTT of Brooklyn presented this report. He stated that nothing had transpired during the current year requiring the special action of this committee. The progressive activity of the State Department of Health was worthy of highest approval and could not but yield results far reaching in benefit, in the control and lessening of disease and the education of the public at large along sanitary and prophylactic lines. The appointment of Dr. Haven Emerson to succeed Dr. Goldwater as Commissioner of Health of New York City was of State-wide interest, as he would not only continue the policies of his predecessor, but his wonderful energy and efficiency as a health officer would be felt as a stimulus throughout the State to those interested in public health.

This report was accepted and the recommendation referred to a reference committee.

Report of the Committee on Legislation.—Dr. JAMES F. ROONEY presented this report. After giving a brief history of the bills upon which the committee had taken position he stated that this committee had appeared at hearings on the bill licensing and regulating the practice of osteotherapy; on all of the bills making changes in the present law relating to the use and administration of habit-forming drugs; the changes of the medical practice act; the annual registration of the physicians and definition of unprofessional conduct; the institution of a system of health insurance. In conformity with a request of the committee a bill had been introduced by Mr. Mills, who introduced the original Health Insurance Bill, to establish a commission to investigate sickness. It seemed imperative that the House at this session make some arrangement for the concerted attitude of the profession either for or against the whole question of Health Insurance, and for the appointment of a committee with power to appear before the Commission instituted under the Mills bill, or some similar bill that might be presented at the next Legislature.

This report was accepted and the recommendation referred to a committee.

Report of Committee on Medical Research.—Dr. FRANK VAN FLEET of New York presented this report. He reviewed the various bills designed to restrict annual experimentation that had been introduced during the meeting of the Legislature of 1916 and stated that he had appeared at all hearings on these bills and as yet not one of them had been reported out of committee.

Place of Meeting.—After considerable discussion a motion was passed that the place and time of the next meeting be referred to the Council with power to act.

Report of Reference Committee on President's Address.—This committee reported in favor of adopting the recommendation embodied in the President's address that steps be taken to interest the Board of

Regents to take steps legally to recognize the Medical Society of the State of New York; and that the Board of Regents should propose that the principles of ethics of the medical profession should be legally given over to the Medical Society of the State of New York to bring charges of unprofessional conduct or breach of ethics and to hear such charges and to fix the penalty. Resolutions were passed providing for the cooperation of the Legislative Committee of the State Society with the Board of Regents having for its object the formulation of a suitable code of ethics and the making of provision for the support by the Board of Regents in the enforcement of this code of ethics on the part of the Medical Society of the State of New York.

Election of Officers.—*President*, Dr. Martin B. Tinker of Ithaca; *First Vice-President*, Dr. Henry L. Winter of Cornwall; *Second Vice-President*, Dr. J. Richard Kevin of Brooklyn; *Third Vice-President*, Dr. Montgomery E. Leary of Rochester; *Secretary*, Dr. Floyd M. Crandall of New York; *Assistant Secretary*, Dr. Albert E. Seltenings of New York; *Treasurer*, Dr. Alexander Lambert of New York; *Assistant Treasurer*, Dr. Harlow Brooks of New York; *Chairman of the Committee on Scientific Work*, Dr. Samuel Lloyd of New York; *Chairman of the Committee on Public Health*, Dr. Joshua M. Van Cott of Brooklyn; *Chairman of the Committee on Legislation*, Dr. James F. Rooney of New York; *Chairman of Committee on Medical Research*, Dr. Frank Van Fleet of New York; *Chairman of the Committee on Medical Economics*, Samuel J. Kopetzky; *Chairman of the Committee on Prize Essays*, Dr. A. VanderVeer of Albany; *Delegates to the American Medical Association*, Dr. Wendell C. Phillips of New York, Dr. William J. Cruikshank of Brooklyn, Dr. Frederic E. Sondern of New York; Dr. Dwight H. Murray of Syracuse, Dr. J. W. Flemming of Brooklyn; *Alternates*, Dr. Arthur J. Bedell of Albany, Dr. May Gage Day of Ulster County, Dr. Sylvester J. McNamara of Brooklyn, Dr. Mary E. Potter of Brooklyn, and Dr. N. O. Brooks, Oneida County. Dr. O. E. Jones of Buffalo was appointed delegate to the American Medical Association, to take the place of Dr. Henry L. Elsner, deceased.

(To be continued.)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

*Two Hundred and Seventy-eighth Regular Meeting,
Held Friday, April 7, 1916.*

DR. JOHN S. THACHER, PRESIDENT, IN THE CHAIR.

Some Mechanical Factors in Colonic Stasis.—Dr. CHARLES H. PECK read this paper. (See page 895.)

Dr. BREWER said that he recalled very distinctly a case in a young school boy who had perfectly definite symptoms of intermittent obstruction with violent pain in the region of the splenic flexure. The case was sent to him as one of renal calculus, on account of the severe pain. He saw, however, that the case was an evident intestinal one, with visible peristalsis. An early bismuth plate was not very satisfactory, but the definiteness of the attack led Dr. Brewer to make a left rectus incision. The case was a peculiar one; the junction of the middle with the left third of the transverse colon appeared too high. It was found that the inferior mesenteric cartilage was cut off at the superior end instead of being cut off below. The artery behind made a vascular fold which in certain positions produced a distinct angulation. A lateral anastomosis was done to the transverse colon. It was evidently this vascular fold at the origin of the inner cartilage which had caused almost a complete obstruction. Dr. Brewer said he would like to ask Dr. Peck the origin of the bands in one case—was there peritonitis, or could that not be studied? Was there anything on the left side?

Dr. PECK said he could not tell; the last case seemed to be a straight peritoneal band. Two others were apparently connected with the left border of the omentum and fixed the gut so strongly that it had little peristaltic motion. None of the patients had any history of any acute inflammatory attacks to account for the formation of the band.

Dr. BREWER said a left-sided case must be rare. One he had in mind was due to new growth. On the right side a lot of gas had accumulated and it required good judgment to decide the location of the lesion. Jackson's veils over any part of the ascending colon did not harm at all; in fact, they might be said to be free from any pathological significance in many cases; but in left-sided cases some of these bands became very fibrous.

In one case where the abdomen was opened and nothing was found the pain continued to be very violent and a diagnosis of carcinoma was made. An exploratory operation was then done and five distinct bands were found very strongly constricting the gut and the actual lumen was small. Relief of the constriction made the patient perfectly well. This occurred ten years ago. Dr. Brewer said he did not understand the origin of the bands, but the patient was perfectly well now. In many cases he had been in doubt as to whether to remove the bands or not. Sometimes a patient had indefinite appendix attacks without inflammatory history. There was indefinite right iliac pain. The abdomen might be opened and some pathological changes might be found in the appendix. With the removal of the appendix the patient did not cease to have pain. There were generally pretty thick folds over the cecum. In one case of this kind Dr. Brewer said he removed the appendix; the next year he was obliged to remove dense thickened bands, which operation finally relieved the symptoms. A recent case was recalled in which the patient, a man who had had his appendix out and had been in consultation with most of the prominent gastric and enterological specialists, finally consented to have an exploratory operation. There were found two or three bands across the hepatic flexure, one just above the umbilicus. The band was as thick as a slate pencil. The cause was not known. It made a loop over which the intestine might be forced. Had Dr. Peck any theory as to the cause of these Jackson's veils?

Dr. DANA said that there was a medical side to the question of mechanical obstruction. Very carefully arranged exercises, posturing, mechanical supports had been combined to secure therapeutic results. Such a system of treatment had been and was being used in certain epilepsies, in recurrent depressions and other neurasthenic states. With time and patience they produced good results. Surgical shortcircuiting the colon was not a wise measure in neuroses.

Dr. WILLIAM H. POLK said he had been wondering when Dr. Dana was speaking if one was not well within the province of exploratory incision to be applied to many patients before subjecting them to this long, rather tedious method of medical treatment. He would like to present this question to Dr. Peck. In earlier days, when the question of abdominal work came up, exploratory work was done by operators as a matter of course. He could well remember a well-known surgeon coming into his ward, where there was a case in which there was a question of a possible diagnosis of fibroids. The surgeon said: "Why bother with investigation; explore!" That was in the days before exploratory incision became so safe as it now was. It seemed to him, however, that to save people who were victims of some neurosis, exploration would not be an undesirable thing.

Dr. ROPER asked Dr. Peck if from the plates they had been able to verify the impression that the obstruction was due to Jackson's membrane? Did the buckling of the ascending colon show in the pictures?

Dr. PECK said that one case was that type. The plates did not show buckling. He said that the picture was taken from both above and below. He had had many cases of the Jackson's type. It was not shown in the plates unless the buckling was sharp enough. It would not show rotation or interference with peristalsis.

Dr. ABBE asked if the method of filling and using the fluoroscope picture would show more.

Dr. PECK said that he did not know that it would.

Dr. BREWER said that if a bismuth meal was given and then a bismuth enema, it would show where the bismuth came from.

Dr. MILLER said that he thought there was a good deal to be said from the medical standpoint which Dr. Dana had presented. Certainly medical men saw a good many cases which presented these symptoms, but perhaps not to the degree that Dr. Peck had described. Medical men were asked to deal with many cases of intestinal stasis. In some cases there was a definite feeling of discomfort and of distention and accumulation of gas on the right side, so that it was a question whether or not a chronic appendicitis was associated with this type of case. With that, or following it, might come a chronic colitis and intestinal toxæmia. These cases happened to be very frequent, and Dr. Miller wondered whether when these conditions persisted for a long time the mechanical factors involved, such as the stretching of the peritoneal folds and the distention of the gut, might not set up a chronic peritonitis which might give

definite bands with obstruction after a time. Dr. Miller said he must confess to a certain amount of doubt as to which type of cases one would surgically treat. Some might perhaps have to be operated on long before such a procedure is even considered at present. He would like to know if Dr. Peck had aids to early diagnosis which would make the condition clear much earlier than it had been customary to recognize it.

Dr. THACHER asked if any of these bands, especially on the left side, were associated with changes in the intestinal wall, such as chronic diverticulitis.

Dr. PECK said he had not seen diverticulitis in any of these cases. The x-ray had not apparently shown the obstruction on the left side, though that amount of distention would suggest that it was there. Repeated plates led the radiologist to believe that the lesion was at the hepatic flexure, and Dr. Peck fell in with that view. The radiologist was very competent and the plates in a series showed some defect in the region of the hepatic flexure.

Dr. BREWER said that it was often impossible to get the bismuth to stay in long enough to fill the flexures. This was not so significant as in the transverse colon.

Dr. PECK said that the great dilatation made them feel that the lesion was at the splenic flexure. He added that he did not feel that his paper covered all the ground of clinical conditions. This group of cases proved to be due to non malignant conditions. Operation gave a marked degree of relief. To cull this group of cases from a number was extremely difficult. The first case was a record of 30 years, and after operation the patient experienced for the first time real comfort. Undoubtedly she could have been operated on many years previously with benefit. Unfortunately there was no adequate means of determining whether the type of case would be benefited surgically. This group of cases was very small. In regard to Jackson's membrane, he noticed that an interesting fact was that in the cases in which the right portion of the omentum was thickened there was an appearance of inflammation, and the left portion appeared perfectly normal. There must often have been chronic peritonitis of a low degree going on in that part of the colon. This may have been due to slow absorption from the colon. In many cases the mere presence of the membrane had no pathological significance at all. Where it was pathological it was apt to assume the type attached to the lateral parietes, and cause longitudinal rotation to the right. These were real obstructive cases. The symptoms they produced were sharp enough to warrant operation. As to medical treatment of these cases by posturing and so forth, Dr. Peck thought they should be tried before trying surgery. Surgery was for those cases which did not respond to medical treatment. Dr. Polk had suggested that exploration was better than letting the condition go on. This point should be decided between the physician and the surgeon. Operation should be done when it was decided that medical help had failed. Dr. Peck said that he had had no success at all in enteroptosis cases. Where that was the essential condition operation certainly did no good.

Dr. ROPER asked Dr. Peck what he had done in those cases.

Dr. PECK said that he had closed up the abdomen and sent them back to a physician.

Dr. BREWER said that he thought in enteroptosis cases operation made the patient worse.

An Unusual Case of Intestinal Obstruction.—Dr. J. C. ROPER presented this case, with specimen of stone and gall-bladder. The patient had been a man of 60. He had a severe attack of typhoid fever twenty years before. There had been two slight attacks of biliary colic in 1913, accompanied by mild jaundice. In 1914, about two years before present illness, he had a severe attack of gall stone colic, accompanied by fever and marked jaundice. He had been confined to bed for three weeks. Since that time he had had no jaundice or urobilinuria, although subject to attacks of asthma that were regarded as possibly due to reflex irritation from the gall bladder. On March 25, 1916, he had developed pain and tenderness in lower right quadrant. Sixteen hours later he began to vomit. This persisted, becoming fecal in character within twelve hours. Operation had been performed thirty-six hours after onset. A biliary calculus about the size of an English walnut was found at the ileo cecal valve. This could not be readily forced through the valve, so it was removed through an incision. The bowels had failed to move after operation and patient had died thirty-six hours later. At autopsy an opening (1.5 x 1 cm., oval in shape) was

found between the gall bladder and the duodenum, about four inches beyond the pylorus. The atrophic gall bladder contained a calculus almost as large as the one removed. It seemed probable that the gall stone had escaped from the gall bladder some time before the onset of symptoms of obstruction, possibly during the severe attack of 1914. It may have increased in size during its stay in the small intestine.

Dr. ABBE asked if pituitary extract was usually effective in relieving these conditions.

Dr. BREWER said he had seen wonderful effects in one case of a man of 50 with paralytic ileus, but had seen no success since.

Dr. ROPER said that Dr. Gibson claimed that he had found it effective. On the patient, however, it had no effect.

Dr. THACHER said the intestinal obstruction by gall stones was not generally due to obstruction of the ileo cecal valve and it was interesting that fairly small stones would sometimes produce obstruction.

Dr. BREWER said he had had three cases of gall stone obstruction in which there was no previous history of gall stone attack. He had had two such cases in two weeks. It was interesting that in some cases there was never any history whatever.

Dr. ABBE said he had seen five cases in rapid succession in about two years, since when he had not seen any.

Case of Esophageal Stricture.—Dr. ABBE presented this case. He said he had recently seen a case of esophageal stricture in a child 6 years old. At 4 years old the child had severe typhoid fever and after recovery could not swallow very well. Finally only milk would go down, then nothing. Dr. Deaver made a gastrostomy and could not find any opening above the esophagus. There was no opening to be found either when Dr. Abbe explored from below. The esophagus was entirely obliterated. The question was, why should this obliteration follow convalescence from typhoid? Was there known to be any ulceration of the mucosa in typhoid which would account for the condition? Was there a phlegmonous gangrene of the esophagus in typhoid?

Dr. THACHER asked if the dysphagia followed immediately after the typhoid.

Dr. ABBE said that after convalescence the child gradually swallowed less and less, until it was at the point of death. No entrance could be made from above or below.

Dr. POLK asked how long a time elapsed between typhoid and complete obstruction.

Dr. ABBE said two years. The child never swallowed anything solid after typhoid.

Dr. ROPER asked how far down was the obstruction.

Dr. ABBE said the bismuth made a little cup-shaped depression at the top of the esophagus. There was no trace of the esophagus at all.

Dr. BRANNAN asked if there had been any attempt at gradual dilatation.

Dr. ABBE said no.

Dr. BRANNAN said that Keen of Philadelphia had recorded in his *Surgical Complication and Sequelae of Typhoid Fever* two cases of stricture of the esophagus following typhoid ulceration.

Dr. THACHER said that typhoid ulcerations might take place at any part of the alimentary tract.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

January 4, 1916.

(Concluded from page 851.)

SYMPTOMATOLOGY.

1. Discuss pericarditis without considering treatment.
2. Discuss the diseases of the mediastinum without considering treatment.
3. Give the causes, symptoms, and signs of aortic insufficiency.
4. Give the causes, symptoms, and urinary findings in chronic interstitial nephritis.
5. Give the symptoms of duodenal ulcer.
6. Give the symptoms of tetanus and distinguish it from strychnine poisoning, hydrophobia, and meningitis.

7. Give the symptoms and complications of acute rheumatic fever.
8. Discuss ascites.
9. Discuss tonsillar infections.
10. Give the symptoms of bronchopneumonia.

OBSTETRICS.

1. Describe local maternal changes at end of first half of pregnancy.
2. Give your method of conduct of a normal labor.
3. Describe mechanism of labor in an L. O. P.
4. Name the positive signs of pregnancy.
5. Etiology, symptoms, and diagnosis of puerperal insanity.
6. Diagnosis and management of placenta previa at the eighth month.
7. Indications and contraindications for use of forceps.
8. (a) How would you control post-partum hemorrhages?
(b) How deliver the aftercoming head?
9. (a) Describe the clinical course of extrauterine pregnancy.
(b) Differential diagnosis of ectopic pregnancy.
(c) What would you carry in your obstetrical bag?
10. (a) Describe briefly your conduct of the puerperium.
(b) Name the three most frequent causes of hyperemesis gravidarum.

SURGERY.

1. Give signs and symptoms of cerebral hemorrhage.
2. Describe tumors of mammary gland.
3. Give differential diagnosis of cholecystitis.
4. Give the signs and symptoms of appendicitis.
5. Give the differential diagnosis of tuberculosis of the kidney.
6. Give the differential diagnosis of arthritis of knee-joint.
7. Give differential diagnosis of injuries of the hip-joint.
8. Give the differential diagnosis of salpingitis.
9. Describe bursitis, synovitis, tuberculous meningitis.
10. Give the signs and symptoms of exophthalmic goiter.

ANSWERS.

SYMPTOMATOLOGY.

1. *Acute pericarditis* is generally due to some infective fever; and the inflammation may result from extension of inflammation from a neighboring structure. The resulting changes are similar to inflammation in other serous membranes. These changes present themselves as acute plastic or dry pericarditis or pericarditis with a serofibrinous, hemorrhagic, or purulent effusion. Varying grades of myocardial inflammation are encountered in combination with pericarditis. The disease is characterized by slight fever, precordial distress and pain, disturbed cardiac action and circulation, dry cough and dyspnea. If the effusion becomes purulent, there will be the additional symptoms of sepsis—chills, pallor, irregular fever, sweats, marked leucocytosis. During the first stage of acute pericarditis auscultation reveals excited heart action and usually a rough to-and-fro friction sound, synchronous with the cardiac sounds, uninfluenced by respiration but often increased by pressure with the stethoscope, heard best at the fourth left interspace. Later as the effusion forms, the cardiac sounds are feeble and deep-seated, especially at the apex. As absorption progresses, the friction sound returns, being replaced shortly by the normal heart-sounds. During the effusion stage, the impulse is feeble or absent and when present is considerably displaced. The precordium may bulge. The dullness assumes a triangular shape with the apex upward and base on a line with the sixth or seventh rib. A characteristic sign is dullness in the fifth right interspace (Rotch's sign). Sometimes an area of dullness is found posteriorly below the ninth rib.—(*Cyclopedia of Medicine and Surgery*.)

2. The chief diseases of the mediastinum, are: *Inflammation*, which is characterized by dyspnea and severe pain behind the sternum. *Tumors*: almost every form has been found here, and they give cardiac symptoms, pressure symptoms, hemoptysis, neuralgic pains, cough, and dyspnea; they tend to develop inward rather than outward, so that erosion of the chest walls is rare. *Emphysema* may occur, independently of emphysema in

the neck; and *abscess* has also been found, chiefly in the anterior mediastinum.

3. **AORTIC INSUFFICIENCY.** *Causes.*—Atheroma, ulceration or rupture of the cusps. *Symptoms.*—None while compensation lasts; hypertrophy and forcible heart action follow as compensation fails, then headache, Corrigan pulse, insomnia, and precordial pain; later on, dyspnea, cyanosis, palpitation, cough, ascites and hepatic and renal disturbances are observed. *Physical signs.*—"Inspection shows that the cardiac impulse is forcible and displaced downward and to the left. The pulsation is visible far beyond the normal apex. *Palpation* confirms inspection. It may at times serve to detect a diastolic thrill over the base of the heart and the adjacent large vessels. The Corrigan's pulse and the capillary pulse are recognized by palpation. *Percussion* serves to demonstrate an increase in the area of cardiac dullness downward and to the left. Occasionally it is increased upward and to the left of the sternum as the result of hypertrophy of the left auricle. *Auscultation* reveals characteristic alterations in the heart sounds. The first sound is forcible; the second sound is replaced or associated with a churning, rushing, or blowing murmur of low pitch, well heard at the second right costal cartilage (aortic area), but most distinct at the junction of the sternum and the fourth left costal cartilage. It is diastolic in time, and is transmitted downward and toward the apex. A presystolic rumbling murmur (Flint murmur) may occasionally be heard over a limited area at the apex."—(Hughes' *Practice of Medicine*.)

4. **CHRONIC INTERSTITIAL NEPHRITIS.** *Causes.*—Often unknown; gout, alcohol, lead, over-eating, and syphilis are likely causes. *Symptoms.*—Insidious onset, dimness of vision, headache, dropsy, retinitis, choked disc, anorexia, nausea, dyspnea, itching of skin, increased arterial tension, uremia, hypertrophy of left ventricle, arteriosclerosis. The urine is increased in quantity, has low specific gravity, albumin is scanty or absent, and a few hyaline casts are generally present.

5. *Symptoms of duodenal ulcer.*—Pain in right hypochondriac region two or three hours after eating, dyspepsia, intestinal hemorrhages (which may be so severe as to cause anemia), tenderness on pressure over right hypochondrium; vomiting may be present.

6. *The symptoms of tetanus are.*—Dysphagia; stiffness of lower jaw; pain; spasms in muscles of back, abdomen, face, limbs; the jaw becomes locked; opisthotonos is present; the features become distorted; convulsions ensue. The diagnosis is made from the symptoms with history of a wound.

In *strychnine poisoning* the history is different, the symptoms develop more rapidly, and there is no early trismus.

In *hydrophobia* there is no trismus, and the history is different, and there is no opisthotonos.

In *meningitis*, the presence of Kernig's sign and of the specific microorganisms in the cerebrospinal fluid will indicate the diagnosis.

7. **ACUTE RHEUMATIC FEVER.** *Symptoms.*—"The onset is usually quite sudden, although there may have been a history of anorexia, sore throat, pains in the affected parts, or a general body "ache." The inflammatory process first attacks the larger joints, which become reddened, swollen, and excessively tender. Often the inflammation may subside quickly in one joint to attack another. The parts most often affected are the joints of the knee, elbow, shoulder, wrist, and ankle. Occasionally, however, one joint alone is involved. There is a sudden onset of high fever, 103° to 104° F., and the pulse is usually greatly accentuated. With the onset of fever acid sweats occur, and the patient may be bathed with the excretion almost constantly. The sour odor is quite characteristic. The urine, as in gout and lithemia, is high-colored, scanty, and loaded with an excess of uric acid and urates.

Complications: "Hyperpyrexia; endocarditis (very common); pericarditis; myocarditis; pneumonia; pleurisy; cerebral symptoms, as delirium, convulsions, meningitis; cutaneous symptoms—scarlatiniform rash, urticaria, purpura; rheumatic nodules; peritonitis."—(*Cyclopedia of Medicine and Surgery*.)

8. *Ascites* is a collection of serous fluid in the peritoneal cavity. The *causes* are: Portal obstruction, chronic inflammation of the peritoneum, abdominal tumors, cardiac disease, Bright's disease, chronic emphysema, anemia, cirrhosis of the liver. *Symptoms.* *etc.*: Generally of gradual onset; abdominal distention, sense of weight and fulness; dyspnea; gastrointestinal

disturbances; lineæ albicantes, presence of fluid may be detected by palpation, percussion or aspiration. If due to heart or lung disease, ascites will occur elsewhere, and the legs are generally affected first; in hepatic disorders the abdominal distention is marked and appears early; in renal disease, the abdominal fluid is generally small in amount.

9. *Tonsillar infections:* Most of the conditions popularly known as "sore throat" are due to bacteria which are normally present in the crypts of the tonsil. The chief of these microorganisms are the streptococci, staphylococci and diphtheritic bacilli. They only become virulent when the general health of the patient is lowered. Ordinary tonsillitis, follicular tonsillitis and suppurative tonsillitis (or quinsy) are the chief infections noted. In all of them there is pain on swallowing, fever (sometimes very high), rigor, malaise, and dryness of the throat.

10. *Symptoms of acute bronchopneumonia:* "Its onset is announced by a gradual rise of temperature to 102° to 103° F., the febrile phenomena assuming a typical remittent character, with rapid, laborious, and shallow breathing, as shown by the widely dilated nares and violent action of all the accessory muscles, while the insufficient distention of the lungs is shown by the great recession of the lower part of the chest-walls and sinking in of the intercostal spaces. The inspiration is short and imperfect, the expiration noisy and prolonged; the pulse is frequent, 100 to 120 or more, and somewhat compressible; the cough, which during bronchitis was loose, now becomes short, hacking, dry, and painful, soon followed by more or less copious mucopurulent expectoration; the appetite is impaired, the bowels somewhat loose, the urine scanty and high colored, and the surface frequently covered with a more or less profuse perspiration."—(Hughes' *Practice of Medicine*.)

OBSTETRICS.

1. *The local maternal changes at end of first half of pregnancy,* are: Enlargement of the abdomen, pigmentation of the linea alba, striæ over lower abdomen and thighs, purplish hue of the vagina, softening of the cervix, the vulva is swollen, the vagina is thickened, hypertrophied and congested, and the mammary glands are enlarged, hard, with prominent nipples and darkened areolæ.

2. *The patient* should receive a full bath before labor begins and all bed-clothing and personal clothing should be clean. If there are any pathological discharges from the genitals, the vagina should be thoroughly scrubbed with tincture of green soap and hot water, followed by a mercuric chloride douche (1:2000); this followed by a douche of sterile water. The physician's hands should be scrubbed for ten minutes with tincture of green soap and hot water, followed by alcohol, and immersion in mercuric chloride (1:1000). All instruments should be boiled for ten minutes or immersed in mercuric chloride 1:1000 for half an hour. Examinations should be made when necessary to determine the position, presentation, size of the fetus, etc.

During the first stage a rectal enema of soapsuds with turpentine (3i) should be given, and when the os is dilated to the size of a silver dollar, the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for three doses.

During the second stage, examinations should be made only when necessary. In multiparæ, the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the

mother's side with its face turned away from the maternal discharges.

During the third stage, 51 of fluidextract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for ten to fifteen minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and four fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied.—(*Pocket Cyclopaedia*.)

3. *Mechanism of L. O. P. position.* 1. Flexion. 2. Descent. 3. Rotation, in the majority of cases all the way round to the symphysis pubis (when, on reaching left acetabulum, it, of course, becomes converted into a L. O. A. position); in the minority of cases backward rotation of occiput to sacrum. 4. Extension of occiput downward and backward over perineum, while forehead, nose, and chin, successively escape under pubic arch. 5. Restitution, internally of shoulders, right one to pubes, left to coccyx; externally of occiput to left thigh (thigh corresponding to the sacroiliac synchondrosis at which it originally presented).—(*King's Obstetrics*.)

4. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

5. *Puerperal insanity.*—Heredity and personal predisposition, exhausting and debilitating conditions, postpartum hemorrhage, excessive lactation, intoxications, primiparity, mental distress, and septic infection are generally given as the etiological factors. The condition generally comes on early, in the first week; it is of a maniacal type, and may be suicidal or infanticidal; persistent insomnia is said to be a precursor of this insanity; when menstruation returns the condition often improves. Puerperal insanity is to be distinguished from lactational insanity; this latter generally comes on later, about the fourth month, and is apt to be of a depressed and melancholic type.

6. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Treatment:* Stop the hemorrhage by vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

Treatment before term: Rest in bed, with or without a tampon, will arrest hemorrhage for the time; the sinuses are closed by thrombi, and the case may go on to term or another hemorrhage. The patient should be allowed cold drinks; opium may be used where pain is present. If the hemorrhage is great, it is safer to induce labor at once than to wait. Occasionally no hemorrhage occurs during pregnancy, not even in labor.

7. *Indications for the use of forceps are:* "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (a) Impending exhaustion; (b) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing $3\frac{1}{4}$ to $3\frac{3}{4}$ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A. Dystocia due to (a) occipitoposterior, (b) mentoanterior face, (c) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 3. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."—(*From Jewett's Practice of Obstetrics*.)

Contraindications: Mechanical obstruction in the parturient canal; incomplete dilatation of the os; non-rupture of membranes; non-engagement of the presenting part; the fetal head being too large or too small; distended bladder or rectum.

8. (a) *Treatment of postpartum hemorrhage:* Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin, or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for

this emergency should be prepared beforehand in every labor.

(b) *Extraction of the after-coming head:* "If the arms are extended by the side of the child's head, they should be delivered first. The posterior arm is located by the position of the trunk and shoulders. To deliver the right arm, the child's ankles should be grasped with the left hand, and the body raised upward and outward over the mother's right thigh. The fingers of the right hand are passed along the posterior surface of the arm beyond the elbow. The fingers are hooked in the elbow, and traction is exerted; the forearm is then delivered by extension. The left arm is delivered in a similar manner. In the *Wiegand-Martin method* extraction of the after-coming head is effected by the insertion of the index finger of the supinated right hand into the child's mouth and making traction upon it, while pressure is exerted through the abdominal wall by the left hand. In the *Mauriceau or Veit-Smellie method*, in addition to the right hand index finger in the mouth, the left hand is also introduced into the vagina, along the back of the child, the middle finger presses against the occiput, while the remaining fingers exert traction over the clavicles. In the *Prague method* the child's ankles are grasped in the right hand, the fingers of the left are flexed over the clavicles, and traction is made. In these methods, when the perineum is distended, the child's body is raised toward the mother's abdomen. *Forceps* may be applied after the child's body has been raised and traction made in the direction of the axis of the parturient canal."—(*Pocket Cyclopaedia*.)

9. (a) *ECTOPIC GESTATION.* The *Symptoms* for the first few weeks are exactly similar to those of normal pregnancy. Later, sharp, cramp-like, periodic pain occurs and is reflected down one thigh. About the third month menstruation returns. The bleeding is profuse and attended by some pain. Flesh-like masses (decidua) are discharged. Nearly all the signs of normal pregnancy are present. Physical examination will reveal a softened cervix, an enlarged and displaced uterus, and the presence of a small cystic tumor, sensitive and adherent, on one side of the uterus. *Rupture* is attended by great pain and syncope. If the hemorrhage is intraperitoneal and extensive, death results in a few hours, attended by symptoms of profound shock; rapid, weak pulse; blanched, cold skin; sighing respiration, and fall of temperature. If the hemorrhage is extra-peritoneal, it will be limited and the symptoms of shock and bleeding will be slight. Before rupture the diagnosis is difficult, but afterward the history of early pregnancy, intense pain, syncope, and collapse will distinguish this condition.

The treatment consists of removal of the affected tube and ovary as soon as the diagnosis is made. In late extrauterine pregnancies it may be necessary, after controlling hemorrhage, to suture the sac-wall to the lower angle of the abdominal incision.—(*Pocket Cyclopaedia*.)

(b) The following tables (from *Dorland's Obstetrics*) give the main points to be looked for in a differential diagnosis of extrauterine pregnancy:

From cornual pregnancy:

EXTRAUTERINE PREGNANCY.

Rupture is most prone to take place at some period during the first three months.

The tumor exists to one or the other side of the uterus, and is usually distinct.

The tumor is exceedingly sensitive and semi-elastic.

The round ligament may be felt attached to the uterus on the inner or uterine side of the gestation sac.

Examination of the removed specimen shows an absence of true decidual tissue.

In interstitial pregnancy the gestation sac communicates with the uterine cavity by the orifice of the Fallopian tube.

CORNUAL PREGNANCY.

Rupture usually occurs between the third and sixth months.

There may be but one tumor, this being dependent upon the degree of bifurcation.

The tumor is not so sensitive and presents the characteristics of a uterine tumor.

The round ligament is displaced outward and is attached to the external side of the gestation sac.

True decidual tissue will be found surrounding the fetal membranes.

The two halves of the uterus are united by a muscular band.

From *pyosalpinx*:

EXTRAUTERINE PREGNANCY.

The uterus is enlarged, with a soft cervix and the peculiar softening of the body that is present in pregnancy.

There is a history of sterility, with the signs of endometritis or salpingitis.

The tumor is small, exceedingly sensitive, but, as a rule, not firmly bound down in the pelvic cavity.

Rupture is likely to occur at some time during the first three months.

The usual clinical manifestations of pregnancy will be present.

From intrauterine pregnancy with fibroid tumor:

EXTRAUTERINE PREGNANCY (TUBAL VARIETY).

There is discovered to one side of the uterus a mass, rounded, exceedingly sensitive, and elastic or semi-fluctuating.

The uterus is enlarged, but not to a size proportionate to the period of gestation.

The menstrual history is irregular, and there may be an early return of the show.

Rupture occurs at the usual time.

Pain is an early and prominent symptom.

PYOSALPINX WITH INDISTINCT HISTORY OF PREGNANCY.

The uterus is probably not enlarged, the cervix is not soft, and there is not the elastic feel that is present in pregnancy.

There is a history of acute attacks of peritonitis occurring at intervals after an attack of gonorrhea.

The tumor is large, moderately sensitive, firmly bound down in the pelvis, and surrounded by a mass of exuded lymph.

The history may have covered a period of months without the symptoms of rupture.

The clinical manifestations of pregnancy are absent or very indistinct.

INTRAUTERINE PREGNANCY COMPLICATED WITH FIBROID TUMOR.

The mass may be rounded; more often it is nodule-like, very hard, non-elastic and non-fluctuating, and not sensitive to the touch.

The size of the uterus corresponds to, or is even in excess of, the time of gestation.

Menstruation is likely to be suppressed.

No signs of rupture follow.

Pain develops only after the tumor has reached sufficient size to press upon the surrounding structures.

(c) The following articles should be taken by the accoucheur to a confinement. Tablets of bichloride of mercury, or some other material for making antiseptic solution; forceps; ether or chloroform, with inhaler or mask; fluidextract of ergot, hypodermic syringe, with tablets of strychnine, morphine, etc.; needles, sutures, and needle holder; nail brush and nail cleaner; umbilical scissors; carbolyzed vaseline; stethoscope; male catheter (rubber); a one per cent. solution of nitrate of silver.

10. (a) *Care of mother during puerperium*: "During the first week the patient keeps the bed, but after the first few hours she has considerable license. She may assume the sitting or half-sitting posture to take her meals and to nurse the baby, and, if necessary, for evacuation of the bladder and rectum. She should assume the lateroprone posture both right and left, several times a day, and lie upon her abdomen for at least an hour daily. Frequent change of position favors uterine drainage and massages the uterine supports. During the second week she has greater liberty, while the greater part of her time is spent on the bed or lounge. She may sit up for her meals, to urinate, and for bowel movements, and she should spend at least half an hour, twice daily, in abdominal and leg exercises to keep up her muscular tone. The third week she may be moved to a chair for a part of the day, having the liberty of the room. After sitting up for any length of time she should be instructed to take the genupectoral position before lying down. Prescribed exercises for the legs and abdominal muscles are to be taken daily. The fourth week, if all goes well, she may leave the room and have the benefits of air and sun. Physical exercises should be continued. The duration of the lying-in period and the degree of freedom to be given the patient after the second week must, however, depend

on the character and amount of the lochia, the general progress of her convalescence, and the rate of the uterine involution."—(Polak's *Obstetrics*.)

(b.) *Three most frequent causes of hyperemesis gravidarum*: Toxemia, reflex irritation, neuroses.

SURGERY.

1. *Cerebral hemorrhage*. Signs and symptoms: "The onset is usually sudden. Headache, vertigo, numbness or tingling pains in the knees may precede the attack.

Primary symptoms: The patient may fall in a convulsion or become unconscious. Hemiplegia is usually present. The face is flushed, the lips are blue, the pulse is full and slow. The eyelids are half open, and the pupils may be dilated or contracted. The respirations are snoring in character. There may be twitching of the extremities and rotation of the head, to one side. There is generally a lowering of the body-temperature, followed by a rise if the patient survives. A very rapid rise of temperature renders the prognosis grave. There are involuntary urination and defecation.

Secondary Symptoms: Restoration of consciousness and motor paralysis occur. Sensation usually remains good. The muscles of the thorax and face generally escape. The tongue, if protruded, deviates toward the affected side. There is rigidity of the muscles on the paralyzed side, and, if the damage to the brain has been extensive, aphasia, loss of memory, etc, may result.—(Pocket *Cyclopaedia*.)

2. *Tumors of the mammary gland*: Adenoid tumors are innocent and encapsuled, and characterized by—(1) spaces lined with cuboidal epithelium, which may be slit-like or distended into cysts; (2) epithelium which shows no tendency to spread beyond the basement membrane; (3) intracystic growths occasionally; (4) an interstitial structure of fibrous connective tissue.

Pure adenoma is rare, but *Fibro-adenoma* is common. It occurs in young adults as a rounded, well-defined movable tumor, which may or may not be painful. The axillary glands are not enlarged, the skin over it does not dimple, and the nipple is not retracted. On section after removal it is encapsuled, pinkish, and foliated, and does not infiltrate the surrounding tissues. Microscopically there is more fibrous tissue than is met with in normal breast.

Sarcoma is not common. It usually occurs in young women. A rounded, rapidly-growing tumor forms, which may lead to ulceration of the skin and fungation. In the early stage it can only be distinguished from fibro-adenoma by the rapidity of its growth. Secondary growths may occur in the axillary glands, or general dissemination may occur. A spurious capsule may be found in the early stage. Secondary changes may occur in the tumor, such as hemorrhages and myxomatous degeneration.

Carcinoma. *Scirrhus* commences in a lobule of the breast. The epithelial cells proliferate, and spread along the lymphatic spaces into the surrounding tissues. There is a tumor, which is usually small, stony-hard, ill-defined in outline, and incorporated in the breast substance. In the early stages the skin moves over it, but soon the suspensory ligaments which connect the breast with the skin are infiltrated and contracted, so that the skin dimples when moved over the tumor. The whole breast may be contracted, so that the nipple on that side is at a higher level than the other. If the galactophorous ducts are involved in the growth, the nipple becomes retracted as the fibrous portion contracts. In time the growth invades the skin and pectoral fascia. The skin may become the seat of a typical scirrhus ulcer, with an excavated, smooth, clean, or, if not kept clean, a sloughy base, and a raised, rampart-like edge. Or the skin may be affected with numbers of separate nodules of growth.

Cancer en cuirasse is a name given to the condition in which the skin over the whole gland and side of the chest is infiltrated. The skin then has a "pig-skin" or "orange-skin" appearance.

When the tumor is adherent to the pectoral fascia, it cannot be moved freely in the direction of the fibers of the pectoralis major with the arm outstretched.

The lymphatic glands of the axilla are early enlarged, first the set running along the border of the pectoralis minor, then the subscapular and remaining axillary sets, and next the supraclavicular glands. The disease may also spread to the mediastinal glands, or to the opposite breast and axilla by lymphatic communications.

Encephaloid cancer is much less common, but is more rapid in growth and more quickly fatal. The tumor

contains little fibrous stroma, so that it is softer, and the signs due to contraction are absent. It quickly ulcerates and disseminates.

Atrophic scirrhus is a slowly-growing form, which may last as long as fifteen years, dissemination only occurring at the end. The excessive shrinking of the stroma destroys the cancer cells. The nipple is deeply retracted, and the tumor and breast converted into a scarlike mass. (From *Aids to Surgery*.)

3. In *cholecystitis* there are pain, tenderness, and muscular rigidity over the area of the gall-bladder, also fever, rapid pulse, vomiting and leucocytosis. In *appendicitis*, the rigidity and tenderness are lower down, and the fever and leucocytosis are not so pronounced at the beginning of the disease. In *gall-stone colic*, the pain is much more severe and radiates to the right shoulder, and the fever and leucocytosis are less marked. In *gastric ulcer*, the pain is referred to the epigastrium, and it occurs daily for long periods of time and within two or three hours of taking food.

4. *Signs and symptoms of appendicitis*.—Sudden pain, generally in right iliac fossa and most frequently referred to McBurney's point; moderate fever; nausea and vomiting; constipation or diarrhea; leucocytosis; tenderness over region of appendix; the right thigh is generally flexed on the abdomen; the right rectus muscle is rigid; sometimes an indurated mass may be felt beneath McBurney's point.

5. *Tuberculosis of the kidney* is diagnosed by the symptoms, which are as follows: Pain, slight at first but severe later; tenderness on palpation; possibly colic from blocked ureter; a tumor of moderate size may be felt; urine is increased in quantity, is acid, contains pus and blood and tubercle bacilli; cystoscopy shows the orifice of the ureter red and retracted or with pointing edges; pain may be felt at neck of bladder; rise of temperature is noted in the evening, also anemia and loss of flesh; methylene blue given by hypodermic is excreted very slowly (or not at all) by the diseased kidney. In *pyelonephritis* there are no tubercle bacilli in the urine; in *renal calculus* there are no tubercle bacilli in the urine; there are present intense colic, with the pain radiating to testicle or leg; the urine is scanty; the attack ends suddenly, and the stone may be passed or become impacted in the urethra, or remain in the bladder; x-ray may demonstrate the calculus.

6. In *arthritis* the joint is distended with fluid, there is severe pain in the knee and also some swelling, the surrounding tissues are edematous, the knee is semiflexed because in that condition the patient is most comfortable; at night the muscles relax and the joint surfaces rub together, causing pain, and thus awakening the patient. In *synovitis* the knee is hot, swollen, painful, semiflexed, adhesions may form and the muscles which move the joint may atrophy; the synovial effusion causes a fluctuating swelling. *Tuberculous disease* is of slow onset, and the synovial swelling is pulpy rather than fluid; the inflammation is slight or absent, there are starting pains at night, and there may be a reaction to tuberculin. *Sprains* are characterized by prompt swelling, marked ecchymosis, and a history of violence. *Charcot's disease* is generally of rapid and painless onset, and is accompanied with the signs and symptoms of *tabes dorsalis* (generally); the synovial distention is marked; deformity is pronounced.

7. *Backward dislocation of the hip* is marked by inward rotation of the thigh, flexion, inversion, adduction, shortening of the limb, loss of function, and the great trochanter is above Nelaton's line; the head of the bone may be felt on the dorsum of the ilium, and there is a hollow over the front of the joint. In *penetrating wounds* of the joint, there may be escape of the synovial fluid, there is no deformity, and arthritis may develop. In *intracapsular fracture of femur* the limb is rotated externally and drawn upwards, but the actual shortening is very slight; the signs of dislocation are absent.

8. *Salpingitis* is marked by a dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesion; there may be an intermittent expulsion of pus accompanied by a burning pelvic pain.

The following tables are given by Dudley in his gynecology:

SALPINGITIS	CYSTIC OVARIAN TUMOR
1. Commonly bilateral. 2. Tube oblong and tortuous. 3. Commonly adherent. 4. Ovary often palpated and distinguished. 5. Usually not larger than fist. 6. May be leucocytosis.	1. Commonly unilateral. 2. Spheroidal or spherical. 3. Less commonly adherent. 4. Tumor is diseased ovary. 5. May grow to enormous size. 6. No leucocytosis.
SALPINGITIS	SOLID TUMOR OF TUBE
1. Common. 2. Usually bilateral. 3. Sensitive to pressure. 4. Usually fixed. 5. Elastic or fluctuating. 6. Result of infection.	1. Rare. 2. Usually unilateral. 3. Not sensitive. 4. Usually free and mobile. 5. Firm consistence. 6. Cause unknown.
SALPINGITIS	PELVIC CELLULITIS
1. Usually sharply circumscribed and of rounded contour. 2. Commonly bilateral. 3. Position relative to uterus: mass usually higher in pelvis near fundus uteri; not connected with cervix. Vaginal vault not depressed.	1. Not sharply circumscribed; may be flattened. 2. Commonly unilateral. 3. Position relative to uterus, usually lower in pelvis, often closely connected with uterus. Vaginal vault commonly depressed.
SALPINGITIS	TUBAL PREGNANCY
1. Mass usually elastic; may fluctuate. 2. Adhesions common. 3. Sensitive to pressure. 4. Uterine end of tube enlarged. 5. History of infection.	1. Consistence often quite firm. 2. Less common. 3. Not sensitive. 4. Commonly normal except interstitial tubal pregnancy. 5. History of pregnancy.
SALPINGITIS (RIGHT SIDE)	APPENDICITIS
1. Tumor felt by vaginal touch. 2. After acute stage, size of tumor may not materially diminish. 3. Recurrence less dangerous and less frequent. 4. More frequently of gonorrheal or tubercular origin.	1. Tumor not usually within reach of vaginal touch, but felt or is tender to pressure on external palpation in region of McBurney's point. 2. After acute stage, tumor apt to disappear. 3. Recurrence more dangerous and more frequent. 4. More frequently due to colon bacillus, less frequently of tubercular origin; never gonorrheal unless by extension from tube.

9. *Bursitis* is inflammation of a bursa. The *acute* form is generally the result of traumatism. The symptoms are a fluctuating swelling which is circumscribed, painful and tender; sometimes crepitus may be elicited. The *chronic* form may follow the acute, or may be due to syphilis, tuberculosis or irritation. The bursa is enlarged and thickened; in tuberculous cases the swelling is doughy rather than fluid.

Synovitis is inflammation of the synovial membrane of a joint, the other structures being unaffected. The joint is distended, swollen, hot, painful, tender; fluctuation is present, and the joint is generally semiflexed; constitutional symptoms may be present. In the chronic form motion is restricted and atrophy of surrounding muscles ensues.

Tuberculous meningitis is "an inflammation of the soft intracranial membranes due to the deposit of gray miliary tubercles. It is usually secondary to tuberculosis elsewhere, and is seen most often in children. The onset is usually attended with various prodromes, such as irritability, anorexia, headache, insomnia, etc. The stage of excitation is characterized by headache, vomiting, convulsions, intermittent temperature, soft, irregular, and compressible pulse, and a red line upon drawing the finger-nail over the skin. This stage lasts for about two weeks and is followed by depression, in which the pulse is slow and compressible, temperature is depressed, and somnolence and stupor alternating with delirium, convulsions, headache, and peculiar shrieking are present. Collapse, coma, convulsions follow, and death usually occurs in from 1 day to 2 weeks. Treatment is unsatisfactory."—(*Pocket Cyclopedic*.)

10. *Exophthalmic goiter*.—The symptoms are tachycardia, exophthalmos, goiter, tremor, insomnia, palpitation of heart, headache, irritability; the eyelids do not completely cover the eyeball, when the eyeball is rolled downwards the upper eyelid is unable to follow it; winking is frequent; the interpalpebral fissure is widened; dyspnea, digestive disturbances, and pigmentation have also been observed.

PUBLIC HEALTH AND THE DEFECTIVE.*

BY MARY SUTTON MACY, M.D.,
NEW YORK
NEUROLOGIST, DEMILT DISPENSARY

SIR GEORGE NEWMAN of London, in one of his recent reports as chief medical officer of the Board of Education, says: "A national scheme of child welfare, . . . including medical inspection, medical care and treatment, and physical education, . . . needs time for its development, and cannot rightly claim to be judged by any other result than the growth of a strong and healthy race of children. For the existence and strength of a nation ultimately depends upon the survival of its children and their physical and mental health."

Systematic medical examination of school-going children has revealed an immense amount of physical defect. The English figures, which I am going to quote just now, have to my mind a bearing of greater general value than many of our American figures, for the reason that the English statistics are compiled from data gathered from urban and rural communities, whereas, most of our American statistics, in fact, all of a generalized character that I have seen have been almost without exception either entirely urban or entirely rural, and therefore for general purposes open to some criticism. The English figures are approximately: Defects of vision, 10 per cent.; defects of hearing, 5 per cent.; ear disease, 3 per cent.; tuberculosis, 2.5 per cent.; malnutrition, 10 per cent.; mental defect, 1.5 to 2.5 per cent.

These figures do not, as far as I can ascertain, include all the blind or all the totally deaf, who in many cases are not in the schools at all, and which form in one sense separate educational problems, though not necessarily distinct public health problems. Neither are these figures inclusive of all the cripples, but only those crippled by tuberculosis.

America is awakening to her responsibility and to the urgent need of her children. Here in New York we have been awake for some time, but our problem has been complicated in large measure by the lethargy of the communities about us, both proximal and remote. We, as a nation, are only beginning to understand that defectiveness of every form must be reduced to a minimum, and that all varieties of preventable disorder must be dealt with by effective agencies. "Safety first!" is a new slogan, and, within limits, an excellent one; multiplied four-fold in its value, if we ally with it two other slogans—one almost as new, the other a little

newer—I mean "Conservation" and "Preparedness."

In this connection it speedily becomes evident that medical science as it concerns and is connected up with educational authority, has a two-fold duty; (1) The control and improvement of all school conditions reacting on the child; and (2) the cure or alleviation of certain well-defined personal ailments, disabilities or maladies, which, tending to incapacitate the child, render him unable to take full advantage of the education provided, or which become, by neglect or lack of supervision, sufficiently widespread to constitute a menace to the physical welfare of the community.

The term defectives, as I shall have occasion to use it, is a very comprehensive one, including, as it must, not only the mentally and morally defective children in the schools or recently out of them, but also the blind, the deaf, the cripple, the generally physical incompetent, child and adult, in relation to the problems of public health and its conservation by means of preparedness and safety first methods.

In the first field of duty which I have suggested for medical science, namely, "the control and improvement of all school conditions reacting on the child," our New York City schools have made opportunity for tremendous strides; far ahead in most respects of other parts of the country. The creation of a department of school hygiene in connection with the department of physical education, under the Board of Education, is theoretically at least a long step in advance looking toward control of this character. It is premature to estimate how this department is to work in practice, as it has been in existence but a short time, and like many other educational activities—or activities of the Board of Education—it has been much hampered by the curtailment of funds. Of this I can have nothing further to say at present.

In the other field of medical duty I mentioned, namely the cure or alleviation of certain well-defined personal ailments, disabilities, and maladies, which, tending to incapacitate the child, render him unable to take full advantage of the education provided, or which become sufficiently widespread to constitute a menace to the physical welfare of the community. New York City has occasion to preen herself upon her magnificent showing in this line of effort. The stupendous work of the Child Hygiene Department of the Board of Health is familiar to you all; it is a source of civic pride to every good New Yorker, and needs no comment or elucidation from me. The equally important and stupendous work of the departments of the Board of Education which have to do with the defective children is another matter. It is a field of medical endeavor less well known than the child hygiene work of the Board of Health for several good and sufficient reasons, first, perhaps, because largely—not entirely—under the supervision of lay directors, the medi-

*A lecture delivered before candidates for a post-graduate (D. P. H.) degree at New York University and Bellevue Medical College, Feb. 10, 1916.

cal work has taken an apparently somewhat subordinate place to the educational work, and second, because the number of medical workers having been very small and the amount of work very large, there has been little or no time—and less strength—left for talking or writing about what they were doing. Of this field of endeavor I may have a little more to say in another lecture, but I have no intention of narrowing the subject to our municipal problems. The defectives are a national problem, may become a national menace, and must be studied and handled on broad nationalized lines, and not narrowed to urban or rural or urban and rural foci.

The guiding principle for conservation and preparedness in the handling of this problem of defectives should be correlation, and the lines along which such action should proceed should be first, prevention, and, second, treatment and remedial measures when, despite precautions, defectiveness appears. If it were possible to make the educational authority responsible for children from birth until they leave school, it would, by making it possible to supervise more closely the health and treatment of the children, make for efficiency and prevent the present hiatus from birth to five or six, and also prevent much overlapping of functions.

The doctor of public health, or whatever title the hygienist of the near future may come to bear, will undoubtedly derive much help from the present-day efforts at segregation, not only of the mentally, but also of the physically unfit, but, if he is to be worth his salt, his main preventive efforts must be directed upon infancy and the early years of life before school control makes segregation possible, and while prevention of the many ills that childhood is heir to is still possible. The questions of infant foods, of housing, of domestic economy and domestic hygiene all have as vital and intimate bearing on the prevention of defectiveness as they have on the prevention of infant mortality, of measles and kindred contagious affections, and of malnutrition *per se*. Dr. Hope, health officer of Liverpool, England, has rightly said, "If the child of school age is found to be underfed, the local educational authority has now power to feed it, but its younger brothers and sisters may be, and commonly are, in just as bad a condition. . . . Classes for mothers dealing with all matters relating to the home should be encouraged and organized, and parental ignorance or indifference, the cause of much unnecessary child suffering, combated. The various organizations dealing with this matter should be linked up with the medical officer of health—and with the school medical officer, too, where these posts are not held by the same officer—and these officers should be ex-officio members of the committees of these organizations."

Beside these general health problems, such as food, housing, etc., and their bearing on the production of defectiveness, the public hygienist of the near future must, among other things, give more attention to the prevention of rachitis or to the prevention of avoidable rachitic deformity once rachitis is acquired. Rickets, as we know, becomes manifest, in a great majority of cases, between the ages of six months and two years. Comby, in his study of 1662 rachitic children, found that 89 per cent. gave evidence of the disease before the second year. Measles is a common starting point for rickets—that is to say, an acute illness, such as measles, may initiate an attack of rachitis or, in later childhood, cause a recrudescence; and the deformities may

appear at any age up to puberty. Kossowitz, in studying rickets in Vienna showed that, though children of all classes of society were liable to rickets in mild or severe form, the more serious deformities were confined to the children of the poor. Kissel, in Moscow, states that deformities are much less severe among the better class children, though rickets prevails equally in all classes. Clement Dukes, at the II International Congress of School Hygiene in London, in 1907, showed the extent of preventable deformities—many of them rachitic—found in boys examined for admission to Rugby School. His figures indicate serious inattention to hygienic principles in the upbringing of children which permits them to reach the age of fourteen showing 44.5 per cent. lateral curvature of spine, 12.6 per cent. pigeon breast, 6.4 per cent. bow-legs, 52.6 per cent. knock-knees, 32.9 per cent. flat feet.

Broadly speaking, rickets is confined to the countries of Central Europe and the United States of America, though even within these limits the plains and high altitudes are exempt. In general its incidence is proportional to the density of the population, and there is a notable concentration of the disease in the large cities, particularly in the congested industrial areas, though it would appear that the various racial elements composing the same town population are affected in varying degrees. Our American population does not suffer to nearly the same extent as do the immigrant races, in particular the Italians and negroes.

All marked deformities, wherever situated, involve serious physical disability. The consequences are specially serious when chest and female pelvis are involved. Rickets is responsible for the physical disablement in 50 per cent. of the children (of whom there are about 750) attending the special schools of the Glasgow School Board for physically defective children. Into these special schools are received only such children as are physically incapable, owing to the severity or nature of their deformities, of making the journey to the ordinary elementary school. In 1911 a census was made in Birmingham, England, by a special sub-committee of the educational authority, of the crippled children and adults: 717 under 16 years of age were found in the city and 11 under the care of the Poor Law Guardians; of these 728, rickets was responsible for 10.1 per cent. of the cripples. The age group above 16 years, numbering 828 cases, showed rickets as a cause in 0.8 per cent. of the cases.

In 1906 an official census was taken of all the crippled children of the elementary school class in Germany. This census disclosed the fact that Germany numbered at least 100,000 cripples under 14 years of age, or 14.8 per 10,000. Of these 100,000 children 56,000 were considered by the medical experts to be cases calling for institutional care, and of these 56,000 crippled children 15,000 suffered also from nervous disorders, 11,000 from tuberculosis, 11,000 were rachitic, 37,000 were epileptic, 344 were deaf and 226 were blind; 97 per cent. of all the crippled children, *i.e.* of the 100,000, were mentally normal. The following definition of a "suitable institution case" (*heimbedürftig*) has been officially recognized: "A crippled child is in need of institutional care when, in consequence of a congenital or acquired nerve, bone, or joint disease, he is hampered in the natural use of his limbs to such an extent that his physical disabilities bring him into total disharmony with his environment; and when

his removal to an appropriate institution offers the only chance of so training and developing his remaining faculties as to procure for him the best possible conditions of health and independence, the institution in question being specially adapted to deal with his individual physical and educational requirements."

The first institution for the schooling and technical training of cripples was established in Munich in 1832. England followed in 1851 and Sweden in 1890. The chief object is to make them self supporting, or partially so, that they may not be a burden on their families or on the community. There are three primary objects in view in the institutional care of these cases: first, orthopedic treatment; second, common school education, and third, and most important to the community is the special industrial training which makes the crippled boys or girls partly or wholly self-supporting. By self-supporting one does not mean supported by the patronage of charitable people, but that the cripple should be so trained that he—or she—may take an independent position in the community. For many of the more seriously deformed and many of the genuinely tuberculous cripples this ideal aim is of course not possible, and for them the only solution is apparently the home or institution, under philanthropic or, better, State control, where necessary provisions for them can be made and where trades adapted to their special needs may be pursued. The famous school at Copenhagen, Denmark, had to resort to this system, and, like others which have tried it, proved the plan to be more than self-supporting, leaving a profit toward the original expenditure even after the wages of the workers have been paid.

In securing ultimate results it is, of course, essential to find for each individual cripple some occupation wherein he has a reasonable chance for successful competition with physically normal workers. In seeking trades in which cripples are to be instructed the object, naturally, is to find those which require the use of such members as are not deformed or incapacitated. The fighting countries of Europe are presented with those problems in gigantic scale, by the immense number of war cripples which their hospitals are turning out into the community. The problem of training crippled children is in some ways more complex, in some ways less so. Many occupations have been tried and instruction in them given to crippled children and the social phase of this work is of great importance. When the crippled child is first encountered he is usually in a thoroughly discouraged state. His helplessness has, intentionally or unintentionally, been impressed upon him from his earliest childhood and he is, more or less, imbued with the idea that his life must be a useless one, as he has been in the past, and probably will be in the future, unable to spend his time in anything but idleness. It is not hard to conceive the mental effect of such an existence, and the first aim in the social care should be to counteract this attitude.

The easiest solution for industrial training has come in the form of needlework for the girls. Most of the crippling deformities—in other than war cripples—appear to affect the lower limbs, leaving the hands and arms in large measure free, and even in cases where one arm or hand is incapacitated some form of rack can be arranged to hold an embroidery frame, and many girls cultivate an astonishing dexterity. For girls who are not too deformed, stenography and bookkeeping offer attractive and well-paid

occupations, and the position of librarian, offering, as it does, work usually done in conjunction with others or independent of active direction, is both pleasant and profitable. For boys there appears to be even a wider choice of trades depending, of course, upon local conditions and individual abilities, and as the handicap for the cripple usually comes in physical ability, special emphasis should be placed on mental work. Thus for example, proof-reading, telegraphy, both the wireless and wire forms, telephone switchboard operating—this is even practical for the girls as well—typographic work, especially where type composition machines are in use, reed and willow furniture work, basket making, chair caning, rush seating, mattress and general upholstering, cabinet making and repair work, copper and silver smithing, mechanical drawing, mosaic art glass work, engraving in its various branches (including brass and steel die work, wood cuts and jewelry engraving), cobbling and tailoring, jewelry making and watch and clock repairing, as clerks and as ticket-sellers, and newsdealers with public service corporations, in theaters and similar businesses.

The general aim in dealing with the cripple is, as we have said, to make his attitude and his position as nearly normal as possible. When the crippled child goes from under the care of the organization that educates him his aim is to become independent. To do this as an adult, he must, as a child, come constantly in contact with people who are not cripples and he must meet them on their own ground and in their own way. The future should always be considered in the care and education of such a child, and to retain the best type of self respect he must make his way on his own merits. Every effort, therefore, should be made to inspire self-confidence in the crippled child; as a matter of fact cripples can do more than most people suppose, and the child should not be treated as an invalid any more than is absolutely necessary; he should be given opportunity and encouraged to do all that his abilities will permit. In short, what the crippled child needs is normal training plus the special aid necessary to offset the handicaps imposed by his deformity. One of our State institutions for crippled children has a baseball team, which plays a remarkable game of ball, especially so if one considers the deformities of the players; whenever it wins, as it does in the majority of its games with the neighboring teams, all the children in the institution, whether ball-players or not, are jubilant, and such healthy interest, together with the pride in the prowess of their fellows, has a most wholesome influence and gives a very concrete form of encouragement.

The provision for crippled children in the United States is very irregular; some localities have many institutions, some have none. New York State, Minnesota, and Massachusetts have each established State institutions for crippled children. There is need for such institutions in every State, particularly for the crippled children from rural districts. From a national standpoint, however, the situation is at present unsatisfactory at best, as most if not all of the existing institutions and schools are grouped around four or five cities. The most serious national defect is in the number and extent of the immense sections, especially of the West and South, that are without provision of any kind. It is of utmost importance that some adjustment should be made, as there are in these sections large numbers of crippled children whose needs demand at-

tention in a most urgent manner, and a little judicial prodding and influence exerted upon the Legislatures might produce the required State provision.

In an article on "Trade Training for Adult Cripples," appearing in the *American Journal of Care for Cripples*, 1914, Dr. Charles H. Jaeger says: "In considering the problem of trade training for cripples, we must first classify them in groups according to the nature of their disability and then state the problem as it relates to each group.

"1. The Congenital Cripples.—Those born with some malformation not amenable to medical or surgical treatment, who must go through life with a physical handicap.

"2. The Cripples from Disease, of which there are two kinds, (a) those who are suffering from some constitutional disease like tuberculosis, which makes the patient, in addition to his diseased condition, weak and incapable, and (b) those who are left crippled by some disease like infantile paralysis or hemiplegia, which leaves them more or less badly disabled but which has no influence on their physical well being.

"3. The Cripples from Accident (the various amputations).—Again we have two classes those crippled in childhood, thus subjected to all the unfavorable influences surrounding the diseased crippled child, and the second class, those crippled by accident in later life. . . . It is the last class which is a very important class, firstly, because of the very large number of people maimed in this country in the pursuit of their daily occupations, and secondly, because we have here a group of people who have had a normal youth, who have acquired no mental kinks and who have been trained to some occupation or trade. . . . Assistance to persons of this type is imperative, as they are the ones psychically most affected by their accident. They easily become depressed, and their long convalescence induces habits of idleness."

From our point of view these three classes mentioned by Dr. Jaeger are of interest both on the safety first and the conservation principles. With regard to the congenital cripples, there is comparatively little that we can do for them after birth, except have organized a general correlation between lying-in hospitals, midwives, and doctors engaged in obstetrical work among the poor and the various orthopedic hospitals and dispensaries, so that there may be a minimum amount of deformity permitted to develop among the congenitally physically unfit. One preventive measure calculated to minimize this congenital deformity, which is or should be within the control of the hygienist of the future is control of the antenatal influences which are conducive to such deformities. In a very interesting little monograph on Child Life and Labor, Dr. Margaret Alden of London has said: "Antenatal influences may be thus classified: (a) Factory labor: When injurious to the health of the expectant mother. (b) Various poisons: Acting through the mother on the child, viz., the poisons of certain diseases, certain drugs, and above all, alcohol.

"(a) Factory Labor when Injurious to the Health of the Expectant Mother. Physical work in itself need not prove injurious either to the mother or the child. It is only when such work is especially arduous, and carried on for long hours under unfavorable conditions that it becomes a danger. . . . Factory labor on the part of a mother acts injuriously on the child in two ways: (1) It brings

into the world immature infants, who are unable to withstand the exigencies of life. The returns of the Registrar-General show that the death rates of infants from immaturity increases year by year, till now some 30 per cent. of the total infant deaths are due to this cause. (2) It induces deformities among infants which largely diminish their chances of life. This point has been clearly brought out by Dr. George Reid, Medical Officer of Health for Staffordshire. He compares the North Staffordshire manufacturing towns, where many married women are engaged in factory work, with the South Staffordshire manufacturing towns, where practically no women are engaged, and so far as abnormalities and still births are concerned, he gets the following results:

	Abnormalities	Still Births
North Staffordshire	15.0	9.4
South Staffordshire	6.0	3.2

"A mass of evidence proves without doubt that among the antenatal causes of infant mortality factory labor of the mothers plays the largest part, and yet we have no legislation which can prevent a woman from doing factory work even up to the very hour of childbirth. The law of England does not contain one clause to protect the mothers of her future citizens in this respect. To use a phrase of Mr. Chiozza Money's, 'The Factory Act is not aware that pregnancy precedes childbirth.'

"(b) Various Poisons Acting through the Mother on the Child." These have more relation to mental than to physical crippling and cannot be considered here just now.

So much for the suggestion we in America may get from our English cousins! While our immediate laws may be better, or worse, than Dr. Alden claims for England, dependent, of course upon what State of the Union we are called on to do our Public Health work in, the situation remains that the prevention of infant mortality and the prevention of infant deformity or congenital physical incapacity are very closely linked up one with the other. Having studied the problem as presented in our individual sphere of work, it becomes our duty to exhaust preventive measures, then to turn our attention, as hygienists, to the alleviation of such deformity as we have been unable to prevent. On the manner of meeting this point we shall have more to say later.

Dr. Jaeger's second class of cripples, i.e. those from diseases, presents even a more acute public health problem. He mentions two subtypes: (a) those from such constitutional diseases as tuberculosis, and (b) those from such diseases as infantile paralysis and hemiplegia. Both types offer problems linked up with disease prevention, and, both may be considered as preventable classes of deformity. It has already been suggested here that a large part of the future work should be directed to the pre-school years in the prevention of rickets, and to this should be added tuberculosis, meningitis, anterior poliomyelitis and similar contagious conditions under Board of Health supervision and control. The work of the contagious disease divisions should not stop at diagnosis, isolation, and quarantine of the sufferer from such contagious conditions; there should be some provision for follow up work, which will protect the child from the crippling sequelæ, or at least see that means and opportunity are provided to minimize the disability by adequate and prompt medical and surgical provision. Here, too, presents the problem of adequate

provision for those whose deformities we are unable to obviate, when we have exhausted all measures of prevention, and this problem should be faced in early childhood and not first approached when the child is already well into the school age, or perhaps beyond it, as is still too often, unfortunately, the case. This problem we will consider in a few minutes.

Take now the third class, the cripples from accident, whether they are adult or child, and we find other public health problems connected up with them in amazing number. Consider only a few of the causes for these accidental crippling and the vista which opens gives one a sensation of individual helplessness, though I trust not one of hopelessness. Safety first! becomes a very emphatic element here. The prevention of accident in congested streets, the control of traffic, regulation of overcrowding of vehicles of public transportation, of buildings, of elevators, and so on ad libitum; the control and regulation of safety devices in factory, mine and shop; the grading of streets and roads with reference to railway crossings, and the maintenance of clear right of way through suburban and through congested urban districts where railway tracks are not enclosed or tunnelled. These and innumerable other problems of similar character suggest themselves to the thoughtful student who aims to promote the control of preventable deformity, and are too complex for us to do more than suggest them here. This accidental crippling of children presents the same type of problem offered by the congenital and the disease class, and is amenable to the same types of solution, if its prevention has proved impossible. For the adult of this accidental group the problem is different, and, as Dr. Jaeger says, "To save a man of this group from pauperism is not only more satisfactory but is of more economic importance. Well-intentioned but ill-advised friends and relations coddle the patient. He is cared for and supported until he has lost his ambition to work. In his idle hours he seeks solace and companionship in the saloon. This environment still further aids in the moral decline. It is an easy step to beg for the money thus needed, and when he once finds out how profitable this is, he loses his desire for work.

"The cripple who can get about easily, for whom the problem of going to and returning from work does not exist, and whose appearance is not objectionable, can easily take care of himself. We have, however, a large class, comprising the victims of severe infantile paralysis, who are confined to a wheel chair, and the spastic paraplegiacs. These manifestly cannot hope for employment in large shops. They belong to the "shut-ins" who must work at home and seek their market outside at some exchange or among private customers. The shut-in cripple needs guidance, particularly in the choice of articles he puts on the market, as well as in discrimination as to design. By offering well designed articles of intrinsic value, the purchasing public, which has hitherto been confined to a few wealthy individuals impelled to buy from charitable motives, will be augmented by the public at large."

Thus it becomes evident that a system of trade instruction, instituted during the patient's convalescence from the accident, with a view to providing a lucrative occupation adapted to the limitations imposed by the acquired deformity, solves at once two difficulties which beset this class of accidental adult cripple; he is prevented from acquiring a

morbid mental and degenerative moral attitude, and he is provided with a substitute gainful occupation or trade adapted to his individual physical limitations. This is the problem of the war-cripple, and our future public health officers in peaceful America may gain much practical and beneficial information by observation of the methods employed in warring Europe to meet and solve the emergency; our field is limited in contrast, but the problem is the same in effect.

To return now to the problem of the crippled child, be it the unavoidable deformity of congenital, disease, or accidental origin, we face the same situation. Two solutions are possible: (1) Institutional care and training, or (2) Home care and day-school training.

The first offers many advantages in that it makes possible the early segregation of the child, and therefore the possibility of avoiding a mental kink due to his early environment and training in idleness and incapacity, and also because it places the child at once where adequate medical and surgical care can minimize to the utmost the extent of his deformity, or the ravages of his disease, or both, but it is open to the very forceful objection that it removes the child from the influences of family life and shifts the parental responsibility, which is always detrimental socially and ethically.

The second solution, *i.e.* home care and day school-training, offers also some advantages and some disadvantages. First, and perhaps most important of the objections, it offers that hiatus from public control between birth and school age, which encourages two very serious results, (a) the development of the mental attitude of helplessness which is so hard to combat in all cripples of school age or older, who have had no occupation but watching their physically able brothers and sisters go out to their daily school or play occupations and live a normal healthful life, and who have consequently acquired a habit of thinking "I am different and useless;" and (b) the development of their disease, or the progressive incapacity induced by the actual physical deformity. Parents are apt to sympathize unduly with the affliction and to underestimate the mental powers of their crippled children, and consequently apt to neglect to give them the necessary preparation for a useful life. These poor, neglected children, if not spoiled by overindulgence or schooled in depravity, are those who best prove that with a little care and effort expended along right lines, the problem of the cripple can be solved. As a matter of fact, however, all too frequently the indulgence of elders during the childhood of the cripples has developed the attitude that the world owes them a living, and not having been inspired with hope or ideals, they readily take to mendicancy or criminality. The manifold incapacities, with their attendant limitations, result in unusual brain process. "We have," says Dr. Jaeger, "those who are precocious, having been reared amongst adults and deprived of the companionship of children of their own age. We have those who have been unduly spoiled because of their affliction supplemented by an appealing child's countenance. We have those whose sauciness was mistaken for cuteness and who have developed into adults of rare impudence in speech and an aggressive attitude toward others. Most cripples are sensitive to an abnormal degree, rendering it difficult to deal with them, as they take offense where none is intended. For this reason they will give up a position, leaving behind them an

impression of disloyalty and ingratitude. As they have rarely had mental training—especially with the view of becoming self-supporting—their schooling has been at least haphazard, so that they have acquired neither concentration nor discipline. For this reason many cripples, after having become proficient in a trade, take up the desultory life of begging and tramping in preference to following their regular occupation. There is also a large class of undeveloped cripples and I cannot emphasize too strongly that work with this type offers the best opportunity for successful results."

In addition to proper surgical and medical care, what the cripple most needs is help to offset or counterbalance the peculiar limitations set upon him by his deformity, and he should be afforded educational advantages fully as advantageous as those offered to the normal child who is his contemporary. For the normal person education is desirable, for the cripple it is necessary, else he becomes a charge upon the State, which is not only uneconomical for the State but also bad for the cripple. An estimate made by Dr. H. W. Orr would show that there are approximately 3,500 cripples to the million inhabitants, or about 3.5 per cent. of the population, and it has been estimated that there are 30,000 cripples in New York City alone. With such numbers of crippled in the country, and especially in cities, who would profit by care in the day schools, it becomes an acute problem as to how the educational facilities are best to be provided while the children are still at a receptive age.

Universally very little has been done along this line, though England has developed a splendid system of day schools for crippled children in conjunction with the organized public school; and New York City has provided some day schools under both State and private auspices; Chicago maintains some classes in the public schools, and Boston has an excellent industrial day school under private management.

Writing in 1910 of Primary Education for Crippled Children, Mr. D. C. McMurtrie says: "For crippled children attending such schools it is necessary to provide in addition to the instruction at the school daily transportation from the homes and nursing supervision over the children's physical condition. . . . In cases where the children are moved daily from place to place, it remains largely a matter of judgment as to whether the clinical work shall be done in the schools or elsewhere, as at hospitals or dispensaries. In view of the fact that removing such work from the schools makes the educational system more normal for the children, this would seem the more advisable course. Where possible it is well to leave as much of the responsibility as possible with the family—where it belongs. If the family can be trained so as to fulfil this, then the most permanent results are attained. The relations of the child to his parents remain natural, and as such they function in the healthiest manner. The home situation is not strained and no unpleasant readjustments are necessary. . . . Such a policy would give him (the crippled child) his education through ordinary means, and as a right, not a charity. It would also make for a more thorough and healthy mental growth and development."

Given the primary education in this manner, the cripple must then be afforded opportunity to fit himself for some particular niche in life, and this appears best accomplished by trade schools and trade

classes for cripples in the organization of the public school system. It is important to select trades adapted to the individual and that are not already overmanned by good workers. After the training is received the question as to the possibilities of obtaining employment is to be faced. Working papers are no guarantee of employment. For various reasons many manufacturers will not employ badly crippled workers at all, and in other cases, only if the workers' skill is most unusual. The new factor of compulsory industrial insurance is also working against the employment of the crippled, because, it is presumed that he is less able to guard himself against injury and therefore accident, insurance companies will not issue a policy to a factory employing crippled men.

All these factors, and many others, work together to render the state institution the most desirable place, and the achievements of other countries illustrate how best to deal with the question. In England governmental orders are executed in custom tailoring for the army and navy by institutions which teach the trade to and employ and provide for cripples. Cripple institutions in Germany buy from and sell various supplies to other governmental institutions, thus carrying out the cooperative idea. In Russia trade classes in a Petrograd hospital make orthopedic braces, which serves the double purpose of teaching the trade and providing at a minimum cost the braces needed for cripples of the poorer or indigent classes.

The type of such institution is most important. To begin with, it should be located in the country, sufficiently close to some city to afford a market for its manufactures, it should be a combination of school, hospital, trade school, shop, and farm, built and managed on the cottage plan system, sufficiently self-centered to provide much of its own produce, and pay reasonable, market wages to such inmates as are capable of doing the various types of work and still, from its shops, afford sufficient income to pay all expenses and some interest on the original investment. There should be a competent orthopedic surgeon resident, to have charge of the hospitals and direct the treatment of the various cases, and a thoroughly competent teaching force, both academic and trade, to have supervision of the educational work, but the largest proportion of workers should be recruited from the crippled inmates themselves.

Turning from the physically crippled child whom we have stated needs a normal child's education plus special aid to overcome his handicap, we come to another form of defectiveness to which the same statement of needs will apply with only a little variation of meaning. The deaf child is not different in general organization or mental character from the normal child, except in the one respect, that he has never heard. This, of course, means that without special training he cannot speak, and that he is apt to be somewhat behind the normal child of his years, because the fact that during the first five years of his life—the years of rapid language formation—he has had no language except the very limited language of natural signs, and that, therefore, the normal education of those first formative five years is lost to him to such an extent that at eighteen years he is usually in a position similar to a hearing child of fourteen years.

Every deaf child, otherwise normal physically and mentally, can be taught to speak and to understand when spoken to and can, therefore, also be given as

good an education by the speech-method, without the use of any form of manual communication, as if it were not deaf. Every deaf adult, possessing moderately good sight and an average alertness of mind, can learn to supplement imperfect hearing by training the mind to associate ideas with visual impressions so that much of the strain and inconvenience of impaired hearing can be removed and obviated. While it is far better to begin the training of speech as early as five years—or earlier, if the intelligence of the family is sufficient to carry out the early instruction—nevertheless it is possible, especially where a pupil is anxious to learn, to teach a person of good intellect to speak who has never spoken a word up to eighteen or twenty years of age.

From the very valuable Special Report relating to the Blind and Deaf compiled from data obtained in the Twelfth Census of the United States, I have culled the following statistics and points which I felt to be of value to us in this discussion of the deaf.

“The age when deafness occurred is definitely stated in 81,590 cases, and of these 59 per cent. became deaf before reaching the age of 20 years, 48 per cent. became deaf before reaching the age of 10 years, 40 per cent. became deaf before reaching the age of 5 years, and 17 per cent. were born deaf. In the Twelfth Census 89,287 persons were returned as deaf, and in 10,115 cases the causes of deafness were unknown. In the remaining 79,172 cases the supposed causes were specified. In many cases, however, the assigned causes are vague and unsatisfactory. To these may be added the curious and fanciful causes of deafness sometimes assigned in individual cases. No less than 1,514 cases of this character were reported. Such causes as these—even if they are connected with the production of the deafness, which is often doubtful—are very remote causes indeed. Scarlet fever and other diseases, usually accepted as legitimate causes of deafness, belong to this same class, for they only act indirectly through intermediate agencies.”

Scarlet fever may be the proximate cause of an abscess in the middle ear; the suppurative process in the middle ear may cause serious injury and even total destruction of necessary parts of the delicate machinery of the ear; and the injury to the ear may thus cause deafness. There are many other diseases, however, that produce a similar injury to the ear and in a similar manner. For example, measles, influenza, diphtheria, pneumonia, erysipelas, smallpox, tonsillitis, bronchitis, etc. In this special report, therefore, all these diseases were grouped together and the deafness attributed to “a suppurative affection of the middle ear.”

It appears that among the classified cases the principal assigned causes were:

Scarlet fever	7,474
Disease of ear	4,210
Measles	2,469
Influenza	1,776
Catarrh	11,792
Colds	8,074
Malarial fever and quinine	6,406
Meningitis	2,001
Brain fever	2,013
Typhoid fever	2,055
Minor causes	40,350
Aggregate classified	79,172

Malarial fever is given as a cause of deafness in some cases, and quinine in others. In large doses quinine is known to affect the hearing; but it is doubtful whether malarial fever, without quinine,

produces deafness. The best disposition of these causes seemed to be to group them together and attribute the deafness to an affection of the internal ear, for quinine is known to have a specific effect upon the labyrinth. Meningitis included all persons returned as deaf from cerebrospinal meningitis, meningitis (simply), or spotted fever. It is probable that brain fever is the same thing under another name; but the number of cases returned under this head seemed to be sufficiently large to justify the retention of brain fever as a specific cause. Catarrh and colds probably constitute one and the same disease; but the number of cases of deafness due to colds seemed to be large enough to demand separate recognition.

Among the assigned cause of deafness in the classified cases, the following are specially predominant: Catarrh and colds, 14,776; scarlet fever, 7,424; meningitis and brain fever, 6,004. These three causes alone include the majority of the classified cases (58.8 per cent.).

It appears that among the unclassified cases the principal assigned causes are:

Congenital	14,472
Old age	3,361
Military service	3,242
Falls and blows	2,243
Sickness	2,143
Fever	1,436
Hereditary	900
Minor causes	27,806
Aggregate unclassified	3,399
	1,205

First in importance and overshadowing all of the others are the congenital cases—14,472 in number. These, with two others, tabulated under the head of “other causes unclassified,” constitute the “deaf from birth”—14,474 cases.

Congenital deafness probably involves the internal ear, for the deaf from birth as a class are totally deaf. Falls and blows also are apt to produce injury to the internal ear. Those deaf from old age are as a class, only partially deaf, so that in their case the internal ear is not incapacitated. It is probable that the defect relates chiefly to the external ear, resulting from impacted cerumen or thickening of the drum membrane. Military service may mean almost anything. Deafness due to the discharge of artillery would affect the internal ear; so would typhoid fever and malarial fever accompanied by quinine. Other diseases incident to military service, like catarrh and colds arising from exposure to the weather, might involve the middle ear. Sickness, fever, and hereditary causes would probably not involve the external ear, but might refer either to the middle ear or the internal ear.

It is clearly seen that the predominant causes of deafness are different in the case of the deaf from childhood and that of the deaf from adult life. Scarlet fever, meningitis, and brain fever, which are among the leading causes of deafness occurring in childhood, are comparatively insignificant as causes of deafness occurring in adult life. On the other hand, catarrh, colds, and influenza, which are the leading causes of deafness occurring in adult life, are of lesser importance as causes of deafness in childhood.

Occupations: The same classification of occupations was adopted for the deaf in this Special Report as was used for the general population at the Twelfth Census. A comparison is therefore possible of the deaf and of the total population ten years of age and over gainfully employed.

	Total Number 10 Years of Age and Over	Number Gainfully Employed	Per Cent
Total population. The deaf	57,949,824 83,388	29,073,233 32,142	50.2 38.5

These figures indicate that deafness is a drawback to some extent in securing employment; but they also show that the deaf as a class are by no means a burden upon the community. Few of the deaf who are under twenty years of age are engaged in gainful occupations, but this is no discredit to them, for the vast majority of these persons are attending school. Of those over twenty years of age 43 per cent. are engaged in gainful occupations.

The census tables relating to occupation reveal the astonishing fact that there are extremely few occupations pursued by the people of the United States in which deaf persons do not find employment. This is not only surprising, but at the same time encouraging, as widening the scope of possible usefulness for the deaf.

There can be no question that the industrial training provided by our special schools has been of material assistance to their pupils in securing employment. The deaf who have attended school show a much larger percentage of their number pursuing gainful occupations than of those who have not attended school. The kind of employment—whether skilled or unskilled—is also largely determined by school attendance.

It appears that the deaf from childhood are more self-supporting than the deaf from adult life. This is especially surprising when we consider the fact the deaf from childhood include practically all of the deaf and dumb, and that most of them are totally deaf; whereas the deaf from adult life include none of the deaf and dumb (at least substantially none), and most of them are only partially deaf. Of the deaf from childhood who were over 10 years of age, 40.6 per cent. were gainfully employed, and of the deaf from adult life only 36.8 per cent. Of the deaf from childhood who were 20 years of age or over, the majority (51.6 per cent.) were gainfully employed, against 36.8 per cent. of the deaf from adult life. The deaf from adult life are undoubtedly better equipped by nature for the task of earning a livelihood, for most of them possess perfect speech and partial hearing, and yet the deaf from childhood seem to be more successful in this respect.

The explanation for this apparently anomalous condition of affairs seems to lie in the fact that many persons who become deaf in adult life fail to accommodate themselves to the new condition of deafness. They lose their positions on account of increasing deafness, and feeling themselves too old to begin life all over again in their crippled condition by seeking some new occupation with which deafness would not interfere, they lose heart and drop out of the struggle, becoming dependent upon their friends for support, or living upon the savings of former years, without entering into new pursuits.

In the case of the deaf from childhood, however, the accommodation to the environment has been complete before the dawn of adult life. Many of these persons have never experienced any other condition than that of deafness; and most of them enter upon the duties and responsibilities of adult life with that feeling of buoyancy and hope that is so characteristic of youth. Nor should we neglect

to notice in this connection the powerful influence exerted on the deaf from childhood by the special schools which have been established for their benefit.

Dr. James Kerr Love of Glasgow, a British authority on the education of the deaf child, states: "Deaf children differ from hearing children in these points, apart from the presence of deafness and its consequences; (1) They have worse eyesight. (2) There is a larger number of mentally deficient children among them—about 15 per cent. (3) Deafness, when congenital, is often hereditary, and so persistently hereditary, in spite of a healthy environment, that congenital deafness becomes one of the chief objects of attention of the medical inspector of deaf children."

For purposes of classification and the discussion of educational needs, we may divide the deaf into the following groups:

1. Children:

A. Under school age, or from birth until about five years.

B. Of school age, including:

1. Those whose hearing has been slightly impaired from infancy;
2. Those whose hearing has been seriously impaired from infancy;
3. Totally deaf from infancy;
4. Those who are adventitiously partially deaf after speech has been acquired;
5. Those who are adventitiously totally deaf after speech has been acquired;

2. Adults:

A. Those whose hearing is but slightly impaired by conditions which will yield to treatment.

B. Those whose hearing is slightly but permanently impaired.

C. Those whose hearing is seriously and permanently impaired.

Class 1, Group A. Children under school age, hearing tests and treatments are usually rather unsatisfactory, but adequate instruction by the parent, provided they are sufficiently intelligent, may do much to obviate the detrimental effects of the deafness. Because even slight deafness in a child interferes with its proper acquisition of speech by imitation of the speech heard from others. For this purpose, if the child has even a moderate amount of hearing, great care should be taken to speak distinctly to the child and near its ear; if the child is evidently very deaf, then in addition the parents should be taught to be careful to have the child's gaze fixed on their lips when they talk to it, in order that it may, even in infancy, acquire the habit of watching the lips, and so gradually and unconsciously learn to associate ideas with movements.

Class 1, Group B. For this class the years from 2 to 10 are the most critical, since in them must be acquired the child's vocabulary and its ability to read lips. The teaching which the child receives during the first three years of his school life is of vital importance to him and he needs then, even more than he will ever need again, the teachers of highest skill and greatest experience. The child with a remnant of hearing will need special care to maintain or improve that remnant. The child who has acquired speech before the adventitious impairment of his hearing will need particular care in preserving his enunciation. Children of all these types need to learn lip reading and the reproduction of sounds in order to acquire the ability to speak.

For the Class II cases the problems are different but the prime essential again is training in lip reading.

Lip reading and the ability to speak once acquired, the problem of teaching the deaf is robbed of its greatest difficulty and the remainder of their education is more on a par with that of normal hearing persons. Unlike the physically crippled, they are not so liable to find much difficulty in securing employment, provided they make the necessary adjustment of their requisites to their defect and for this reason institutions for the permanent care of the normal deaf are not so vital a State need as are institutions for the permanent care of the crippled. In sections remote from good day schools where instruction can be given to the deaf child by qualified teachers of the oral method, it becomes necessary to provide institutions for such education of the deaf of tender years in order that they may acquire the ability to speak and to understand speech, but once this ability is acquired the urgent need for institutional care is past.

It cannot be too strongly impressed that for the deaf child, as for the crippled child, the future must always be considered and the best type of self-respect maintained by placing the child in such position that he makes his way on his own merits and recognizes that this is so, and that he is not an object of pity and philanthropy. His early environment and the shut-in mental attitude his deafness entails, all tend to start him with a sense and feeling of dependence, and a duty, which education owes him, is to inspire his sense of personal independence by the manner in which it places in his hands the weapons of lip reading and articulate speech, with which he, on an equal footing with his hearing brother, may combat the exigencies of life.

Still another group of defectives, the blind, demand similar care, and their education as a group proceeds along similar lines to that of the cripple and the deaf. That is to say, they are capable of and entitled to a normal education plus the special attentions necessitated by their handicap. The blind can and do become self-supporting and efficient citizens, and the system of public health and public education which neglects their interests and welfare is open to grave criticism on the ground of inefficiency.

The conditions which are responsible for blindness may be classed under certain broad heads: (1) Blindness due to causes which are in their nature accidental. (2) Blindness due to general, and in many cases, preventable, diseases. (3) Blindness due to congenital deformity.

In the first group is included a very large proportion, approximately 45 to 48 per cent., of blindness, and it reinforces the value of the motto "safety first"! because with the prevention of such accidents as produce the blindness we can obviate much unnecessary suffering and wasteful expenditure of money and energy in the re-education, or in the education, of the blind. Of the blind children in the London County Council Schools, 44 per cent. were grouped as cases due to accidental causes. Mr. Bishop Harman says of them: "In most of these blindness has followed destruction of the eyes by reason of the accidental inoculation of the surface membranes with some virulent microorganism. In a few the eyes were injured by blows, foreign bodies entering the eyes, etc., which set up inflammation of such a serious kind that the eyes were destroyed. Of this group of cases 84 per cent. (or 36 per cent. of the total blind) were blinded by the purulent

ophthalmia of the newborn. Of the remainder, purulent conjunctivitis in later years accounted for 7 per cent., accidental injuries and sympathetic inflammation arising therefore for another 7 per cent., and smallpox for 2 per cent. In days not far remote in our own land, and even now in the Orient, purulent inflammations in the later years of life blinded innumerable eyes, and the present smallness of the total blindness arising from this cause is striking evidence of the efficacy of modern medicine. Smallpox was formerly even more notorious as a blinder of the eyes of the young, but now the tale has shrunk to insignificant proportions, and let it be noted those on my list so affected had not been vaccinated."

The second class of blind, that is blindness from general diseases, many of them preventable, includes approximately 30 per cent. of the blind, and a larger proportion if we include in this class the cases from ophthalmia neonatorum.

The third group, *i.e.* congenital blindness, includes approximately 25 per cent., and is, of course, the least subject to public health control.

The principal facts concerning the blind set forth in the general tables of the Special Report from the Twelfth Census are those relating to sex, color, general nativity, marital condition, present age and age at which blindness occurred, causes of blindness, and occupations.

The general relation of these data to the blind, distinguished as totally and partially blind, is shown briefly in the tables and comments:

"Sex.—Of the 64,763 blind reported, 57.2 per cent. are males, 42.8 per cent. are females."

Regarding the degree of blindness, it is shown that 35,645, or 55 per cent., of the blind are totally blind, and 29,118, or 45 per cent., are partially blind. Of the totally blind, 56.5 per cent. are males and of the partially blind, 58.1 per cent. To state these facts in another way, blind males show a smaller proportion of their number totally blind than do blind females. The figures indicate that blindness, both total and partial, is more common among males than females.

The number of blind per 100,000 of population is considerably greater among the foreign born white population than among the native white (foreign born whites, 104.7; native whites, 80.4).

Of the totally blind, 2,317, or 65 per 1,000, have been blind from birth, and 2,084, or 58.5 per 1,000, became blind after birth but under 2 years of age. Of the partially blind, 2,413, or 82.9 per 1,000, are blind from birth, and 1,352, or 46.4 per 1,000, became blind before reaching 2 years of age. Thus the number who lost their sight, either entirely or partially, before reaching the age of 2 years, is 8,166, or 126.1 per 1,000 of the blind at all ages. Of the specific causes of blindness, those to which the greatest proportion of cases per 1,000 from all causes are: Cataract, injuries, accidents, and operations, congenital, old age, and sore eyes. Unknown causes are responsible for a slightly greater proportion than any of the above, namely, 123.6 per 1,000.

Considered with reference to the degree of blindness, the percentage totally blind is considerably greater than that partially blind when the defect is due to the following causes: Meningitis, glaucoma, congestion or disease of brain, scarlet fever, small pox, venereal diseases, injuries, accidents, and operations, neuralgia, grip, and colds, while the percentage partially blind is greater in the cases due

to granulated lids, old age, scrofula, catarrh, measles, and military service. The causes resulting in a greater proportion of blindness among the whites than among the colored were: Granulated lids, catarrh, colds, measles, scarlet fever, smallpox, cataract, neuralgia, glaucoma, congestion, or disease of brain, congenital, military service, and grip.

The great disparity between the white and colored in the occurrence of blindness as the result of granulated lids and glaucoma confirms the opinion, generally held by observers in America, that granulated lids, or trachoma, which is so fruitful a cause of blindness among the Irish, the Russians, the Jews, and the Italians, is almost unknown among the negroes in this country.

The causes producing a greater proportion of blindness among the colored than among the whites were: Scrofula, sore eyes, venereal diseases, exposure to heat and cold, old age, injuries, accidents, and operations, strained eyes, and unknown causes.

Of the 20,704 persons who were blind from childhood, 4,728 were born blind—about 23 per cent.—the other principal causes being injuries, accidents, and operations, sore eyes, cataract, measles, and scrofula.

Cataract, injuries, accidents, and operations, old age, affections of the nervous apparatus, military service, sore eyes, and neuralgia were the principal causes of blindness among adults.

Excluding congenital defects and injuries, accidents and operations, there are 2,556 who lost sight after birth but under 1 year of age, and in 644, or 25.2 per cent. of these cases the cause of blindness was probably ophthalmia neonatorum, or "babies' sore eyes," since other diseases of the eye causing blindness under 1 year of age are extremely rare. The importance of these figures lies in the fact that this disease, which is very malignant and which attacks the infant at birth or immediately after and almost always results in total destruction of the sight—usually of both eyes—or in very seriously impaired vision, is now considered preventable, and if proper measures had been instituted at the time of birth few or none of these cases would have occurred.

"Occupations.—Of 62,456 blind 10 years of age and upwards, 12,506, or 20 per cent., were reported as engaged in definite remunerative occupations. The per cent. of the general population similarly employed was 50.2."

Classifying the occupied blind by degree of blindness, the number reported as totally blind is 5,581, and the number reported as partially blind is 6,925. In other words, 16.2 per cent of the totally blind 10 years of age and over are gainfully employed and 24.7 per cent of the partially blind. The figures show that there is a larger percentage of totally blind persons gainfully employed engaged in professional pursuits, trade and transportation, and manufacturing and mechanical industries than is found in the general population, while the percentage engaged in agricultural pursuits and domestic and personal service is less.

The type of schooling needed by the blind is not essentially different from that for normal individuals, except that their books must be so printed that they can be "read by hand" instead of by eye, and that adaptations must be made of all things in their environment to obviate, so far as possible, the psychical defect due to lack of visual impression. Here applies the same truth iterated for the cripple and reiterated for the deaf. The individual must

be taught self-confidence in competition with normal individuals as quickly as possible after adjustment is made to compensate for the actual defect.

It must be clearly borne in mind in any consideration of defectives that there are numerous cases of compound defect; for example, there are a goodly number of crippled-deaf and of crippled-blind, as well as blind-deaf. I cannot place my hand on any percental or estimated figures by which their relative importance to the uncomplicated cases of single defectiveness can be weighed in the balance; neither have I been able to obtain any figures by which to justly estimate the numbers of crippled-mental defectives, of deaf-mental defectives (except Dr. Love's statement already quoted), or of blind-mental defectives, but in the latter case the relative number does not bear on the side we are at present considering; as they, *i.e.* the crippled, blind and deaf aments,—may be more justly said to complicate the problem of the treatment of mental deficiency rather than the problems of the physically or sensorily defective; the thing to fight against most in such cases is the mental deficiency rather than the blindness, or deafness, or deformity.

The problem of the ament is a very large one and must be taken up at another time in our next lecture. There still remains for our discussion to-day the following problems among defectives, and we can only touch them briefly: (1) The generally-physically-incompetent child or adult, and (2) the partially blind or deaf child.

Among the large group which compose the generally-physically-incompetent class of individuals, we find the non-crippled tubercular, the profoundly anemic but non-tubercular, the non-crippled scrofulous or rachitic child, the neurotic individual, who is not plainly insane nor plainly mentally deficient, but usually delinquent, frequently non-social, and always a burden on the state, either in juvenile reformatory, in jail, in prison, or in almshouse, and the type of physically unbalanced individual who, while never distinctly so ill as to require hospital care, is generally so ailing as to be incapable of sustained physical effort, and, who is just beginning to be recognized as a subthyroid, a subpituitary, or a subadrenal case, amenable to rehabilitation by means of proper treatment and care.

For the non-crippled tuberculous class a species of sanitarium care, or of systematic supervisory, follow-up home care, such as is maintained by our New York City Department of Health, is the only type of solution that is socially or economically thinkable in the present age of conservation. Restored to health, or even to a modicum of physical capacity, these defectives are an economic asset which the state cannot afford to neglect nor to support in idleness. This fact has been brought home to the public until the truth of it is widely appreciated by the splendid and systematic work in the fight against the great white plague. It is a fact that applies with equal force to the other forms of general physical incompetency which I have mentioned, and the sooner the truth is recognized and impressed upon the public mind and conscience, the sooner there will be an efficient economic conservation of the public health, the public wealth, and the public welfare. The neurotic defective to which I have called attention in this classification approaches so close to the mental defective that we shall have more to say about him later in that connection. In school care all these types of physically defective should be placed in open-air

classes and receive the education of normal children.

It is sufficient to point out at present that this type of generally-physically-defective is a public health problem, the bulk of which is at present neglected and ignored, which the hygienist of the future will find looming large in his field of work and endeavor, and the solution of which must be sought and found in the field of prevention, as much, or more thoroughly, as in the field of cure.

The problem of the partially blind or deaf child is largely one of educational hygiene, aside from its strictly medical aspect of visual or auditory conservation. The proper lighting and acoustic properties of school buildings; the character of paper, type, etc., used in text-books and for composition; the length of study periods, the amount of home study, as well as the seating of the individual pupil in the class-room, are all questions in practical school hygiene and sanitation, which concern the school physician, and therefore the public hygienist, quite as much as the problems of (1) providing hospital, dispensary, or medical care for the individual children with the object of conserving as much sensory function as possible, and (2) of substituting the training of the totally blind or totally deaf in those cases whose progressive deficiency cannot be arrested or whose partial deficiency renders them unable to receive a maximum benefit from the education of the normal individual.

Briefly then to summarize the problems presented to us by the cripple, the deaf, the blind, and the generally-physically-defective, we have (1) prevention, (2) cure, or alleviation, and (3) conservation and correlation.

Prevention involves not only public health control of the physical defectives in a community, but the regulation and prevention of all causes contributing to the production of defectiveness, so many of which are allied to other general health problems such as Infant Mortality, Contagious and Infectious Diseases, Factory Inspection, Congestion of Population, General Municipal Sanitation, and so on.

Cure or alleviation involves the diagnosis and registration of the defect and a system of follow-up supervision, as well as the immediate medical or surgical treatment of the defective.

Conservation involves a system of public health propaganda whereby the amount of actual physical inefficiency may be minimized and the amount of individual efficiency utilized to the utmost for the production of work of social and economic value to the community as well as to the individual. And Correlation involves either a centralization of control, such as might be effected by a National Board of Health linked up with the present National Education and National Labor Departments, or else a larger spirit of cooperation between existing organizations, public, philanthropic, and private, wheresoever their fields of endeavor meet, approximate, or overlap.

101 WEST EIGHTIETH STREET.

Incipient Mental Disease.—Floyd M. Alpin states that in his early observation of suspected mental cases there are four major points he uses in much the same spirit as a woodsman would the four points of a compass. First, is the patient above normal in spirits, lowered in his religious habits, bold in manner, free with money and remiss in home relation? Second, is he below the average in spirits? Third, what about any peculiar ideas if any are present? Fourth, does there exist or likely to exist a decrease of mental capacity?—*Wisconsin Medical Journal*.

THE LEGACY OF THE INTEMPERATE USE OF TOBACCO.

By ROBERT ABBE, M.D.,

NEW YORK.

SENIOR SURGEON TO ST. LUKE'S HOSPITAL.

"THE public looks to the medical profession for advice—not for reform." Doctors are better observers than moralists, use tobacco quite generally, and deal tenderly with the smoker until he gets into trouble with nervous overstimulation, heart irregularities, precancerous condition, or well-developed cancer of the mouth, or, possibly, with throat cough, or indigestion only.

Patients showing the ill effect of tobacco are only those who have been *intemperate* in its use. Intemperate is a word with shifting meaning. Every man's limit of tolerance for tobacco is different. Some can never touch it without suffering. Others seem to be immune and have no limit. This apparent freedom to use it without restraint constitutes the danger. In this class are found all the victims of its dangerous effects.

I once said I had never seen serious mouth disease in any patient who had not smoked more than three cigars a day. A larger experience confirms that statement. I also said, several years ago, that I had not seen such bad effects from cigarettes, but closer study of many cases has shown me numerous serious cancerous or precancerous mouth conditions in men who used only cigarettes. The last one smoked daily two boxes of ten each. He was a comparatively young man.

The insidious increase in the amount used is associated with the slow augmentation of its effect, usually unrecognized by the victim. The cumulative results in bringing about ultimate degenerative changes are capable of mathematical determination. Indeed, the only safety for those of us who enjoy tobacco in moderation is that we live threescore and ten years instead of twice that. Else we, too, would suffer in larger proportion.

I have been more impressed of late years with the number of men, in commercial life especially, who are inveterate smokers, whose vest pocket bulges with cigars, who sit in an office smoking and being smoked at, forgetful of the successive hours during which they smoke. While there is less drinking of liquor, there is more smoking. The corner saloon is being replaced by the convenient corner cigar store, a welcome social change. The effect in practice is, that we see fewer cases of cirrhosis of the liver and alcoholic gastritis, but more cases of cancer of the mouth. Physicians may well take note and wisely advise the *temperate* use of tobacco for those who find it an agreeable habit at home and a help in business. Strangely enough, it seems to be a helpful stimulant to business men of some temperaments. A charming gentleman and successful merchant once told me he couldn't conduct business sitting "dry-mouthed" on opposite sides of a table with a man, unless they had cigars. But if he had a cigar he could always talk and think better and get the advantage of his customer. Such is competitive business!

The intemperate use of tobacco is apt to be a legacy. An intelligent Italian of middle age recently appealed to me for relief of cancer of the tongue, too far advanced for hope from any known remedy. Not long after, his well-to-do brother came to see if the burning pain on his tongue was the

beginning of cancer. Both brothers had been heavy smokers from boyhood. The father and mother smoked constantly. On inquiring details the son said his dear little old mother always had her pipe in her mouth. For three years before her death she was crippled with rheumatism. Every joint was crippled so that she could only lie awkwardly in bed, from which she was lifted in and out. He imitated the cunning way in which she would twist her hand up to her mouth with the ever-present pipe, and if at night she couldn't sleep she would have a pipe by her bedside and smoke at 3 A. M.

The son was quick to see that he and his brother were victims of tobacco and abruptly stopped it. He had in his mind a new generation of his own children.

That same week two fine young men, brothers, came to me with beginning cancer of the mouth. They might have been twins in appearance and in disease. They could not remember when they had not smoked, beginning with cigarettes at twelve years old. I asked if their parents sanctioned it. "Why, yes. Father smoked all the time himself." I asked about *his* health. "Very well except until lately he had a cancer of the whole lower lip and the doctors had to cut it all away and make him another." Both men gladly and easily broke the smoking habit, and one told me, two months later, he was "gaining flesh, was less nervous, and never felt so well or was so successful in his business."

To make clearer the point of the legacy of tobacco, let me state briefly the case of a gentleman who recently consulted me for an early stage of mouth cancer, to whom I gave the usual counsel that I could do nothing until he gave me his help by stopping his inveterate smoking. He said he had once stopped for a few weeks and he could do it again. I said this time it must be for good. His wife said she would see that he did. In two weeks he came to report his success and was ready to be treated. I had advised him to get all his cigars out of his room to avoid temptation and asked him if he had cleared his desk and library of tobacco. He said, "Yes, indeed, I gave *all* my paraphernalia—pipe, cigar cutters, everything—to my son." "What," I said "to *your* son? That's a nice legacy!" "Oh," he said, "he's one of the steadiest of men—very temperate. I can trust him not to overdo it." I could not help reminding him that one of our great national heroes smoked incessantly, as everyone knew, and suffered and died from the consequence of disease of his throat. His distinguished son, also a heroic figure in our army, adopted the same habit, smoked equally incessantly and suffered and died of the same terrible consequence. This is a heavy price to pay for the intemperate use of such a throat irritating and unnatural habit.

Tobacco smoking is increasing year by year in our country. Collegians are lured by seductive advertisements, which are excluded from two college papers only, and form a large part of the paying advertisement. Of the senior class in one of our finest universities, among 230 members were 136 smokers, 50 of whom began after entering college—a legacy of the college to its alumni.

There is no reason to believe that smoker's cancer is in any sense an inheritance, but merely the legacy of a habit which, when intemperately indulged, results in identical bad results, in a certain number of cases. Whatever the frequency of this grave result, the fact of its unquestionable relation to intemperate use of tobacco is established.

Every smoker must determine for himself what his comfortable limit is, and use his God-given intelligence to safeguard his own and his children's future.

More than ever we need a nation of strong men, not undermined in health by any deleterious habits, which can be just as well diminished as increased. Good medical counsel is something of a nation's life insurance.

13 WEST FIFTIETH STREET.

THE VALUE OF EXAMINATION OF APPLICANTS FOR INDUSTRIAL EMPLOYMENT.

By ALVAH H. DOTY, M.D.,

NEW YORK.

The examination of applicants for employment in The Western Union Telegraph Company, which has been in operation during the past two years, was not inaugurated solely for the purpose of securing a healthy and desirable class of employees, but also for the protection of those already connected with the service, chiefly by guarding against the introduction of communicable diseases.

The importance of protecting employees against infection is now so fully recognized and yields such valuable results, so far as the preservation of health is concerned, that no additional evidence is required as to the need of such a measure. However, it may be said in passing that the medical representatives of this company have found many cases of communicable diseases among those who present themselves for examination. For instance, during the year 1915 thirty-six cases of tuberculosis and forty cases of suspected tuberculosis were detected in this way, besides various other sources of infection.

Aside from the protection against communicable diseases, the examination of applicants for employment is otherwise of interest and importance to those already connected with this service, who sooner or later are likely to participate in the very generous benefit fund provided for their comfort, which also must be carefully guarded, for no employer can indefinitely extend substantial aid in this direction if such a fund is improperly or too heavily drawn upon. The importance of this is more seriously appreciated when it is borne in mind that The Western Union Telegraph Company has 40,000 employees.

Physical examinations are not popular chiefly for the reason that those who are personally concerned are often either conscious of some physical defect or fear that something of the kind may be found. Sometimes modesty is the dominant reason why an examination is objected to. This applies particularly to women. Furthermore, there are those who, although not personally concerned, do not look with favor upon the examination of applicants for employment because it is likely to exclude many who at the time are fully able to work, and would make faithful employees yet may have some physical defect. It has been asked if these persons are excluded everywhere, by what means may they earn a living? There is sufficient reason in this criticism to entitle it to careful consideration.

No one will question the propriety of excluding those who are a menace to the health of others, and it is also entirely proper for an employer to reject those who are incapable of properly performing the work they apply for. For instance, the service of The Western Union Telegraph Company is practically indispensable to the public, and is held respon-

sible for the prompt transmission of important messages throughout the world. Oftentimes, a mistake in the wording of a telegram may cause irreparable damage to someone. Therefore, those who are to enter this service should be mentally and physically fit to perform their duties. This is in the interest of the public as well as the employer.

In preparing a plan for the examination of applicants for employment, The Western Union Telegraph Company has given careful consideration to the various factors related to this subject, and has endeavored to carry out this means of protection in a reasonable as well as a scientific manner and in a way which will be of benefit to the employees as well as the employer, and reject only a minimum number of applicants. This has been a feature of special interest, for it differs somewhat from the means usually employed, in the physical examination of those seeking work.

In order that the examinations throughout the United States and Canada may be uniformly carried out there have been 317 physicians appointed as medical examiners. This very large number is required, for there is hardly a place in the United States, no matter how small it may be, that does not contain one or more employees of The Western Union Telegraph Company. These medical examiners have been selected with the greatest care, and include many leading members of the medical profession. These officers do not receive a salary, but are paid a fee for various services rendered. The examination of applicants is paid for by the company.

The character of the examination is shown by the blank presented in connection with this article. It serves the purpose well, and contains the information required by the Medical Director in approving or disapproving the many applications which are presented for final decision.

REPORT OF MEDICAL EXAMINER

(Signature—Examining Physician)

While no special place is assigned in the examination blank for the report of venereal diseases, the medical examiners are quick to detect any evidence of these affections which may present themselves during the examination, and record is made under the heading "Other Diseases." Beyond this it is not deemed justifiable, at least at the present time, to deal more closely with these affections.

The character of the examination is unobjectionable, and requires no inspection below the waist, except in the case of men, and then only to ascertain if hernia is present.

During 1915 there were 7,201 applicants examined—4,919 males and 2,282 females—and while it is impossible at all times to avoid some little misunderstanding, I am aware of no complaints or criticisms which have been made concerning the method

of examination, for every precaution is taken to render it satisfactory to all concerned. So far as practicable, trained nurses are present during the examination of female applicants.

Organic disease of the heart and kidneys, hernia, and other defective physical conditions, are often found among those who present themselves for examination. While at the time these maladies may not impair the usefulness of those concerned, this may occur later on, particularly if care is not taken to maintain good health, for it is well known that in almost all of these conditions the extent to which disability occurs depends largely upon the mode of living. This fact has been given due attention in arranging an examination which is liberal in dealing with this class of applicants. Further details connected with this part of the subject will be of interest.

The examination records show that 149 cases of organic disease of the heart were found (111 males and 38 females) during the year 1915. Of these cases 101 occurred in persons under 20 years of age. At this period of life there is usually good compensation and but little disturbance of the heart action, and unless a very careful examination is made the disease is usually overlooked. There is probably no affection in which the unpleasant results are more apt to be postponed by the proper observance of the rules of hygiene than organic disease of the heart. Therefore, applicants having this malady are informed that the company will accept them under certain conditions. This relates to a waiver of benefits in case of disability caused directly by heart disease. This acts as a very effective stimulus in maintaining care in the preservation of health, and it is largely for this purpose that the waiver is required, for simply a promise to do this would very likely be forgotten soon after entering the service. Furthermore, a waiver interferes but little or not at all with disability benefits or the granting of a pension later in life.

This plan is also followed in connection with hernia and some other conditions. Those found to have hernia are informed of the value of an operation to effect a cure. If they are unwilling to submit to this treatment they are accepted after signing a waiver. In several instances an operation has subsequently been performed and the waiver annulled, or at least a good fitting truss is selected and greater care observed to prevent any of the unpleasant results of hernia.

There is not the slightest doubt that this arrangement constitutes a very valuable means of preserving the health and life of those who are disabled, and in the various ways above described is quite sure to make reliable and satisfactory employees, for under these conditions the persons affected are more apt to lead a regular life than others.

The results concerning the examination of the eyes and teeth are also of interest. During 1915 about 10 per cent. of the applicants for employment were found to present evidence of defective vision, and frequently were not aware of this condition, or had taken no means to correct it. A large number of them suffered from headaches and certain nervous manifestations, which very properly might be attributed to this cause. Of those having defective vision 199 were far below the standard required by this company, i.e., 20/20 in one eye and 20/40 the other (Snellin's Test Type). In some instances the sight of one eye was gone or practically useless.

The company's medical examiners have been very careful to explain to those with defective vision the great value of having their eyes tested or refracted and glasses fitted, and furthermore that if they will give this proper attention and their vision is sufficiently corrected they will be admitted into the service of this company if otherwise in proper physical condition. Out of this group of 199 applicants, 89 took advantage of the offer, had their eyes refracted and returned for re-examination and were employed, and probably for the first time enjoyed good eyesight. Some of the remainder did not attend to this on account of the expense. As a matter of assistance a number of these were given temporary employment until they were financially able to have their eyes refracted and glasses fitted, and were afterward given permanent employment.

Defective teeth were found to be the rule rather than the exception. The frequency with which this occurs has been so fully and generally reported that further comment is uncalled for. Not only were the teeth in bad condition, but in many instances there was marked pyorrhea with evidence of infection.

Special instructions were given by the medical examiners regarding the urgent need of having defective teeth promptly treated, and warning was given of the unpleasant results which might follow carelessness in this direction. Applicants were requested to report for re-examination after this had been attended to. A large number of applicants were given temporary employment until they were financially able to consult a dentist. It may be added that the examination of teeth revealed a display of bridge and crown work, which not infrequently was largely responsible for infection.

Simply to inform applicants for employment or those already in the service that they should consult an oculist or dentist is quite apt to leave them undecided as to the wisest course to pursue, for many of them have had no dealing or experience with these specialists, and as a result often fall in the hands of those who do not properly perform the work or who charge unreasonable fees, or both.

This has led to the adoption of a plan by The Western Union Telegraph Company which has proven exceedingly valuable to those personally concerned. The medical examiners throughout the service have been requested to select an oculist and dentist upon whom they can depend to render proper service to applicants for employment as well as employees and who will charge a reasonable fee for it. There has been a very general and satisfactory response to this request for cooperation on the part of the medical officers of this company.

A careful study of this subject in its various phases will show that the examination of applicants for employment cannot longer be regarded as of interest and value only to employers, but that it is equally important to employees. It is a means of protection which all employers should extend to those already in their service. It is hardly necessary to say that this valuable preventive measure goes hand in hand with the careful and constant observation of employees to detect the presence of disease or ill health and the means best suited to educate them regarding the importance of personal hygiene, and also to provide them with offices and workshops which are in good sanitary condition and supplied with modern appliances all of which go far to maintain the health and comfort of those under observation.

205 WEST FIFTY-SIXTH STREET.

STERILITY IN THE FEMALE.

By WILLIAM P. HEALY, M.D., F.A.C.S.

NEW YORK.

PROFESSOR OF GYNECOLOGY, FORDHAM UNIVERSITY SCHOOL OF MEDICINE.

It may be said that every woman, almost without exception, who marries harbors within her a maternal instinct which creates a desire on her part to become a mother. When such a woman carrying on normal sexual relations has not become pregnant before the end of the first year of married life she usually consults her physician in an effort to ascertain the reason for the sterility. Very few of these women go to specialists, at least in the beginning, but consult a physician in general practice.

It may be of interest to review briefly the more common etiological factors found in these cases, with particular reference to diagnosis and treatment.

When a woman complaining of sterility presents herself for examination it is important to secure from her a careful and accurate menstrual and past history. The former because any congenital abnormality present will probably show an irregular menstrual history. The latter in order to ascertain whether or not there has been a previous pelvic inflammation.

For purposes of classification one may group diseases or pathological conditions occurring anywhere in the human body under four headings, (1) Malformations or congenital anomalies, (2) Inflammations and infections, (3) Injuries, (4) Tumors.

Practically all cases of absolute sterility belong etiologically in the first and second groups. Instances of relative sterility occur in the fourth group in which we have the cases of one child sterility and miscarriages so frequently associated with fibroid tumors of the uterus, or in the third group in which we may have miscarriages as a result of uterine displacements or traumatic lesions of the pelvic organs, following previous pregnancies.

The form of inflammation with which we are chiefly concerned as a cause of absolute sterility is the one resulting from infection by the gonococcus during sexual intercourse. This infection may have been of the explosive type, resulting in an acute widespread involvement of all the pelvic organs and a well-marked pelvic peritonitis, or it may have been a slow, chronic, insidiously progressive type of infection never incapacitating the individual from active work, but gradually resulting in a low-grade inflammatory disturbance throughout the endometrium and the uterine tubes and showing itself clinically in an increased or prolonged menstrual flow with some dysmenorrhea, and a yellowish mucopurulent vaginal discharge with no special urinary or bladder discomfort. This chronic form of infection may be present without the patient's knowledge. Gonorrheal infections travel by surface extension and very infrequently by the lymphatic or blood stream; in these chronic cases therefore practically the entire lesion may be limited to the endometrium and the mucous membrane of the uterine tubes, with little or no gross change in the organs, so that a bimanual examination gives negative findings and repeated microscopic examinations of smears made from the cervical discharge may fail to show the gonococcus. However, the organism can in many instances be

obtained by expressing the secretion from Skene's tubules at the urethral orifice. Any case of absolute sterility associated with a mucopurulent cervical discharge is practically always the result of a gonorrheal infection.

Another group of cases, many of which are of gonorrheal origin, is that associated with chronic endocervicitis evidenced by the presence of a tenacious plug of mucus in the cervical canal and blocking the external os, but without any pus in the discharge. Such cases are practically always sterile, the mucous plug in the cervix seeming to present an impassable barrier to the spermatozoa.

Many cases of sterility belong to the group of congenital malformations. Of course, cases in which there is a total absence of the vagina or uterus or ovaries are not under consideration, but rather those cases in which all the pelvic organs are present but have failed apparently to reach complete maturity in their development. As a matter of practical observation and clinical experience this lack of complete development is observed more constantly in the uterus than in any of the other pelvic organs, which is fortunate, for we are at present able to cope reasonably successfully with cases exhibiting certain uterine defects.

The clinical findings here fall usually into one of three groups: (a) a small, poorly developed uterus with scanty menstruation, (b) a small uterus with anteflexion and a normal period except for dysmenorrhea, (c) a uterus normal in size but with a long, conical cervix and a stenosis of the cervical canal, the menstrual period tending to be profuse and prolonged and associated with considerable dysmenorrhea. Any one of these groups may be complicated by a retroversion of the uterus.

Occasionally we have cases of absolute sterility resulting from the endometritis accompanying intramural or submucous uterine fibroids. Very rarely one will come across tuberculosis of the endometrium as a cause of sterility.

A certain small number of cases of sterility are dependent apparently upon some other factor than those already mentioned, for a careful examination discloses no congenital defect and no evidence of past or present infection, no injury to the pelvic organs, no neoplasm, and yet with an apparently healthy woman conception does not occur. In such cases one will occasionally find the explanation in an increased acidity of the vaginal secretion as a result of excessive decomposition with lactic acid fermentation, and these cases are often cured by using saline or bicarbonate of soda douches at bedtime.

Sometimes apparently healthy women will go for years without a pregnancy, and then at last when they have reached the menopause and the symptoms of the climacteric are establishing themselves they will become pregnant. In my opinion in such cases we have had to deal with abnormal tubal, uterine, or vaginal secretions which, with the lessening activity of the impending climacteric, have become more normal.

Treatment.—Assuming, then, that we have made a careful examination of the patient and that we have classified her, if possible, in one of the above-mentioned groups and have assured ourselves that the husband is not at fault, how shall we treat the condition found?

If the examination is negative and the woman appears perfectly normal I would say she should use a physiological salt douche at bedtime and

intercourse should be restricted to the week preceding the menstrual period, as in many of these cases I believe there is too frequent intercourse, with increased ovarian and uterine congestion, resulting in the production of a uterine secretion which inhibits or is detrimental to the activity of the spermatozoa.

In cases of sterility associated with uterine anomalies I believe that groups (a) and (b) can be greatly benefited by a thorough dilatation of the cervix, a superficial curettage of the endometrium above the cervix, and the use of a stem pessary retained by a suture and left in for about three weeks. Group (c) can be helped by a dilatation and curettage and a Dudley operation on the elongated cervix.

A retroversion occurring in any of these groups should be corrected by the use of an appropriate pessary or by an operation.

Sterility due to gonorrheal infection is least satisfactory to treat. As a rule the infection is no longer active when the patient comes for advice and one has to deal with end results which vary according to the extent of the primary inflammation. If the bimanual examination does not disclose any lesion of the tubes or ovaries, one is justified in performing a careful dilatation and curettage of the uterus and in ordering only saline douches. Should the patient not become pregnant within a year and there is an undoubted history of previous gonorrheal infection, and an examination of the husband shows plenty of normal, active spermatozoa, then I believe one is justified in assuming that the tubes were probably involved in the inflammatory process and in advising an exploratory celiotomy for the purpose of freeing adhesions and opening the tubes if they are found to be closed.

The acceptance of this advice will depend upon how anxious the patient is to leave nothing undone that may aid her in obtaining a cure, and as a matter of fact the patient has to assume the burden of responsibility in cases of this particular type, for the exploratory celiotomy may not disclose any lesion of the tubes, although in many cases chronic salpingitis with adhesions and blocking of the tubes will be found.

Gonorrheal cases which are quiescent but present a definitely palpable lesion of the tubes and ovaries require not only a curettage of the uterus for the purpose of restoring the endometrium to normal, but must also undergo an abdominal operation to permit of plastic surgery on the tubes, which in all probability will be found closed at their fimbriated ends.

Where the sterility seems to be due to the presence of fibromyomatous tumors in the uterus, one should do a curettage and, if possible, a myomectomy.

The following case reports will serve to illustrate some of the foregoing conditions:

CASE I.—Mrs. A. S., age 24, married six months. Menses occur every twenty-eight days, duration four days, moderate flow but with severe pain for the first day and a half. Complaint, sterility and dysmenorrhea. Examination, uterus retroverted, freely movable, normal size, tubes and ovaries apparently normal. Treatment, uterus replaced in position, a retroversion pessary inserted, ordered a vaginal douche of salt solution at bedtime. She promptly conceived, showing that the hindrance to conception was very slight and was easily overcome.

CASE II.—Mrs. H. T., age 26, married two years. Menses occur every four weeks, duration seven days, moderate flow but with very severe pain. Complaint, sterility and dysmenorrhea. Examination, cervix short

and flattened, external os very small, body of uterus slightly below average size and rather sharply ante-flexed. Tubes and ovaries apparently normal. Treatment, the cervix was dilated, the uterus curetted, and a stem pessary inserted for three weeks. The patient became pregnant within five months.

CASE III.—Mrs. N. C., age 28, married 2½ years. Complaint, sterility. Menses occur every four weeks, duration three or four days, free flow, not much pain. Patient has had a yellowish, sticky vaginal discharge since marriage. Husband had gonorrheal urethritis before marriage and was supposed to have been cured. Examination, a thick yellow mucoid discharge was exuding from the cervical canal, the posterior lip of the cervix was eroded, the body of the uterus was heavy, slightly enlarged, and slightly ante-flexed. The right ovary was small, the left ovary slightly enlarged and the tubes were not palpable. Although smears of the discharge from the cervix were negative for gonococci this was undoubtedly a chronic endometritis secondary to a gonorrheal infection.

Treatment: the uterus was thoroughly curetted, a large quantity of thick, mushy endometrium was obtained, and the uterine canal was irrigated with a weak iodine solution and then the pure tincture of iodine was applied. The operation was done in October, 1906, and the patient was under observation and treatment by vaginal douches, tampons, and local applications almost constantly for three years thereafter before she became pregnant, she went to term satisfactorily and has had two additional pregnancies since.

CASE IV.—Mrs. J. V. C., age 36, married five years. Complaint, sterility. One sister died of tuberculosis. Menses began at age of 12, recurred every six weeks until one year ago, now every thirty days, duration six days, moderate quantity, with some pain. Examination, uterus retroverted and freely movable, pelvic organs otherwise normal. Treatment, dilatation, curettage, and Gilliam round ligament suspension of the uterus through a transverse suprapubic incision. The pathological report on the curettings was tuberculosis of the endometrium. The operation was done in 1912 and the patient has not yet become pregnant, although she appears to be in excellent general health.

CASE V.—Mrs. E. N., age 30, married five years. Menses recur every twenty-eight days, duration three to four days, moderate quantity, no pain. Complaint, sterility, frequent micturition, pain in the right ovarian region. Examination, patient has a fibroid the size of an orange in the anterior wall of the uterus. Treatment, curettage, myomectomy, left salpingo-oophorectomy, partial right salpingectomy, Gilliam round ligament suspension. Patient has since had one miscarriage and one full term pregnancy.

CASE VI.—Mrs. J. McC., age 45, married seven years. Menses recur every four weeks, duration three to four days, moderate quantity, occasional pain first day. Complaint, amenorrhea for past four months. Examination showed the patient to be in the fourth month of pregnancy, greatly to her surprise, as she supposed she was entering upon the change of life. She had not done anything at any time to prevent conception. She went to term and was delivered of a male child by medium forceps.

CASE VII.—Mrs. B. M., age 33, married two years. Menses recur every four weeks, duration three to four days, moderate quantity, very little pain. Complaint, sterility. Examination, marked vaginal hyperesthesia, uterus slightly below the average size, pelvic organs otherwise normal. Treatment, dilatation, curettage, and stem pessary. Five years later the patient's periods were recurring every four weeks, but lasting for only a few hours and the flow was exceedingly scanty. The following year she became pregnant and was delivered of a healthy male child at term by a breech extraction.

It is of interest to note that this patient had been examined by a prominent gynecologist of experience and ability who advised her to adopt a child, as in his opinion she would never become pregnant.

46 EAST EIGHTY-THIRD STREET

Operation for adenoma of the prostate should not be long delayed if the patient is a "good surgical risk," even though obstruction is not marked, for sometimes these adenomata conceal small areas of carcinoma, unrecognizable except by the microscope. Removed thus early, the patient is usually cured; left to grow into the capsule and surrounding tissues, the condition is usually hopeless.—*American Journal of Surgery*.

MEDICAL LITERATURE AS A SPECIALTY.

By F. ROBBINS, M.D.,

NEW YORK.

"THE need for medical men who will specialize in medical bibliography and history, and devote themselves exclusively to medical journalism and medical literature, is becoming more apparent every day. Advanced teachers, like Professor Cushing at Harvard, are already beginning to encourage some of their pupils to take up the literary side of medicine, as a set-off to an ordinary success as internists or surgeons exclusively."

This passage from a recent paper by Fielding H. Garrison (*The Uses of Medical Bibliography and Medical History in the Medical Curriculum—Journal of the Am. Med. Assoc.*, January 29, 1916, p. 323) calls forth a few comments from the personal experience of a pioneer in this field; for the specialist in library research was already in demand many years ago, and as far back as the end of the nineteenth century, Dr. George Dock pointed out the importance of medical literature to his class in the University of Michigan. In 1904, the writer was advised by Dr. Joseph Collins to follow the literary side of medicine as a specialty, and since that time has worked along these lines uninterruptedly and exclusively. Some practical suggestions to future workers in this field may therefore not come amiss from one whose ploughshare has turned many a sod in the acres of medical literature.

Those who contemplate the adoption of this specialty, men or women, should take careful stock of their assets, meaning their general fitness and special qualifications for this work. One of the writer's Ann Arbor professors, Dr. Charles de Nancrede, when asked for advice by senior students concerning their selection of a specialty, was wont to say: "Do not pick out a specialty: let your specialty pick you!" There is much wisdom in that remark. Just as the bird will fly when his wings have grown, so will the man endowed with the historical sense dig, dig, dig into the mines of medical lore and renew his strength, like Antæus of old, with each touch of the friendly earth. Medical literature is exacting in its demands, and requests the unflagging devotion of its followers. Nothing is as tantalizingly elusive as a lost reference, and to those who have the innate hunting instinct, no satisfaction is comparable to the running to earth of an especially slippery specimen of that ilk. If the ardor of this chase appeals to you—if you are willing, nay, eager, to trace unlisted or worse, mis-listed references, to their lair—unwatchful of the clock, unmindful of personal reward—then you are equipped with one of the truest arrows in the quiver of the successful bibliographer. As the country doctor wearily but undauntedly plods through the snow and the mire to the bedside of the stricken, proverbially forgetful of his fee, so must the devotee to medical literature be willing to pursue untiringly the host of incomplete or erroneous references which many a careless writer in the more or less remote past has planted in his path. Amusing "literary curiosities" are often encountered in the course of bibliographic work; for example, a sequence of bibliographies reproducing through many years a *Tumeur du Sein* (Breast Tumor) as a *Tumeur du Rein* (Kidney Tumor); evidently taken on faith by one compiler after the other, until the original typographical error became

the bugbear of a wrong reference. Six cases of bileduct anomalies in the French literature have grown into ten (*dix*) cases, through a similar typographical error; and good luck to him who tries to trace the four phantom cases of the inkwell! Encounters of this kind, instead of discouraging the literary detective, should only strengthen and sharpen his own sense of personal responsibility.

A thorough knowledge, not a mere smattering, of at least two modern languages, besides English, is imperative for even a modicum of success in medical literature. French and German are barely sufficient, and a reading knowledge of Italian and Spanish as well as of the Scandinavian languages, is extremely desirable. The acquisition of Russian or Japanese will place a literary specialist of the future in an enviable position by himself. To have recourse to the brief and often belated abstracts provided by American periodicals, instead of tapping the spring itself, is to cripple the work from the start. Deficient linguistic equipment of physicians has already led to the invasion of this field by what for want of a better term may be called the quack in medical literature. Our libraries are invaded by a host of understudies, recruited from the ranks of nurses, clerks, stenographers, secretaries, governesses, and what not, who in the long run are bound to discredit this side of the profession. Medical literature, like other specialties, belongs by rights to those alone who have devoted years of their youth to the winning of the medical degree not only, but to the cultivation of that fine sense of personal responsibility, and the *esprit de corps*, which is perhaps nowhere so well developed as among the disciples of Hippocrates. Only a brother practitioner will serve the patron's interests in the most efficient way, and with absolute self effacement.

The bibliographer of the future must aim at such high standing in his specialty that the fact of his being responsible, for example, for a compilation of cases of a given disease, will serve as a sufficient refutation against the statements of a non-specialist, no matter how high his rank as a surgeon or clinician, who claims in a discussion the existence of a series of cases not included in the list. Not all skillful operators are at home in the library, and for them to claim proficiency in medical literature is well nigh as absurd as it would be for the bibliographer to deem himself an adept in gastroenterostomy, because he has had occasion to compare the merits of many different methods of operation.

Next to a mastery of English, and control of some other languages, an important requirement in the outfit of the medical bibliographer is *perseverance*; a gift still rarer than the philologic or historic sense. Make it a rule to be found day after day at a given hour (and for many hours to come) in the same place, so that your personality becomes identified with your chosen occupation. Allowance should be made for an unremunerative preparatory period, time well spent in the acquisition of the necessary library technique. While the expert specialist has learned how to secure, at once, information along any line of medical or surgical inquiry, none know better than he that there is no short cut in honest work, and the more storehouses of knowledge he is aware of, the more material will he feel in duty bound to overhaul, in the interest of his client. The verifying of the original article, in the journal where it is published, instead of taking on faith the often

incorrect and usually incomplete reference in some year-book, will inevitably lead those to whom the author's language is no barrier, to a perusal of the article, often with interesting sidelights on its contents, and incidentally, many a series of valuable cross-references. Indefatigability in taking from the shelves tome after ponderous tome is a part of the work which requires some training, aside from a stock of physical endurance not possessed by all. Good health is an important asset in this work, and it would be a grave mistake to select the literary specialty on account of its apparently guaranteeing a protection against long irregular hours, or unkind elements. The hunting of references by the enthusiast will interfere with meal hours or "amusements," so called, just as inevitably as the hunting of grouse by the sportsman on the Scottish heather. In this specialty, as in many others, "he rides the fastest who rides alone." Domestic shackles, even in form of inflexible meal hours, are not compatible with the serenity of mind that takes no heed of the passing hour, in the pursuit of date or name.

The question of residence is a vital one in this respect, and all would-be literary specialists must realize from the start the necessity of being residents of the few cities which have large medical libraries—New York, Philadelphia, Boston, Washington—and moreover, of living within walking distance of the book shelves. "Married men have better halves, bachelors have better quarters." The best is within a store's throw of the library, beyond the tender mercies of surface, elevated or subway service. A central location is moreover desirable for another reason: the vicinity of a post office open until midnight is very useful, so that all packages, registered and other letters, may be sped on their way without delay. At a time when every minute was at a premium, on account of a rush of other important work, the writer has been asked by telegram from Texas to supply material for a local medical meeting, leaving barely enough time for the discharge of Uncle Sam's mail service! The distribution to the South, North, and West, of notes gathered in the stack rooms of the library is a stimulating experience in itself. Punctuality, in form of immediate replies to correspondents and unfailing deliveries of material on the promised date, is extremely important in this specialty. Although he may not mention the fact, it is quite possible that the man who calls for literary assistance from a distant city, may wish to make a good showing before some society meeting, and if the notes reach him on the cold gray morning after, the better they are the more will his soul be vexed. *Bis dat qui cito dat*—is an excellent rule to follow!

Perfection is never, perhaps, attained in any line of human endeavor, but competence in literary research is within the reach of all who are honest with themselves and others, diligent, faithful, and last, not least, actually interested in the work itself. *A thoroughly congenial occupation* can never degenerate into drudgery. The enthusiasm in his subject of the man who asks for bibliographic services is transmitted as a living spark to the true literary collaborator. It is one of the fascinating features of this work that it will naturally bring the medical bibliographer in contact with those who rank highest in the profession.

In behalf of all who contemplate the adoption of this specialty, the writer repeats a protest against the threatened competition of purely commercial interlopers. The field belongs to those who have given

years of study and preparation to fit themselves for the tilling of this treacherous ground, on which the lights of medical ethics do not shine. The time is overdue for the institution of a reform movement akin to that so successfully inaugurated by the American Medical Association, in the weeding of the field of medical education. If only such articles were published as are the fruits of the author's experience by the bedside, on the operating table, or in the laboratory, the standard of literary assistance as well would of necessity be raised so high as to exclude non-graduates. Unfortunately, entirely too much of modern medical literature is made up of abstracts or arrangements of the work of other men, and that excellent rule is seldom obeyed: Have something to say. Say it. Stop as soon as you have said it. (Billings, J. S. *Our Medical Literature. Trans. Internat. Med. Cong. Lond. 1881, I, 54.*)

Perhaps in subconscious realization of the ephemeral character of their own achievements, some men are notoriously satisfied with the poorest and cheapest literary assistance. It is no excuse to say that the verifying of a reference, the compiling of statistics, or the mechanical translation of a paragraph do not require a medical graduate. Doctors, this is doctors' work! No item is too humble in the polishing of a literary gem perhaps destined to shine long after its author has joined the silent majority. Furthermore, while collaboration of this kind is perfectly proper and legitimate *within the profession*, conditions differ when a man of parts entrusts the preparation of his work for publication to those who are not members of the profession, and as such alone able to understand, and if necessary, to defend his reason for seeking their assistance.

Ambition as to personal fame, *except as a bibliographer*, must be curbed in the interest of this retiring specialty. Not only must the abstract-maker and compiler of medical literature apparently have no view of his own, or at any rate reveal no bias, but he may be asked to merge his own personality altogether in a paper that he has prepared for publication under another name. In the Paris Salon, on Varnishing Day, admiring crowds gather before certain pictures signed by a "master's" hand, and bearing some familiar evidence of his brush, in a cottage fence, a floating cloud, or a bit of blue water in the background; the rest of the large and carefully elaborated painting is the work of some poor devil of an artist whose shadow never darkens the hall of fame. What is true for art, is equally true for science, and not all boats fly their own flag that sail proudly on the sea of medical literature. Instructive comments upon this and other points connected with the "new" career of medical bibliography and literature may be found in a clever editorial from the pen of the late Dr. De Santos Saxe, which appeared eight years ago in the March number of the American edition of *La Tribune Médicale* (Vol. IV, No. 3, 1908, p. 71), entitled "The Literary Ghost in Medicine."

Following the third rule of Billings—although the end may be abrupt—this is the place to stop, but not without a welcome to the future worker in the Library of the New York Academy of Medicine, and the wish that he may after many years be able to say, with the writer, that his lines have fallen upon pleasant places, in a most congenial bookish atmosphere, brightened by the beautiful spirit of competent helpfulness on the part of the librarians.

41 WEST FORTY-FIFTH STREET

ARTERIOSCLEROSIS.

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL NEUROLOGY, COLUMBIA UNIVERSITY.

ARTERIOSCLEROSIS is a condition which has been recognized for a great many years. Osler says there are four great factors in its causation: the wear and tear of life, acute infections, various intoxications, and persistent high blood-pressure. The vast majority of cases occur in males who are advanced in life; there are many instances in which it has been found in young persons, and over a hundred cases have been reported as occurring in infancy.

Syphilis is the one of all the infections and lead is the one of all the intoxicants which is most liable to cause arteriosclerosis. Alcohol is a cause, but it is not nearly so important a one as is generally supposed, nor nearly so potent a one as excessive eating. Large quantities of food, and faulty elimination, added to the strenuous life of the big city, make up a combination which will inevitably inaugurate high blood-pressure and bring about arteriosclerosis.

I want to call attention to three points which are not sufficiently recognized. One is that the sclerotic process does not affect equally all of the arteries. The temporal and radial may be neither tortuous nor thickened, yet the autopsy may reveal patches of atheroma in the aorta and sclerotic vessels in the kidney. Another is that in different individuals the process may, and very likely will, affect different coats of the vessels. Thus in one the lesion may be in the media, in another in the intima. Another point is the variability of the character of the process. Thus in one the lesion may show itself as an atheromatous patch, or as an area of softening, while in others there may be a calcification, a distention, or an obliteration of the lumen of the vessel.

If these points are borne in mind, it will be seen that the sclerotic process is diffuse, multiple, and varied. The symptoms which the particular patient manifests will, of course, be dependent upon the type and the location of the lesion. Therefore, one should not expect a particular set of complaints, but rather a train of symptoms multiple and varied.

The following case will illustrate some of these conditions:

Mrs. M. was sixty-four, but appeared much older, and seemed considerably broken, both physically and mentally. Her parents had died of senility, one brother of epilepsy. She had been married and had given birth to five children, of which three were born still. She had always been healthy, with the exception of children's diseases, and slight rheumatic attacks. There was no history of lues, or drug taking. She admitted to being a moderate alcoholic and an excessive teardrinker. Her menstrual life had been regular up to the age of forty-three, when the menopause occurred.

She began to feel sick towards the end of November. At first there was nothing definite, more a feeling of weakness with slight mental impairment, but nothing more than she felt she had a right to expect in the third decade. The onset was insidious and progressive. Soon she noticed attacks of vertigo. At first they were infrequent and of short duration, later on they became well defined.

Things appeared to be revolving in a vertical plane towards her. She now knew that her chief complaint was dizziness. The attacks became more and more frequent, and of longer duration. Her walk began to be affected; she would lean backwards, and tend to fall not sideways or forwards, but backwards. She felt very uncertain when on her feet, and walked like a

drunken woman. In the attacks she thought that the color of objects changed. Then the attacks came even when she was lying down. In other words, the condition was distinctly progressive.

Physical examination showed her to be well nourished, but as one who was chronically ill. She was slightly deaf. The apex of the heart was in the fifth space, $5\frac{1}{2}$ -inches from the midline. Neither the pulmonary second nor the aortic second was accentuated; there was a murmur heard at the apex. The chest expansion was good, with a normal percussion note and normal vesicular breathing. The abdomen was negative, except for a slight umbilical hernia. The edge of the liver was palpable one-half inch below the costal margin. The glandular system seemed normal. The reflexes were normal. There was no Kernig, no ankle clonus, no Babinski. There was a marked arcus senilis, the pupils reacted to both light and accommodation, but were unequal, the left being the larger. There was a slight nystagmus.

There was a marked coarse tremor of the hands, inconstant and intentional in character.

The circulation was slow, the memory poor, and the patient showed some signs of mental confusion and deterioration. It was evident that there had been some degree of cerebral softening.

The examination of the ears which was made by Dr. Dench showed that both drum membranes were thickened, retracted, and calcified. There was no spontaneous overpointing, nor spontaneous nystagmus. Both labyrinths were active to colonic tests. The ophthalmoscopic examination made by Dr. Wiener showed little that was unusual. There was a marked thickening of the vessels, the discs appeared pale; the outline was dim, shading off slowly into the fundus.

The Wassermann was negative. The urine was 1020 specific gravity, turbid, contained a very faint trace of albumin, no sugar, and an increase of indican. There were a few leucocytes.

The gait was unusual, and not typical. It was not ataxic, but rather tottering. She walked slowly, with great feebleness and uncertainty. There was a constant tendency to fall backwards. The blood-pressure was 180 to 230. The pulse ranged from 78 to 90.

Autopsy.—The left pleural cavity showed strong adhesions over the lung; the right was negative. The pericardium showed a large amount of fat about it, and contained about 5 c.c. of clear, straw-colored fluid.

Heart.—The left auricle showed nothing noteworthy, the mitral valve admitted one finger, and was retracted and thickened. The wall of the left ventricle measured $2\frac{1}{4}$ inches in thickness. The circumference is 8 cm. the aortic valves were markedly sclerosed, and the aorta itself showed numerous atheromatous patches. The valves looked fibrous. The coronaries showed slight changes. The circumference of the aortic valves was 7 cm. The right auricle showed nothing noteworthy. The tricuspid valves admitted three fingers; its circumference was about 11.5 cm. The wall of the right ventricle measured about 5 cm. The pulmonary valve showed nothing noteworthy; its circumference was 7 cm. The weight of the heart was 350 grams.

The left lung was practically airless, and bound down by tough adhesions; it floated. The bronchial lymph nodes showed nothing noteworthy. The right lung showed nothing noteworthy. The stomach was small and empty. The spleen measured 12.5 by 5 by 3.5. The capsule was dark. On section, the follicles showed up slightly fibrous.

The left kidney showed a large quantity of fat; the capsule was rather adherent; it measured 12 by 6 by 4 cm. Cortex thinned, markings distinct. The right kidney was similar to the left. It showed a cyst and measured 10 by 5.5 by 3.5 cm.

The gall-bladder was distended with bile. No stones. The liver was pale, the capsule smooth on section. The pancreas showed nothing noteworthy. The uterus showed nothing noteworthy. The ovaries were sclerotic.

The brain, which so far has only been examined in gross, showed some edema. It was a question whether there was any marked sclerosis affecting the anterior and posterior cerebral vessels. This will have to be determined by the microscopic examination of the sections, which will be done later and on which I shall make a further report.

In this case there was an arcus senilis, an inequality of the pupils, attacks of dizziness, a tendency to fall backward, and a slight nystagmus.

The circulation was slow and there were signs of mental confusion.

Here, then, was a train of symptoms most varied, one which could only be explained by a diffuse and multiple process. One which did not affect all the vessels equally, and yet did affect a great many. The autopsy showed the variability of the type of lesion, as in the aorta were numerous patches of atheroma, while the coronary vessels showed but slight changes. The vessels of the ovaries were markedly sclerotic.

THE ANATOMICAL CAUSE OF THE FREQUENCY OF HYDROCEPHALUS IN CHILDHOOD.

BY WILLIAM BROWNING, PH.D., M.D.

BROOKLYN, N. Y.

THE relative frequency of hydrocephalus in the developmental years, and particularly in young children, is a matter of common knowledge.

Some distinction can be made even clinically between the general run of adult and of youthful cases of this disorder. The adult forms are not only fewer in number, but more uniform in type and more definitely fatal, except such cases of youthful origin as live over to adult life. The adult forms may also occur in younger years, but are so infrequent in comparison they are not apt to impress us. Youthful cases are less uniform; many are so slight in degree as to be ignored; some recover; some live on indefinitely; some progress; most run a slow course; prognosis is less certain.

In the production of hydrocephalus we find two complementary conditions—secretion and retention, both processes normal within limits. Unless there is an abnormal damming-back of the fluid there can be no accumulation, and it is this phase that is considered here.

Many partial and indirect factors have some bearing on this youthful potentiality—narrower passages, softer tissues, thin bones, metabolic growth-errors, etc.

But back of all these is an anatomical and mechanical peculiarity that does not appear to be appreciated or perhaps known by our clinicians. This side of the question in the human was worked out by the author some years ago, though not correlated specifically on this point. The facts upon which the present paper is based are to be found more fully described in the writer's "Circulation in the Central Nervous System," 1897,* and in the article on "Pacchionian Bodies" in the "Reference Handbook" (new edition).

From a mechanical standpoint there are three causes of hydrocephalus: (a) over-secretion (as by block in the vein of Galen, leading to excessive production of fluid). (b) Closure of the outlets from the ventricles (as at the foramen of Munro, the iter, or the three outlets from the fourth ventricle). (c) Interference with the efferents from the subarachnoid space. The possibility of an intermediary form (between b and c), as claimed for so-called meningitis serosa, does not affect the correctness of this general classification of causes.

The first two (a and b) are relatively rare, may

*The above mentioned studies may not be known to workers in this field, as the major part of the edition was promptly destroyed by fire in the establishment of the publishers (Lippincott). Copies of it are to be found in some of the larger medical libraries.

occur at any time of life, and are so simple in origin that they need no further explanation. While the third form (c) may occur at any time of life (as from inflammation, exudate, etc.), there is an anatomical peculiarity during the early years of life in the human that greatly favors the accumulation of fluid at that time. It is to that fact and its application that attention is here directed.

There are two recognized general classes of these efferents for the fluid from the subarachnoid space. One of these may be termed the animal or quadruped type; the other the (postnatal) human type. There may be additional minor outlets, as along the cranial nerves or by direct absorption through the surrounding tissues, but any such are limited, slow, and entirely inadequate.

The animal type of discharge consists of minute channels or vessels (perhaps comparable to lymphatics) that lead from the spinal subarachnoid space along outgoing nerves to extraspinal tissues. Quinke (1872), from experimental injection of cinabar emulsion into the spinal subarachnoid of living dogs, found that, "in several cases the cinabar could be followed on the lumbar nerves to the region of the lumbar plexus between the origins of the psoas, as well as in the sciatic plexus beyond its entrance into the pelvis." And Key and Retzius (*Arch. f. Mikroskop. Anat.*, 1873, Bd. IX), in Fig. 9, picture the injection of the sacrolumbar plexus from the spinal subarachnoid. In the writer's experience this type of exits can be better demonstrated along the lower spinal nerves than along the upper. These spinal efferents persist in animals during adult life.

But in the human we meet with a very different condition of things. Such spinal outlets for the cerebrospinal fluid *exist in the human only during fetal life*. This conclusion was based on a series of injections in human subjects ranging from the sixth to the seventh month of intrauterine life up to 69 years of age.

These spinal efferents in man are demonstrable up to the time of birth at full-term. After that for a very brief period one or another short stump of a passage may be found, but even that promptly disappears. At the time of publication of the above work a full-term fetus was lacking to complete the series. This was subsequently obtained and agreed with the just-given résumé.

It follows from these facts that while animals have an ample system of spinal exits for the fluid, the human must develop some other type or system to serve for this purpose after fetal life.

It is evident that the animal method of discharge would be illy suited to organisms like the human that walk upright. Monkeys, as was also shown by the writer, are intermediary in type. If the animal method persisted in man, the fluid, owing to gravity, would be too rapidly drained off. Some substitute mechanism evidently had to be developed in the process of evolution from quadruped to biped existence. To this we can now turn.

Injection work of various observers has shown that the Pacchionian structures are efferents for the cerebrospinal fluid in man. And such appears to be the generally accepted conclusion. That there may be accessory minor means of exit, as toward the nasal cavity, does not invalidate the essential and dominant rôle of the Pacchionians. These deliver the fluid largely into the parasinual spaces, and thus into the veins and sinuses and the general circulation.

In animals generally, however, these so-called granulations are not present (brains of sheep, calf, rabbit, dog, and cat examined). Luschka found them only in the horse. Bluntschli (1910) describes them in apes, even on the spinal arachnoid, but found none in the lower animals. It is consequently clear that, barring the monkey (*i.e.*, all primates), there can be in animals practically no absorption of the fluid by Pacchionian formations. In them the spinal efferents, as we have seen, serve for this purpose.

In the human these granulations are largely a matter of postnatal development. They increase with the years. Up to the twentieth year they are not apt to develop very greatly. In circulatory troubles, local or general, there may be a precocious development of these bodies.

From all the above facts it appears that the human for a time after birth has but a very limited efferent system for the spinal fluid. This, however, develops with such regularity that, by the time full growth is reached, a system of efferents is in effect that suffices for all ordinary and even many extraordinary demands.

Childhood is the favorite time for the occurrence of hydrocephalus. This finds its explanation largely in the closure of the spinal outlets from the time of birth in the human, and the imperfect development of the Pacchionian bodies at this period. The Pacchionians increase and the frequency of hydrocephalus decreases as childhood progresses. This explanation rests on established data; it meets all the requirements rationally, and it accounts for much that is otherwise obscure.

The conditions that lead to prenatal hydrocephalus may also find a collateral interpretation.

This rearrangement in the system of discharge of the spinal fluid adds another to the list of adaptive modifications of the body and its functions, that accompanied the evolution of man from the four-footed to the two-footed or erect style of body-carriage.

Questions regarding secretion of the cerebrospinal fluid may doubtless, with customary allowances, be investigated by experiments on animals. But in the matter of resorption of the fluid, because of the radical difference in method, the results of experiments on animals are not directly transferable to the human.

54 LEFFERTS PLACE

The Frequency of Epilepsy in the Offspring of Epileptics.—D. A. Thom studied the records of 1,536 epileptic patients admitted to the Monson State Hospital. He found that one out of every six was married; that 80 per cent. of the marriages resulted in children; that 138 marriages resulted in 553 offspring, an average of four to each marriage; that of the 553 offspring it was possible to obtain a history of epilepsy in only ten cases or 1.8 per cent. Of these ten epileptics, six died in infancy, two became confirmed epileptics, and two cases were arrested, one for 17 years and the other for 36 years. The study of the family history in 138 epileptics revealed epilepsy in one of the parents eight times, and the study of the offspring of these same patients showed that it had been transmitted ten times; but in two instances there were two children in the same family who had convulsions, so the epilepsy was inherited and transmitted in 5.8 per cent. of the cases. From this study the writer concludes that it would appear that epilepsy is transmitted directly from parent to child less often than we have hitherto been led to believe.—*Boston Medical and Surgical Journal*.

THE INDIGENT MIGRATORY CONSUMPTIVE.

SEVERAL recent publications of the United States Public Health Service are devoted to the problem of the interstate migration of tuberculous individuals, and are very instructive in this connection. The seriousness of this question is there forcibly brought home to us. After a careful consideration and study of the entire situation, the investigations lead one to certain definite and valuable conclusions which may be here enumerated. It is estimated that from ten to fifteen thousand persons afflicted with tuberculosis migrate annually to the West and Southwest to obtain the benefits of the climatic conditions there existing. The States particularly affected by this influx are California, Arizona, Colorado, New Mexico, and Texas.

The conclusion is reached that from one-third to one-half of those tuberculous patients who make this westward journey are really hopeless cases. So true is this that perhaps 15 per cent. die within one month after their arrival in their new place of abode, and it is believed the total number of hopeless cases here mentioned probably terminate fatally within a half year after arrival. In fact so great is the number of those who die in almshouses and charitable institutions, and who must seek charity in other ways, that a bill on this subject has recently been introduced in the House of Representatives dealing with federal aid in co-operation with the various States, for certain classes of tuberculous patients in financial distress. When one remembers that in the great majority of these hopeless cases the patients could in all probability have received at home a proper degree of care and attention for their remaining days under more satisfying and more pleasant environment, at least with friends, family, and other relatives near at hand, the tremendous import of this problem is impressed upon us in some measure. In surveying these reports one is struck by the remarkable fact that of all those who die of tuberculosis in the States referred to from four to nine out of every ten are from other sections of the country, or in other words have migrated to the West or Southwest on account of their tuberculosis. The States of New York, Illinois, Ohio, Missouri, Tennessee, and Kentucky alone furnish half of this number.

What should be our general conclusion from this distressing state of affairs? Although it is true

that those who are in financial condition to defray expenses for their sojourn, and who furthermore are not too far advanced in the disease, may find the climatic conditions of the western and southwestern parts of the United States of value in the treatment of their condition, nevertheless it should be remembered that in the average case one ought not to start out on a trip of this sort, unless the following conditions can be met: (1) The individual should have at least \$1,000, over and above his traveling expenses; (2) his family should be left in comfortable financial condition; (3) he should not be in an advanced stage of tuberculosis, but on the other hand, should preferably be in an early or moderately advanced stage of the disease; and (4) he must take careful medical advice before he leaves or decides on such a trip, and should be in competent hands after he reaches his goal.

Above all the physician should not forget, and should impress it upon his patients and the public in general, that tuberculosis can be cured and is being cured in any and every part of the United States—in fact of the world. The ordinary workman, the ordinary individual who suddenly learns that he has tuberculosis and is only of moderate means financially, had far better enter a sanatorium right at home, in his own county or State, rather than go West under unfavorable conditions, where he may find himself in financial straits, perhaps even without proper medical care, let alone food. Although climate has a certain value in many cases of tuberculosis, its exact value is still problematical or undetermined. At least there are many differences of opinion on this point. That its value has been much overestimated in the past is surely true and is acknowledged even by those who are firm believers in the climatic advantages of certain sections of the country for the treatment of this disease.

As a final remark it must be said that many practicing physicians are not abreast of the times in this matter, that they do not appreciate the problems involved, and that they are not competent to give advice to their patients because they have not given sufficient attention to and studied this problem. It is for the interest and welfare of our patients and their families, that thorough and adequate knowledge regarding this subject should be spread broadcast among the rank and file of the medical profession.

CONSERVATIVE TREATMENT IN THROMBO-ANGIITIS OBLITERANS.

THROMBOANGIITIS obliterans (often called "Buerger's disease" since Leo Buerger of New York was the first accurately to describe the pathology and appreciate that this form of blood-vessel disease constitutes a distinct clinical entity) is a disease of early adult life, most of the cases occurring between the ages of thirty and forty, and, in typical form, only in the male. Most if not all of those afflicted have been of the poorer classes. The majority of the patients are Polish or Russian Jews, although cases affecting men of other nationalities have been reported as, for example, Swedes by Ochsner and

Japanese by Koga. A large percentage of the patients seen in New York are tailors or cutters and it has been thought that occupation might be an etiological factor; but so many other occupations have now been represented that it is questionable whether this has any influence. The etiology is still obscure, although Buerger is convinced that the disease is the outcome of an infectious process. According to him (*Surgery, Gynecology and Obstetrics*, November, 1914) thromboangiitis obliterans is a process in which an acute inflammatory lesion and occlusive thrombosis of arteries and veins are the characteristic lesions; and he also concludes that from the mechanical point of view and from the standpoint of symptomatology the thrombotic occlusion is the most important phenomenon. The ultimate result is a gangrene of the extremities affected (most often the lower, sometimes both), and until within the past few years the ultimate form of treatment was amputation at progressively higher levels as the disease advanced. With the development of blood-vessel surgery, arteriovenous anastomosis has sometimes been practised, with occasional favorable results; and in a few instances the femoral or brachial veins have been ligated, likewise with some successes and some failures. These are, of course, radical measures, and while simple ligation is easily performed, arteriovenous anastomosis is difficult of accomplishment, the continued patency of the anastomotic opening is problematical, and many question its value even when technically successful.

In view of the uncertainty of improvement following these measures, as well as their difficulty and considerable degree of danger, there has been a persistent effort to develop a non-operative conservative treatment which could be easily applied and would also promise as great and as lasting improvement symptomatically as any operative procedure short of amputation. Two forms of treatment have been most employed: (1) the affected extremities have been treated by superheated air (baking); and (2) since Koga (1913) reported thirteen cases of this disease treated by hypodermoclysis of Ringer's solution, on the basis of Mayesima's theory of increased viscosity of the blood, and noted improvement in every case, this procedure has been employed extensively in this country.

Among the investigators in this field none, with the possible exception of Buerger himself, has been more ardent in the search for a therapeutic measure that would postpone or render ultimate recourse to surgery unnecessary than Willy Meyer. Following a particularly interesting and lucid exposition of the essential facts and theories regarding this disease, Willy Meyer (*Annals of Surgery*, March, 1916) considers the various conservative methods of treatment that have been proposed by others, and to this adds the report of the use (in conjunction with Garbat) of transfusion by the citrate method and of intravenous injections of a 2 per cent. watery solution of sodium citrate, four patients being treated by each of these methods. On the basis of having personally treated thirty cases of thromboangiitis obliterans and having seen many others by

the courtesy of colleagues, and through his intimate knowledge of the literature of this subject, he concludes that conservative treatment should be resorted to before amputation in typical cases. He advises superheated air, best combined with systematic hypodermoclysis of Ringer's solution, and, if these measures fail, what one may call the conservative operation of ligation of the femoral vein or arteriovenous anastomosis. Superheated air may bring about an improvement in the symptoms, but seldom a lasting beneficial effect. The systematic hypodermic injection of 400 to 500 c.c. of Ringer's or of physiological salt solution daily, or every second or third day, deserves a place, he says, in the treatment of thromboangiitis obliterans. Even the further progress of gangrene may be stayed by hypodermoclysis, old and obstinate ulcerations may heal, and otherwise uncontrollable pain can be relieved. A simultaneous administration of organotherapeutic preparations deserves a careful test.

Inflammation of the wall of the arterioles or venules is apparently responsible for the thrombosis. It is possible also that an altered quality of the blood may contribute to the occurrence of the thrombosis and subsequent gangrene. If this is so, measures which tend to reduce the coagulability of the blood within the body, Willy Meyer says, deserve to be tried, and therefore intravenous injections of anticoagulating substances, such as a 2 per cent. water solution of sodium citrate, may prove to be a useful adjuvant to systematic hypodermoclysis.

RECENT SPECULATION ON THE NATURE OF ECLAMPSIA.

"ECLAMPSIA cannot be the same condition as uremia; for if it were every nephritic woman who becomes pregnant would develop it, and this very seldom happens." This old assertion has never been successfully disputed and is more convincing than many of the fine spun distinctions based on laboratory work. It has recently been shown that neither affection develops as long as the liver can perform vicariously the work of the kidneys. Eclampsia has indeed long been looked upon as an expression of hepatic insufficiency, but this point is not driven home in the case of uremia, because it rests largely on animal experiment. In the clinic "hepatogenous uremia" is not yet an entity. Parrott, however, was able years ago to produce typical uremia by establishing an Eck's fistula in a dog, and Steenhuis by ligation of a branch of the portal vein in rabbits—thereby eliminating part of the liver—could at will set up hemorrhagic nephritis with the entire picture of uremia. Gessner, in a polemical article addressed to R. Schröder (*Berliner klinische Wochenschrift*, March 6), defends his theory from the latter's criticisms. Cystoscopic studies of gravid women have shown that in nearly one-half of all cases there are disturbances of the renal functions of largely mechanical origin, the right kidney being more frequently affected. The causes of eclampsia are therefore twofold, general and local. The kidneys are mechanically crippled by pregnancy, and oliguria results; but before eclampsia can develop there must be insufficiency of the liver. The immediate cause, however, is failure of the renal function.

SIGNIFICANCE OF SEXUAL DISEASES FOR THE
INCREASE OF POPULATION.

IN Germany every tenth to fifth marriage is sterile, and in over one-half of all cases this sterility is due to gonorrhea; or otherwise stated 8 per cent. of all marriages are sterile because of that disease. This does not include one-child sterility. As a result of gonorrhea the annual increase of population is cut down by nearly 10 per cent.; and as about 2,000,000 children are born annually in Germany this equals a loss of some 200,000 from this disease alone. Corresponding figures for syphilis are not readily obtainable. We know, however, that by far the greater number of non-criminal abortions are due to this affection. It is also known that from 20 to 25 per cent. of all syphilitics die as a consequence of their infection. As 10 per cent. of all Germans may be reckoned as syphilitic, 2 per cent. of all deaths are to be ascribed to this disease. We can now cure syphilis in its primary stage in almost 100 per cent., and in its secondary stage in 90 per cent., and we can destroy its ineffectivity. Deaths, of course, occur principally from later developments. Nevertheless, the presence of war antagonizes the successful treatment of syphilitic soldiers, for one dare not use salvarsan in uncontrolled subjects. Married soldiers suffer very frequently—in fact to the extent of 30 to 40 per cent. of all syphilitic soldiers. These facts were brought out in a discussion of a paper by Richter (*Deutsche medizinische Wochenschrift*, March 2) on the subject of the decreasing birth rate which was read last December at a meeting of a local medical society of Königsberg in East Prussia.

RECENT VIEWS OF ADDISON'S DISEASE.

THAT Addison's disease ever exists without lesion of the adrenals is hardly believed by those with unusual opportunities for autopsies. Cases in the older literature to the contrary very likely represented errors in diagnosis. In recent years syphilis has been recognized as one cause of this malady through the production of specific lesions of the adrenals. The latter structures may, however, be the seat of neoplasms which do not give rise to a single Addison symptom; instead there is sometimes seen a change in secondary sexual characteristics in the female which is due apparently to some arrest of the function of the ovaries. Some neoplasms of the adrenals are able to continue the functions of the latter and to produce adrenalin. At a recent session of the Aertzlicher Verein of Hamburg (*Münchener medizinische Wochenschrift*, March 28) there was a discussion on Addison's disease, in the course of which Korach mentioned fulminating cases which can destroy life as if by a powerful toxic action in a few days, and protracted cases which may last ten years. The syndrome of melanoderma plus asthenia may be caused by occult cancer. Hypotonia is the most characteristic symptom of Addison's disease, and low systolic blood pressure (70 to 80 mm. Hg.) is very constantly associated with it. In cases of gaseous degeneration distinctly subnormal temperature is the rule, while on the other hand hyperthermia is usually an indication of the presence of a neoplasm. There is no characteristic blood picture. Large doses of arsenic are sometimes beneficial in Addison's disease, but injections of tuberculin and adrenalin apparently only aggravate the symptoms.

News of the Week.

New York's Death Rate.—During the week ending May 13 there were reported in New York City 1,515 deaths, giving a death rate of 14.15 per 1,000. This is a slight increase in mortality as compared with the same week of last year, when the deaths numbered 1,472 and the rate was 14.04 per 1,000. While the mortality of all the acute and infectious diseases, with the exception of whooping cough, was lower during the week than during the corresponding week of 1915, that of cancer, chronic heart disease, nephritis, pulmonary tuberculosis, and lobar pneumonia was increased. The death rate for the first twenty weeks of 1916 was 15.34, as compared with 15.55 for the corresponding period of last year.

Chicago's Death Rate.—During the week ending May 13, the death rate in Chicago was 14.2 per 1,000, as compared with 12.6 for the corresponding week of last year, the total number of deaths being 680 and 591 respectively.

Public Cancer Meeting.—In association with the New York Academy of Medicine, the American Society for the Control of Cancer held its annual public meeting at the Academy on May 18. The speakers were Dr. Louis I. Dublin, statistician of the Metropolitan Life Insurance Company, Dr. Francis C. Wood, director of cancer research in Columbia University, and Dr. George D. Stewart of Bellevue Hospital. Dr. Joseph C. Bloodgood, Dr. John A. Hartwell, Dr. Eugene H. Pool, Dr. David Bovaird, and Dr. William R. Williams joined in the discussion which followed the formal papers. The results of the discussion were discouragingly inconclusive as regards both causation and treatment.

New Red Cross Hospital.—The New York Branch of the American Red Cross announces the receipt of a gift of \$24,000, from Mr. and Mrs. George Blumenthal, to be used for the equipment of a base hospital in connection with Mount Sinai Hospital, New York. This makes the fourth unit to be organized under the branch, those previously provided for being in connection with the Presbyterian, the New York, and Bellevue Hospitals. As already announced, each unit consists of twenty physicians, forty-six nurses, and 125 orderlies and assistants. The equipment of each base hospital will be stored in New York, subject to the instant call of the Government.

Infant Mortality in New York.—In connection with the recent celebration of Baby Week, the Department of Health of New York City prepared some interesting statistics covering infant mortality in the city. The mortality rate for the entire city during 1915, based on the 141,256 births reported, was 98 per 1000, or approximately 1 in 10. As showing the variation in the death rate according to location, however, it was found that in Central Park West 25 babies out of every 1,000 born died in the first year; in the Dyckman section of Manhattan, 50 out of every 1,000; in the lower East Side, 73 out of every 1,000, and in the San Juan Hill district, around West Sixtieth Street, 314 out of every 1,000. The rate for the entire city compared very favorably with the rates for other large cities, that for Chicago being 114 per 1,000 births; for Philadelphia, 105; for Pittsburgh, 110; for Washington, 110; for Baltimore, 120; for Boston, 104, and for Denver, 131. In Los Angeles, however, the rate was only 67 per 1,000 births; for Indianapolis, 89; for St. Louis, 82, and for Rochester, 84. It is interesting to note

that many of the densely crowded quarters of the city show infant death rates far below that of the entire city. Thus, in a number of Health Districts, all situated south of Third Street and east of Broadway, the mortality rate varied from 47 to 91 per 1,000 births. In all districts where the negro population represented at least 10 per cent. of the entire population, on the other hand, the infant mortality rate varied from 124 to 314 per 1,000 births. It is also noteworthy that in some of the districts peopled by persons of considerable means the death rate from congenital malformations and defects was markedly higher than in the poorer quarters. The cause of this difference has not been determined.

Fire Scare at Bellevue.—A small fire in the medical building at Bellevue Hospital, New York, on May 15, caused some alarm among the patients. The fire was, however, confined to some packing of excelsior and paper in the basement, and was extinguished without difficulty.

Dr. Carlisle Honored.—Dr. Robert J. Carlisle of New York on May 16 completed thirty years of service as visiting physician at Bellevue Hospital and attending physician to the Bellevue Nurses' Training School and Nurses' Home. The nurses of the hospital took advantage of the occasion to present to Dr. Carlisle a gold watch with platinum chain and pencil as a token of their appreciation.

Association of Anesthetists.—The second annual meeting of the Interstate Association of Anesthetists will be held at the Hotel Seelbach, Louisville, Ky., on July 26 and 27, in conjunction with the National Dental Association. Full information as to the details of the long and interesting program which has been prepared may be obtained from the secretary, Dr. F. H. McMechan, Avon Lake, Ohio.

Alumni Association of the Medical Department of the University of Buffalo.—The forty-first annual reunion of the alumni of this college will be held in Buffalo on May 30-June 2, 1916, under the presidency of Dr. Lesser Kauffman. The secretary is Dr. Julius Richter of Buffalo. An interesting program is offered for the first three days of the meeting; the fourth day will be given up to the university commencement exercises in the morning and a ball game between the Universities of Rochester and Buffalo in the afternoon.

Instruction Camps Abandoned.—Announcement is made by the Surgeon-General of the United States Army that owing to the withdrawal of troops from their regular stations for duty on the Mexican border, the War Department has been compelled to abandon the camps of instruction for officers of the Medical Reserve Corps, that were to be held during the coming summer.

Harvard Red Cross Unit.—The Cunard liner *Andania*, which left New York on Saturday for Falmouth, carried fifty-eight physicians and nurses, composing the third Harvard Red Cross unit for France. The contingent was in charge of Herbert H. White of Cambridge, Mass. When the party arrives in England Dr. Hugh Cabot of Boston will take direct control. Among the surgeons are Dennis R. W. Crile, Thomas A. Foster, Ralph Matson, Carleton R. Metcalf, George B. Packard, Jr., George C. Shattuck, Henry R. Viets, Jr., and Harold W. Stevens.

Charitable Bequests.—By the will of the late Mary D. Tenbrook of Philadelphia bequests are made as follows: \$15,000 each to the Orthopedic Hospital and Infirmary for Nervous Diseases and the

Presbyterian Hospital for the endowment of free beds in memory of Henry Davis, Mary S. B. Davis and Mary Davis Tenbrook, and \$1,000 to the Home for Incurables.

By the will of the late Sarah Cresson of Philadelphia the sum of \$5,000 is bequeathed to the Women's Southern Homeopathic Hospital.

By the will of the late Eliza Y. Henderson of Philadelphia the sum of \$2,000 is bequeathed to the Home for Incurables.

Philadelphia General Hospital.—Dr. Robert G. Torrey has been appointed visiting physician in succession to Dr. William Pepper, resigned. Dr. E. J. G. Beardsley has been appointed visiting physician to the tuberculosis department.

Medical Society Elections.—AMERICAN ASSOCIATION OF IMMUNOLOGISTS.—At the meeting of the association held in Washington on May 11 and 12 the following officers were elected: *President*, Dr. Richard Weil, New York; *Vice-President*, Dr. John A. Kolmer, Philadelphia; *Treasurer*, Dr. Willard J. Stone, Toledo, Ohio; *Secretary*, Dr. Martin J. Synnott, Montclair, N. J.; *Members of the Council*, Drs. William H. Park and Arthur F. Coca, New York.

ARIZONA MEDICAL ASSOCIATION.—Annual meeting at Phoenix on May 1. Officers elected: *President*, Dr. Robert Ferguson, Bisbee; *Vice-Presidents*, Dr. William W. Watkins, Phoenix; Dr. Arthur C. Carlson, Jerome; and Dr. F. T. Wright, Douglas; *Secretary*, Dr. Clarence E. Young, Prescott; *Treasurer*, Dr. R. D. Kennedy, Globe.

KANSAS MEDICAL SOCIETY.—Annual meeting at Topeka on May 4 and 5. Officers elected: *President*, Dr. James W. May, Kansas City; *Vice-Presidents*, Dr. M. T. Sudler, Lawrence; Dr. Alfred O'Donnell, Ellsworth, and Dr. T. A. Jones, Hutchinson; *Secretary*, Dr. Charles S. Huffman, Columbus; *Treasurer*, Dr. Lewis H. Munn, Topeka.

LOUISIANA STATE MEDICAL SOCIETY.—Annual meeting at New Orleans on April 25 and 26. Officers elected: *President*, Dr. William H. Seemann, New Orleans; *Vice-Presidents*, Dr. Thomas S. Jones, Baton Rouge; Dr. Charles V. Unsworth, New Orleans, and Dr. J. M. Bodenheimer, Shreveport; *Secretary-Treasurer*, Dr. Laurence R. DeBuys, New Orleans.

WINDHAM COUNTY (CONN.) MEDICAL SOCIETY.—Annual meeting at Windham on April 20. Officers elected: *President*, Dr. Marguerite J. Bullard, Putnam; *Vice-President*, Dr. L. I. Mason, Willimantic; *Secretary-Treasurer*, Dr. Laura H. Hills, Willimantic.

ASSOCIATION OF RAILROAD CHIEF SURGEONS.—Annual meeting at Chicago on May 3. Officers elected: *President*, Dr. Oscar Leseure, Detroit, Mich.; *Vice-President*, Dr. Daniel Z. Dunott, Baltimore; *Secretary-Treasurer*, Dr. L. J. Mitchell, Chicago.

KENTUCKY STATE HOMEOPATHIC MEDICAL SOCIETY.—Annual meeting at Louisville on May 5 and 6. Officers elected: *President*, Dr. Howard P. Fischback, Newport; *Vice-President*, Dr. Frederick L. Juett, Lexington; *Secretary*, Dr. A. H. Seibert, Louisville; *Treasurer*, Dr. Paul E. Kerkow, Covington.

AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.—The thirty-third annual meeting of this society was held in Washington on May 9 to 11, when the following officers were elected: *President*, Dr. Judson Daland, Philadelphia; *Vice-Presidents*, Dr. William L. Dunn, Asheville, and Dr. John E. Elliott, Toronto; *Secretary*, Dr. Guy Hinsdale, Hot Springs, Va. Surgeon General William C. Gorgas,

U. S. A., was elected an honorary member of the association. The next meeting will be held at Lakewood, N. J., in May, 1917.

WISCONSIN SURGICAL ASSOCIATION.—Annual meeting at Milwaukee on May 10 and 11. Officers elected: *President*, Dr. Charles H. Lemon, Milwaukee; *Vice-President*, Dr. R. H. Jackson, Madison; *Secretary-Treasurer*, Dr. Daniel Hopkinson, Milwaukee.

SOUTHWESTERN KENTUCKY MEDICAL ASSOCIATION.—Forty-sixth annual meeting at Paducah on May 9 and 10. Officers elected: *President*, Dr. E. B. Willingham, Paducah; *Vice-Presidents*, Dr. John F. Kirksey, Sedalia, and Dr. Oliver R. Kidd, Paducah; *Secretary*, Dr. Elbert W. Jackson, Paducah; *Treasurer*, Dr. Henry G. Reynolds, Paducah. The next semi-annual meeting will be held in October at Clinton.

HAMPSHIRE DISTRICT (MASS.) MEDICAL SOCIETY.—Annual meeting at the State Hospital, Northampton, on May 11. Officers: *President*, Dr. Charles A. Byrne, Hatfield; *Vice-President*, Dr. Arthur G. Minshall, Northampton; *Secretary*, Dr. Joseph D. Collins, Northampton; *Treasurer*, Dr. Justus G. Hanson, Northampton.

FRANKLIN DISTRICT (MASS.) MEDICAL SOCIETY.—Annual meeting at Greenfield on May 9. Officers: *President*, Dr. Harry N. Howe, Greenfield; *Vice-President*, Dr. Charles Milne, Sunderland; *Secretary-Treasurer*, Dr. Alfred E. Johnson, Greenfield.

ESSEX SOUTH DISTRICT (MASS.) MEDICAL SOCIETY.—Annual meeting and banquet at Lynn on May 10. Officers: *President*, Dr. Emile Poirier, Salem; *Vice-President*, Dr. John J. Egan, Gloucester; *Secretary*, Dr. Hamlin P. Bennett, Lynn; *Treasurer*, Dr. George Z. Goodell, Salem.

WORCESTER DISTRICT (MASS.) MEDICAL SOCIETY.—112th annual meeting at Worcester on May 10. Officers: *President*, Dr. George O. Ward, Worcester; *Vice-President*, Dr. Michael F. Fallon, Worcester; *Secretary*, Dr. Ernest L. Hunt, Worcester.

BRISTOL SOUTH DISTRICT (MASS.) MEDICAL SOCIETY.—Annual meeting at New Bedford on May 11. Officers: *President*, Dr. Arthur C. Lewis, Fall River; *Vice-President*, Dr. J. C. Da S. Pitta, New Bedford; *Secretary-Treasurer*, Dr. Alanson J. Abbe, Fall River.

Obituary Notes.—Dr. JOHN ROBERT EVERITT of Jersey City, N. J., a graduate of the Long Island College Hospital, Brooklyn, in 1872, died at his home on May 15, aged 71 years. Dr. Everitt had been city physician for thirty years at the time he retired, four years ago, and was also formerly physician to the Emergency Hospital, Jersey City.

Dr. WILLIAM H. SLEDGE of Mobile, Ala., a graduate of the University of Alabama School of Medicine in 1881, and a member of the American Medical Association, the Medical Association of the State of Alabama, and the Mobile County Medical Society, died at his home on April 30, after a long illness, aged 61 years.

Dr. FRANCIS B. BISHOP of Washington, D. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1883, and a member of the American Medical Association and the Medical Society of the District of Columbia, died at his home on April 30, after a short illness, aged 63 years. Dr. Bishop was president of the American Electro-Therapeutic Association in 1898-99, and was delegate from the United States to the International Association which met at Liège, Belgium, in 1901.

Dr. EDWARD M. PATERSON of San Jose, Cal., a

graduate of Harvard University Medical School in 1871, and a member of the medical examiners for the Province of New Brunswick, the California Medical Society, the American and British Associations for the Advancement of Science, and the American Medical Association, died on April 24, aged 72 years.

Dr. CHARLES B. GASSETT, formerly assistant superintendent of the Rhode Island State Sanatorium, Wallum Lake, R. I., a graduate of the Baltimore Medical College in 1905, and a member of the Rhode Island Medical Society and the Providence District Medical Society, died at his home in Framingham, Mass., after a long illness, on May 6, aged 36 years.

Dr. ALBERT WICKMAN of Newark, N. J., a graduate of New York University Medical College in 1894, and a member of the American Medical Association, the Medical Society of New Jersey, and the Essex County Medical Society, died at his home on May 13, aged 50 years. Dr. Wickman was surgeon to the German Hospital.

Dr. HENRY HORLBECK of Columbia, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1897, and a member of the American Medical Association, the South Carolina Medical Association, and the Richland County Medical Society, died in Summerville, S. C., on May 4, aged 43 years.

Dr. CHARLES P. HARVIELLE of Salt Lake City, Utah, a graduate of the Washington University Medical School, St. Louis, in 1896, and a member of the American Medical Association, the Utah State Medical Association, and the Salt Lake County Medical Society, died in Denver, Colo., on May 2, aged 41 years.

Dr. AUREN ALFRED STAFFORD of Alameda, Cal., a graduate of Cooper Medical College, San Francisco, in 1896, and a member of the American Medical Association, the Medical Society of the State of California, and the Alameda County Medical Society, died on May 7, following an operation, aged 47 years.

Dr. WILLIAM W. REED of Jefferson, Wis., a graduate of the College of Physicians and Surgeons, Keokuk, Iowa, in 1863, and a member of the State Medical Society of Wisconsin and the Jefferson County Medical Society, died at his home, on May 10, aged 91 years. Dr. Reed had been a member of the State Board of Charities for twenty years, and for thirty-six years was county physician.

Dr. N. NOBLE VANCE of Bement, Ill., a graduate of the Medical College of Ohio, Cincinnati, in 1868, died at his home, after a long illness, on May 10, aged 71 years.

Dr. C. PERCIVAL BULSON of New York City, a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1896, died at his home on May 18.

Dr. A. HOWARD POWERS of Boston, Mass., a graduate of the Boston University School of Medicine, Boston, in 1885, died at his home on May 13, following injuries received in an automobile accident a month before, aged 61 years. Dr. Powers was surgeon to the Massachusetts Homeopathic Hospital and the Roxbury Homeopathic Dispensary.

Dr. JOHN D. ZWETSCH of Gowanda, N. Y., a graduate of the Cleveland University of Medicine and Surgery, Cleveland, Ohio, in 1882, and consulting physician and surgeon to the Gowanda Hospital, was killed in an automobile accident, on May 6, aged 58 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

COUNCIL FOR COMBATING VENEREAL DISEASES—L. G. B. WILL MAKE A GRANT—OBITUARY NOTES.

LONDON, April 29, 1916.

THE Local Government Board last week informed the national council for combating venereal diseases that the treasury is prepared to make a grant to carry out the Royal Commission's recommendations to provide facilities for diagnosis and treatment. This they will do by grants in aid of the local authorities to the extent of 75 per cent. of their expenditures in this matter. They will not set up special hospitals for this purpose as they consider treatment can be effectually carried out in existing institutions. The Commission looked for benefit from wide public knowledge of the great danger of neglected, untreated cases and the reasonable expectation of cure by thorough treatment at the earliest stage. This report is being criticised as an event of national importance and deserving attention even amid the stress and strain of a great war. It may in fact be doubted whether even this war when finished will have shortened a larger number of lives and decreased the "physical and mental efficiency of a larger number of persons than the venereal diseases during a single generation." If this report could be forced on the attention of the public, the statements it contains might give rise to a change in the conduct of sufferers inducing them to seek relief for the earliest symptoms, instead of postponing any application for advice, as they so frequently do, until the disease has established itself in their tissues.

Dr. John Kent Spender of Bath died on April 14. He was for many years physician to the mineral water establishment. He took the double qualification in 1852 after a curriculum at King's College and in 1868 while in practice added the M.D., Lond. As physician to the spa he saw many cases of rheumatoid arthritis and recorded in various contributions the views he entertained on its liabilities, complications, and management. Spender's spots, often observed in this disease, are named after him. His description of them is an illustration of his careful and vigilant observation and others might easily be culled from his writings.

Fleet Surgeon Charles Strickland died on March 25, aged 56, after an illness of about nine months. In early manhood he was threatened with tuberculosis and went to South Africa. On this account he began the study of medicine at a more advanced age than the majority of his fellow students. He was an earnest worker there as he was in the public service afterward. At the outbreak of the war he was in the Royal Marine Infantry in which he continued until his health failed and he was obliged to enter a sanatorium. His funeral, a naval one, took place at Southsea on March 31.

Captain Rob F. Hebbert, I.M.S., has died lately in the Persian Gulf. He qualified in 1906 and at once entered the Indian medical service. He took the Cheselden prize and some hospital distinctions at St. Thomas's.

Mr. H. S. Lyle, surgeon general to Liverpool Cancer Hospital, died on the 29th ult. after twenty-four years' earnest work. You will probably remember his name as a dermatologist of Liverpool.

Arthur G. J. Barker's name will be familiar to

you as surgeon to University College Hospital and teacher of surgery for many years. He died on the 8th inst. while on active service within a month of completing his 66th year. He qualified at the two royal colleges of Ireland in 1870 and 1875, proceeded to the fellowship of the surgeons the next year and became surgeon to the City of Dublin Hospital until 1885, when he was appointed full surgeon to University College Hospital. He was Hunterian professor R. C. S. 1889, and held other important posts. His manual of surgical operations and contributions to the systems of surgery and addresses at the associations were always well received. He reported in 1886 a successful case of gastroenterostomy for cancer, and this seems to be the first in this country. He contributed other papers on abdominal surgery and some on the surgery of the joints. He was the translator of Frey's Histology, and had been a lieutenant-colonel in the R. A. M. C. and consulting surgeon to the southern command. He met his death at Salonica.

Lieut. John Wilson, R. A. M. C., was killed in action on March 9, aged 29. He graduated at Edinburgh University in 1909. When several wounded were reported to be in a trench without aid, Wilson at once volunteered to cross a most dangerous part to afford them help. He reached them, bandaged those needing it and did what he could for all. But on his way back was shot and died at once, the bullet having entered just above his heart. He is much lamented by his fellow officers and the men of his company. Only ten days before his death he had been recommended for the military cross.

Lieut. Percy H. Berry, R. A. M. C., died on March 10, aged 27. He was trying to rescue a drowning man at Barrani (Egypt). Plunging into the heavy surf with his clothes on, an enormous wave broke over him and carried him away at once out of the sight of all onlookers. Five hours afterwards his body was found. There were large wounds on the head, apparently ante mortem. He was buried with military honors on March 11 in Egypt.

Progress of Medical Science.

1. Methods for Testing Donors for Transfusion of Blood. George G. Minot.
2. Use of the Duodenal Tube for Diagnosis and Treatment. Franklin W. White.
3. Gastric Ulcer Experimentally Produced. Edgar C. Steinharter.
4. The Fallacies of Group Treatment. Herbert J. Cronin.

1. **Methods for Testing Donors for Transfusion of Blood.**—George G. Minot with regard to methods for testing donors for transfusion of blood summarizes and concludes as follows: A donor for transfusion of blood should be not only healthy, but should belong to the same iso-agglutination group as the recipient. Simple and quick methods for testing this have been described. What these tests show *in vitro* can be taken as reliable evidence as to what may happen *in vivo*, so far as agglutination and hemolysis are concerned. Even when the donor and patient belong to the same iso-agglutination group there may occur, however, after transfusion, reactions of unknown nature, which are probably of not so severe or serious a nature as hemolysis. Agglutination often does not occur *in vivo*, and if it does, does not always cause a severe reaction because of the following three factors: Interference with agglutination by an excess of non-agglutinable cells, absorption of the agglutinin by the agglutinable cells, and the degree of concentration of the agglutinin. Hemolysis does not

always occur *in vivo*, when donor and recipient belong to different iso-agglutination groups because but about 20 per cent. of sera that are agglutinable are hemolytic. Hemolysis, however, never occurs without being preceded or associated with agglutination. If hemolysis is present in the plasma of donor or recipient, or both, hemolysis may not occur, or may cause but a slight reaction *in vivo*, because of the following factors and their quantitative relation to each other: concentration of the hemolysin, concentration of the anti-hemolysin, and a certain degree of absorption of the hemolysin by the hemolyzable cells. In discussing these factors it was pointed out that in certain instances the knowledge of the strength of the anti-hemolysin might be of value.

3. Gastric Ulcer Experimentally Produced by Means of the Staphylococcus Organism.—Edgar C. Steinharter states that the purpose of his note is to record briefly some observations relating to the production of gastric ulcers by means of the staphylococcus organism and a decinormal solution of acetic acid. The organism was obtained from a case of septicemia in man. Rabbits were used in all the experiments. Based on the study of forty injected animals, the following statements are made: 1. Typical peptic ulcers varying from one quarter of an inch in diameter were produced by injecting locally into the stomach wall the staphylococcus organism of certain grades of virulence and a weak acetic acid solution. As staphylococcus cultures would not answer the purpose, an organism of especial virulence, for instance, one freshly isolated from the appendix, was necessary to produce the lesion. (a) The injection of the organism alone usually caused the development of a small localized and firmly walled off abscess at the point of injection. Such an abscess as a rule was absorbed in the course of four to six days and never showed any involvement of the mucous or peritoneal coats. In some cases no abscess was formed. (b) The introduction of the acid alone into the stomach wall beyond causing more or less edema provoked no gross pathological change in the tissues. It certainly never caused an ulcer; but it did seem to increase the susceptibility of the area for localization of the staphylococcus injected into the general circulation. 2. The tendency of selective localization in certain organs was found to depend, among other things, upon the virulence of the organism and could be modified by cultivation in functioning tissue. For instance, a culture of the organism isolated from a joint was apt to form on intravenous injection a septicopyemia with abscesses predominating in the skeletal and myocardial muscles, that from the appendix showed an affinity for the intestinal tract, so that at times the appendix was the only organ revealing any gross lesion. In the light of the above results, it seems possible that the staphylococcus is responsible for certain cases of gastric ulcer in human beings. If by some means through an erosion, or trauma, etc., a hyperacid gastric juice enters the tissues of a limited area of the stomach wall and the staphylococcus of proper virulence, for example from the appendix finds lodgment there, it does seem quite probable that the necessary conditions used in producing the experimental ulcer would be duplicated.

6. Longitudinal Inversion of the Colon.—Robert T. Morris points out that the study of focal infections is one which is to engage the attention of the medical profession more and more. In this line of observation we are to find explanation, not only for infections of the joints, and for certain obscure lesions of the vital organs, but we are to bring up the whole question of physical decadence under microbic influence. There is no question that the colon carrying an excess of bacteria of many kinds has been responsible for distant effects to an extent of which we were not cognizant in the past. The prompt relief or disappearance of certain neuroses, and even of certain psychoses as a result of some of the more severe operations of the school of Lane, will stimulate us to devising milder means for attaining the same end. Some years ago Blake devised a method for infolding the wall of the distended cecum, and it seemed to Morris that we might extend this idea to include practically the whole colon, leaving simply room enough for the passage of mucus. When we are to dispose of the colon in this way it is desirable to make a short circuit of the bowel between the cecum or lower ileum and a part of the sigmoid colon. This first step is accomplished in any one of the easiest ways. The next procedure consists in carrying a silk or linen suture in mattress form between two lines of longitudinal muscles of the colon in such a way as to invert the wall of the colon and to retain it in the folded-in position. This procedure narrows the lumen of the colon longitudinally, but we at once perceive a tendency for pouching of parts of the colon which lie between longitudinal muscle bands. They bulge and escape from the suture. In order to overcome this feature a suture is introduced which we may call the accordion suture. The accordion suture traverses two or more protruding colonic pockets and then is brought back upon itself in such a way that when the suture is tied these pockets are compressed very much as the folds of an accordion would be compressed when the instrument is closed. A series of the accordion suture introduced rapidly just beneath the peritoneum, or through the muscle coat, not only disposes of the bulging parts of the colon, but shortens the bowel very decidedly. The procedure is not practical for patients who have a fat, heavy omentum, or large masses of fat epiploic appendages. The condition, however, is one which we are not so apt to find in the class of patients who are suffering from chronic colonic toxemia. They are more apt to be of the thin nervous type. We shall sometimes find it necessary to divide one leaf of the great omentum in order to carry the suture properly, but when the omentum is thin and devoid of fat such division is not necessary. The question which arises in the mind of Morris is whether these sutures will remain permanently in place, and if the adhesions which follow suturing will maintain the bowel in its new form. We all know the natural tendency for structures to return to normal conditions. In cases in which Morris has employed this method the colon apparently has not escaped, but he has no way of determining the point.

7. The Five-Glass Catheter Test.—Abr. L. Wolbarst in the MEDICAL RECORD, April, 1906, and in *International Clinics*, 1912, described and reported a multiple glass test for the determination of the source of pus and shreds in the male urethra. The five-glass catheter test is performed as follows: The patient presents himself with a full bladder, having retained the urine several hours, the longer the better. The meatus is cleansed so as to remove adherent secretion. The anterior urethra is first irrigated with a bland solution of sterile water, the washings being collected in a clean receptacle

held between the legs. Either a hand syringe or an irrigator may be used. In the average case of chronic urethritis, from three to five ounces of irrigating fluid are usually sufficient to thoroughly empty the anterior urethra of its inflammatory contents. The washings are poured into a clean glass cylinder. One or more subsequent washings determine the fact that the urethra is absolutely clean as far backward as the cut-off muscle. The clean washings are poured into a second cylinder. A sterile catheter of fine caliber is now introduced into the bladder. This constitutes the unique feature of this test. An ounce or two of urine is now drawn off into glass 3. This is the bladder urine obtained without contact with the posterior or anterior portions of the urethra. If this urine is clear and sparkling as normal urine should be, we know beyond peradventure that the bladder and upper urinary tract are not the source of the pus or shreds. The catheter is now withdrawn and the patient voids an ounce or two of urine into glass 4. It is evident that pus or shreds passed in this urine must of necessity originate in the posterior urethra, both the bladder and the anterior urethra having been eliminated. If the prostate is normal, however, the urine passed by the patient over the cleansed anterior urethra will of necessity be as clear as that drawn from the bladder, via the catheter. A further step is to massage the prostate vigorously, and have the patient urinate in glass 5. This gives us the "massaged prostatic urine." And if we desire to proceed with further refinements we may strip each of the seminal vesicles separately, each time having the patient void his urine into glasses 6 and 7 respectively. Wolbarst does not attach much significance to the last two glasses, as a rule, because of the inherent difficulty of separating the prostatic from the vesicular secretions. We are thus enabled to obtain washings from the anterior urethra, posterior urethra, and bladder in a most unmistakable and certain manner, in addition to the urine obtained after massage of the prostate and stripping the vesicles. Wolbarst firmly believes that a more widespread knowledge and employment of the five-glass catheter test, as described above, would result in more accurate diagnosis, and consequently more satisfactory therapeutic results, in difficult and obstinate lesions involving the lower urinary tract. This applies to the determination of the source of blood as well as pus.

3. **Umbilical Dyspepsia.**—Charles D. Aaron explains that a defect in the abdominal parietes preventing closure of the umbilical canal results in what is known as a congenital opening. This opening may be at first very small, so small as to escape the notice of the examining physician and later assume large dimensions, but is always congenital in origin. All these patients have symptoms of nervous dyspepsia due to increased

irritability of the autonomic nervous system. Appetite is apt to be capricious, while sometimes a food will agree with a patient and sometimes disagree. Complaint is made of fullness of the head, headache, inability to work, vertigo, lassitude, and depression. He may have a feeling of heaviness after eating. The patient is usually constipated and the nutrition so long as he partakes of adequate nourishment is good. Deep palpation with the ball of the finger over the umbilicus elicits severe pain. This may radiate in different directions or be referred to some distant part of the abdomen. As soon as the pressure is released the pain ceases. The diagnosis is made by the pressure pain over the umbilicus, together with the discovery of the failure of parietal union. The chemical examination of the stomach contents in all these cases shows a hyperacidity. As for treatment the principal idea is to eliminate irritation of the umbilicus. This is best accomplished by bringing the edges of this congenital opening as close together as possible with adhesive plaster, 12 inches wide and long enough to extend from 2½ to 4 inches on either side of the umbilical opening. The surface of the abdomen where this is to be applied is thoroughly cleansed with soap, water, and alcohol. One must be particularly careful that the umbilicus itself is well cleansed. If there is an excessive growth of hair on the abdomen, it is shaved off with a safety razor. The first piece of adhesive is applied in the following manner: The edges of the navel are approximated by an assistant and the strip of adhesive is applied directly over the umbilicus and drawn as tightly as possible. Without an assistant the binding can be done by applying the adhesive to one side of the abdomen and then pressing with the hand on the opposite side, and fastening the other end of the plaster to this side. The remaining two strips of plaster are fastened so as to overlap the central strip above and below. In this manner Aaron has been able to give almost immediate relief from pain and the distressing symptoms. This treatment is usually continued from four to ten weeks. The medical treatment is determined by the character of the gastric secretions. In cases of hyperchlorhydria the alkalies are given. The presence of vagatonia necessitates the use of belladonna or its alkaloid, atropin. Aaron has also found the bromids of valuable assistance in bringing about recovery, especially in cases which show symptoms of depression. The appetite may often be stimulated, if necessary, by the use of stomachics or other bitters. The diet should be composed of rich, nourishing, easily digested foods, it being advisable to increase the amount of butter, milk, eggs, cream, and other articles of a similar nature.

6. **Sex Gland Implantation.**—G. Frank Lydston points out that he has already shown that for hormone therapy purposes, successful total or partial hetero-implantation of human sex glands in both male and female is practicable. By "successful" implantation he means the formation of new blood supply, and a more or less prolonged existence of the gland with coincident hormone production. The prospect of success from anastomotic implantation, with resulting generative functioning, at present is not brilliant, though possibly not hopeless. Glands taken from the living subject are most desirable, though rarely obtainable. Glands taken from the healthy dead body at any time prior to the beginning of decomposition are of therapeutic value equal to that of those taken from the living, if implantation is successful. In human beings the glands of the male may be successfully implanted on the female and probably the reverse obtains. The tissues of the female apparently are more hospitable to the implanted male sex glands than are the tissues of the male. All conditions incidental to sex gland mutila-

tion in either sex afford a positive indication for sex gland implantation, the probability of benefit being inversely as the length of time that has elapsed since the mutilation, and dependent on the age at which it occurred. In properly selected cases successful implantation ought inevitably to increase physiological efficiency with all the benefits accruing therefrom. In general, all morbid conditions, in which malnutrition exists are likely to be benefited by the sex hormone, which is a powerful physiological cell stimulant and nutrient. As Lydston has already demonstrated, microscopic sections of implanted glands apparently show regeneration of the circulation and of the interstitial connective tissue which inferentially produces the so-called internal secretion. What is true of the sex glands also is true of all other glands which produce hormone. All hormone-producing glands from dead bodies are available sources of material for hormone therapy. Emulsions of glandular organs from dead bodies apparently are available sources of material for hormone therapy. Emulsions of glandular organs from dead human bodies, acting in a less degree but in a manner similar to implantation, may be of therapeutic value, and possibly superior to the so-called extracts, and to desiccated substances from the glands of the lower animals. Lydston gives some cases in which he had performed implantation from one of which he drew the following conclusions: (1) A relatively large dose of hormone is necessary to perfect development of secondary sex characteristics. (2) A very small dosage is sufficient to preserve virility. (3) Once virility is established, an extremely small dosage of sex hormone will preserve the psychosexual and physiosexual characteristics that are so essential to potency. Not only does he feel strengthened in his heretofore published impressions of the value of sex gland implantation, notably in the matter of increasing physical efficiency, but also is convinced that when technique and material are right, and the recipient properly selected, preservation of hormone production by the implanted gland for at least a prolonged period is certain. That permanent physiological and therapeutic advantageous results are equally certain, he is now strongly inclined to believe. Thus far he has observed no case in which the implanted tissue had completely disappeared, or even practically so, prior to twelve or eighteen months.

7. Intravenous Injections of Sodium Citrate.—A. L. Garbat says that before the adoption of the sodium citrate method of transfusion as developed by Lewisohn and Weil, can be more universal, two points of prime importance will have to be definitely established. (1) Is the sodium citrate *per se* harmful? Can it be repeatedly injected? (2) Is the blood when suspended in sodium citrate and transfused still viable and able to functionate? The last question will be answered by more numerous statistics than are at present available. Thus far most of the reports show encouraging results. From Garbat's experience of forty transfusions at the German Hospital, the beneficial effects compare favorably with those obtained by methods in which unmixed blood is used. In four patients not suffering from anemia who received repeated intravenous injections of a 2 per cent. solution of sodium citrate in distilled water Garbat states that by far the majority of the injections were well tolerated and were not followed by any apparent untoward symptoms. The examination of the urine showed no evidence of renal irritation. Thus it was concluded that sodium citrate *per se* is not harmful, even if repeatedly injected over a long period of time. These conclusions are then reached by Garbat: (1) The sodium citrate method of transfusion is not to be considered in any way dangerous because of the

sodium citrate employed. (2) A 0.25 per cent. solution of sodium citrate has been found more reliable in preventing coagulation.

4. Intramine: A New Antisymphilitic Remedy.—Harold Spence discusses the use of intramine, otherwise known as diorthoaminothiobenzene, in the treatment of syphilis. Intramine was introduced by Mr. J. E. R. McDonagh, and is a synthetic preparation of sulphur, and pending McDonagh's report, which will be made shortly, Spence gives a brief and non-technical summary of his views as therein expressed. Intramine is a mustard-yellow crystalline substance, soluble in alcohol, ether, and acetone, but insoluble in water. For intramuscular administration, the only manner in which it is at present employed, it is suspended in oil in the proportion of 1 gram in 10 cubic centimetres. This readily passes through an ordinary intramuscular needle, and is administered precisely as gray oil is given, the needle-hole being preferably sealed with collodion to prevent leakage, and the possible supervention of a slight dermatitis. Up to 12 grams have been given, but full therapeutic effect is obtained with 1 or 2 grams, repeated in a few days, if required. Local pain after administration is a variable symptom, some patients complaining of severe and persistent pain, while others, and especially those accustomed to intramuscular injections of mercury, may experience nothing more than slight stiffness. There seems no objection, however, to the addition of a local anesthetic, particularly with female or nervous patients, and Spence prefers quinine and urea hydrochlorid, the anesthesia from which lasts several days. Injections are best made at the point midway between the anterior superior spine of the ileum and the upper end of the natal cleft the needle being directed forward, inward and slightly upward. From 24 to 48 hours after injection a rise of temperature and some malaise may be looked for, but rarely does the thermometer reading pass 103° F. The induration at the site of injection disappears in a few days and with ordinary care there should be no sloughing. The arsenic in salvarsan and similar remedies is not parasitotropic, but acts as a catalyst, multiplying the protective power of the host. This is of a chemico-physical nature, and consists in a process of absorption between the lipoid-globulin molecules of the serum and plasma cells and those of the parasitic. For its consummation the presence of active oxygen is necessary; supplied to the body chiefly through the action of a peroxidase upon a peroxide. Arsenic as a more powerful peroxidase greatly increases the natural defence. Aluminium and iron are even more potent and are non-toxic. After a time the ability of the host to produce active oxygen directly is lessened; hence it must be produced indirectly, by means of reduction, through the action of a perhydridase. The peroxidases are metallic, the perhydridases non-metallic; and in later stages of syphilis act in a manner analogous to aluminium, iron, and arsenic in early syphilis. Diortho-

minothiobenzene is an efficient symptomatic remedy, particularly in later secondary syphilis and its complications, and in recurrent and tertiary lesions. It has proved effective in some chronic processes non-syphilitic in character—*e.g.* lupus vulgaris and chronic leg ulcers.

6. Note on a Case of Heart-Block Showing Large Auricular Waves in the Femoral Tracing.—A. W. Falconer states that the following case was admitted into the Aberdeen Royal Infirmary on June 17, 1915, under the care of Professor A. W. Mackintosh, to whom the writer is indebted for permission to publish it. The patient, a male aged 60, had for some two months suffered from shortness of breath or exertion, but he had continued at work up to June 15. On that date he had an attack of giddiness and vomiting. On attempting to get out of bed next day he lost consciousness and came to himself on the floor with a cut on his head. On admission to hospital the patient lay in bed in any position without discomfort. His only complaint was the frequent occurrence of "queer turns," during which he frequently lost consciousness. While under observation he had numerous typical epileptiform attacks, associated with marked slowing of the pulse. The apex beat of the heart was in the fifth interspace, just inside the nipple line. There was a slight mitral systolic murmur. The ventricular beats were at times as slow as 12 a minute, and between the ventricular beats regular auricular beats could be very distinctly heard. These contractions could be heard both at the base and the apex, but were most distinctly heard over the apex. For some time after admission the pulse rate varied from 12 to 18 beats a minute. Two weeks after admission it rose to 60, but in a week it again fell to between 32 and 40. During the first two weeks the patient had numerous long ventricular pauses, many of which were accompanied by epileptiform or giddy attacks. During this period the breathing was very markedly of the Cheyne-Stokes type, but later with the diminution of the heart-block the Cheyne-Stokes respiration disappeared. For some days after admission the ventricular rate varied from 12 to 18 a minute, the auricular rate remaining constant at 78. The ventricular rate was never absolutely regular for more than a few beats, and there were frequent long ventricular pauses.

2. The Toxic Effects of Ethylhydrocuprein on the Eye.—George H. Oliver draws attention to the fact that it has been demonstrated that in certain infections induced artificially by virulent strains of the pneumococcus the microorganisms can be destroyed and the lives of the majority of the animals saved by the administration of ethylhydrocuprein. Frankel used this drug, which is a quinine derivative, in a number of cases of pneumonia, which was then epidemic in Berlin. His results were unsatisfactory as a very disagreeable complication occurred. This complication is the occurrence

of amblyopia. Oliver describes a similar case to which he was called in, where disastrous results ensued from the administration of ethylhydrocuprein. The patient took in all 120 grains and had practically lost his sight in a year's time from the administration of the drug. After that time he began to improve and has continued to do so up to date. Ophthalmoscope: Both discs now quite white with no trace of color; details not discernible. Vessels seem to have increased in size a little and a few very fine branches may be seen on the discs. Vessels in left eye are smaller than in right eye, and both arteries and veins have a double outline which extends far away from the disc. Apart from these changes, the fundus is quite normal in appearance. Pupils are dilated and contract very slightly to light and still oscillate. The writer is afraid that there is little hope of this patient being able to earn his own living in the future. The conclusion is that ethylhydrocuprein is a dangerous drug and its administration is to be carefully avoided. It may happily be discovered that much smaller doses than those given heretofore will suffice to destroy the pneumococcus.

4. Fecal and Intestinal Vomiting and Jejunostomy.—Victor Bonney, in November, 1910, published a paper in the Archives of the Middlesex Hospital, entitled "Post-operative Paralytic Obstruction of the Intestine, with Special Reference to Its Treatment by Jejunostomy." Therein he pointed out the fatal result in these cases was due to toxic absorption from the upper intestinal tract brought about by an acute ascending infection by *B. coli communis* and other organisms of the lower intestine in a state of exalted virulence and activity. He further pointed out that in these cases the bowel may be divided into three segments, each of which is in a different condition: 1. A collapsed portion. 2. A portion above it much distended with gas and fluid matter; and 3. A portion above that distended with gas and fluid matter, the fluid being more or less faeculent in character and identical with that vomited. He showed that in these cases it was proper to open the upper fluid containing segment in order to drain the reservoir of toxicity, and useless to open the middle gas-containing segment. During the time that has elapsed his confidence in the correctness of the views then expressed has been strengthened, and he holds strongly that in all cases of paralytic intestinal obstruction, whether primary or secondary to an organic obstruction or to peritonitis, when advanced to the stage of fecal, or short of fecal, intestinal vomiting should be treated by jejunostomy. The character of the vomited matter indicates the condition of the upper part of the intestinal tract, for where the vomit is fecal or intestinal the stomach forms the highest part of the fluid containing segment. This upper segment does not necessarily reach as high in every case of intestinal obstruction when it first comes under clinical observation, nor need it at first include any part of the small intestine; for if the primary obstruction is situated low down in the large intestine, the total area of distension may not, at first, extend above the ileocecal valve. In this phase, however, the vomit is neither fecal nor intestinal, but simply the stomach contents. In all cases of obstruction, however, the stomach and jejunum will eventually be included in the fluid-containing segment, and so soon as this occurs the fact is made patent by the change in the character of the vomit, which at first becomes intestinal and finally fecal.

8. The Treatment of Diabetes.—John Hume thoroughly inspects the mouth, has any defective teeth removed, and enjoins the necessity for thoroughly cleansing the teeth and washing out the mouth frequently. The fast he begins with is generally of about

fourteen hours duration. The best time to commence is in the evening, when he allows a light meal at about 5 p. m. Two hours after he gives a dose of castor oil. The patient can rinse out the mouth with warm water, if desired, two or three times during the fast, but on no consideration must anything be swallowed, not even water, as he finds the results are not so satisfactory when water is allowed. At 9 next morning he gives a second dose of castor oil and then no food for two hours. By 11 A. M. the bowels have, as a rule, acted, and he allows the patient to have breakfast. There is, therefore, a period of absolute fasting between the two medicines. In succeeding fasts salines can be used, the object being to secure a through evacuation and to reduce the intestinal flora as far as possible. The patient can easily go through the same routine every second night, and after he has become accustomed to the treatment the duration of fasts should be prolonged by beginning earlier in the afternoon and extending them next day. At the end of two weeks a fast of twenty-four hours can easily be done two or three times a week. It is better in the earlier fasts to keep the patient in bed, as he finds they are more easily managed and it is pleasanter for themselves as they can more readily keep warm and do not have the same temptation to stop the fast as they would have if they were going about. In many cases the disappearance of the sugar is complete. He generally recommends, however, that there should be one fast of eighteen hours each week carried out in the same way. If a small quantity of sugar persists he recommends two fasts each week of about fourteen hours, and finds this quite sufficient to prevent the other symptoms of the disease from manifesting themselves and to allow the patient to attend to his duties.

Münchener medizinische Wochenschrift.

April 18, 1916.

Renal Edema.—Meyer refers primarily to edema of the kidney itself. We often find in autopsies on victims of Bright's disease that these organs are larger and heavier than natural because of serous saturation of both parenchyma and interstitial tissue. Edema occurs in both nephroses and diffuse glomerulonephritis, and in different stages of either; and it disappears after recovery, but also after cirrhosis has set in. Thus far we have known nothing clinically concerning renal edema, and of course there has been no indication for treatment. The author gives a specimen case, in a young woman with a high degree of anasarca, and other evidences of a nephrosis, as marked oliguria and hydremia. The causes could not be determined. It was necessary to puncture the limbs, since neither diet, heart stimulants or diuretics could unburden the kidneys. In the first twenty-four hours nearly 12,000 c.c. of fluid were evacuated in this manner, and on the second day over 2000 more. Diuresis now came about per se, but after five days of free secretion of urine the former state of edema and oliguria returned and necessitated further puncture. The resulting benefit was more lasting and patient now responded properly to salt-poor regimen; but has by no means recovered, as the ankles remain swollen and albuminuria persists; in fact, the kidneys are clearly the seat of a degenerative process or nephrosis. All evidence from the urine, when the affection was at its worst, pointed to a condition of dropsy of the kidneys—of edematous stasis—with production of a vicious circle. The pent-up serum must have compressed the functioning renal cells. The patient complained of headache, vertigo and vomiting, but there were no changes in the fundus oculi, and the

heart and blood pressure remained normal. In theory decapsulation was indicated, but the author obtained a good result with a much safer intervention. Evidently there are two types of cases in regard to indications for the two forms of surgical relief.

Etiology and Therapy of Pruritus Vulvæ.—Heusler-Edenhuizen, a woman gynecologist, reports a number of cases of this condition concerning which, aside from the diabetic form, she does not find clean-cut views on nature and treatment. The secretory surfaces, i.e. those upon which secretions may stagnate, appear to be the areas of predilection (clitoris, inner side of labia minora, perineum). From these localities the affection may extend forward and backward respectively, involving the external genitals and anus. The secretions, whether urine, mucus, or leucorrhea, become pent up in certain positions, and escape when the latter are changed. Lack of cleanliness, action of microorganisms, and decomposition products are all factors. The irritating discharges cause excoriations and other secondary lesions, to which must be added effects of scratching, of menstruation, etc. Hence vicious circles are constantly at work. Practically cases fall under two heads. In one there is no fluor albus, no external lesions, and the author simply sterilizes the vulva and applies iodine tincture, 10 per cent., with powdered zinc oxide as a desiccant. There may be needed a second application of the iodine, but the pruritus usually subsides under simple cleanliness. In the second group of cases we have to deal with an eczema or dermatitis, with at time thickening and fissuring of the integument. These alterations, even when chronic, can undergo involution if the irritating secretions can be dealt with. The author keeps the vagina dry by means of a dry tamponade, but this resource can only be used at the outset because of the need of frequent change of dressings. The introduction of dry powder into the passage is the principal dependence. To allow the eczema to heal, water must not be allowed to come in contact with the altered surfaces. Oil is applied about the meatus and anus before urination and defecation. Iodine tincture is applied as in the milder cases, and much use is made of zinc-oxide powder as a desiccant.

War Psychology.—Fuchs states that the great war has passed from the status of an expedition to that of a steady occupation. God knows when it will end, and in some respects it is just beginning. How does the psyche react to such convictions? At first it did so in a sort of martial ecstasy. When the siege, the deadlock feature became confirmed, two viewpoints were manifest. One was that of resolution to go ahead with what had been begun. This stable, constant fraction was much larger than the other, which showed a decided lability, probably a reaction from initial over-optimism. Euphoria was succeeded by a state of resignation. Were this viewpoint held by a majority it would mean that the Germans were not a people of the first order. The great mass of the people, although disillusioned in some ways, remain steadfast, but firmness is now associated with scientific insight—clearness of view with clenched jaws. We recall, says Fuchs, the seven-year-long struggles of the great Frederick, which would have been seven times seven had the need arisen. As is always the case the man in the hinterland, whose life is not directly menaced, is the one who wants peace, who acts as a boding Cassandra. The warriors learn daily more of the art of war, and war is a series of adaptations. The Germans are now in a new phase of psychic development, which has brought about the pacifist schism, but ultimately it must pass into still another, with everyone active for his own existence, and then will come solidarity.

Münchener medizinische Wochenschrift.

April 11, 1916.

Sudden Death in Chloroform Narcosis.—According to Hering, cats and dogs may die at the beginning of chloroform narcosis, and the more excited they are the more suddenly death may impend. This form of death is due for the most part to overexcitation of the cardiac chambers or heart flutter. In other words, we have a secondary cardiac death. In man the same mechanism doubtless holds good, whenever all at once the action of the heart is not in evidence, although respiration persists. In these human cases excitement also plays a rôle, and if these deaths were more closely studied it would no doubt be found to coexist more frequently than we think. As extrasystole stands in some relationship with heart flutter and can even pass directly into the latter it is best to give no chloroform to any patient with extrasystole, even when the latter occurs only episodically. We also have means for determining latent extrasystole and should extend the contraindications to chloroform to this class as well. Adrenalin may be made to provoke extrasystole in a heart already affected, but not in a heart which is clinically sound. Irritation of the cervical vagus may produce not only an occasional extrasystole but at times extrasystolic tachycardia and even auricular flutter.

Anatomy and Histology of Typhus Fever.—Bauer states that Fraenkel's original discovery of the specific histological character of the typhus exanthem has now been abundantly corroborated. It is the last refinement in differentiating typhus from typhoid and other conditions. In doubtful autopsy cases in which the intestines are not involved simple microscopic examination of a section of nodule will make the diagnosis of typhus. The author here cites a case in which the viscera exhibited nothing characteristic of the latter and states that another specific lesion, to wit in the spleen, made the diagnosis of typhus. This lesion is a hyperplasia of the lymph follicles in a nearly normal spleen. It has thus far never been encountered in typhoid, malaria or other affection. The question naturally arises, is there any connection between the changes in the skin and those of the spleen? and may similar changes be found in other organs which may suffer in typhus such as the kidneys? *A priori* the likelihood of such a homogeneous find is great because in Fraenkel's lesions of the skin the arteries formed the starting point. The author now submitted to examination sections of the spleen, kidneys, stomach, intestine and thyroid and in every organ found the characteristic changes in and around the intima of the arteries. Again if we inject the blood of typhus patients into the veins of guinea-pigs, and after about three weeks chloroform the animals to death we find not only gross lesions which resemble those of typhus but also the characteristic alterations in the small arteries. These discoveries will be of the greatest importance. No longer can typhus mask itself as typhoid or influenza or cerebrospinal meningitis or under the extreme variations of type sometimes seen, for it will only be necessary to make the histological test, preferably in the corium.

Experience with Albee's Operation for Spondylitis Tuberculosis.—Vulpus, the veteran orthopedic surgeon, reports a series of thirty cases of the above association. He saw Albee operate in Germany, but the intervention is still hardly known in that country. That is to say, while the operation may be known *per se*, nothing is known of end results. Hence from the last viewpoint twenty-four cases once operated on have been re-examined, and six others have been heard from by mail. The ages of patients varied from 3 to 45 years. The technique of operation is very simple and the course of

healing was smooth in all but three cases in which small sequestra had to be expelled. The intervals between operation and the last examination extend up to 2½ years. The subjective improvement was prompt and striking. Pain ceased, the patients became supple and active, on their feet most of the time. The rigidity of the spine at the site of the operation was compensated by increased mobility of the other vertebrae. The grafted bone appears eventually to undergo a certain amount of absorption. There was a single death in the series, in a child, from tuberculous meningitis. Paralysis was never seen. In summing up Vulpus commends the operation earnestly.

Intravenous Infusion in the Field.—Friedemann agrees with many of his army colleagues in pronouncing ordinary subcutaneous saline infusion a failure on the battlefield. Intravenous infusion of the continuous drip type gives much better results. The rate of infusion is from thirty to 200 drops per minute and it may be kept up for hours after the operation. Digalen, strophanthin and adrenalin may readily be exhibited in the infusion. Before operating on a severely wounded patient who is shocked, anemic, and practically pulseless, the cubital vein is at once opened with scissors; a glass cannula sutured in and connected with a piece of tubing and container for the infusion. A Martin's glass ball makes the dripping perceptible, and a screw-clamp regulates the water flow. Water is allowed to infuse until the pulse beat can be felt, and not until then is it allowed to drip at the rate of 200 drops per minute. In a given case of abdominal wound laparotomy is now performed and blood and fecal matter removed. If the pulse is beating well the rate of dropping is reduced to 100 per minute, then to sixty, then thirty. Too much water can do harm, and an attempt must be made not to exceed four or five liters in twelve to twenty hours. The indications are medical as well as surgical—cholera, dysentery and severe diarrhea, as well as shock and hemorrhage. While the rectal drip may replace the method in mild cases, it should not be used as an accessory, because useless then.

Fermentative Diarrhea in Infants.—Lewis Webb Hill discusses the carbohydrate form of fermentative diarrhea in infants. He says it must be remembered that the condition is due to one thing, a fermentation of carbohydrate in the intestine and excessive acid production, with consequent irritation of the mucosa, and increased peristalsis. Hence the stools are always acid and the one obvious and important principle in the treatment of a case of this kind is to give a food low in carbohydrate until normal conditions are restored. If at the same time this food can contain a considerable amount of protein, in a form which is easily digested, a great deal will have been gained. It is these characteristics which have made the "eiweiss" milk of Finkelstein and its various modifications valuable. The great drawback to these is their difficulty of preparation. The use of skim milk dilutions with the addition of powdered casein meets the indication, and such mixtures are infinitely more simple of preparation than any of the "eiweiss" milk preparations. The writer has treated his cases of fermentative diarrhea with a soluble form of calcium casein which he has found highly satisfactory. For babies under six months of age a mixture of skim milk and water is used with enough calcium casein to bring the protein percentage up to 2.60 per cent., giving the formula: Fats 0.25; sugar, 2.25; protein 2.60. The writer gives formula suited to different ages and weights of infants and recommends the use of malt sugar in making up the formula, as it ferments less easily than the other sugars.—*Boston Medical and Surgical Journal*.

Book Reviews.

THE PRACTITIONER'S MEDICAL DICTIONARY, containing all the words and phrases generally used in medicine and the allied sciences, with their proper pronunciation, derivation, and definition. By GEORGE M. GOULD, A.M., M.D., author of "An Illustrated Dictionary of Medicine, Biology, and Allied Sciences," "The Student's Medical Dictionary," "Pocket Medical Dictionary," etc. Third edition—revised and enlarged by R. J. E. SCOTT, M.A., B.C.L., M.D., Fellow of the New York Academy of Medicine, editor of Hughes' "Practice of Medicine," Gould and Pyle's "Cyclopedia of Medicine and Surgery," etc. Based on recent medical literature, with many tables. Price, cloth, \$2.75; leather, \$4.50. Philadelphia: P. Blakiston's Son & Co., 1916.

Great Scott! Where's Gould? is the involuntary exclamation of the reviewer opening this volume, which purports to be the latest of the so-called Gould series of word books. There is barely a trace of the eccentric spelling which has marred this series from its inception, and which rightly or wrongly has been attributed to the editor who gave his name to the work—the *e* is returned to the alkaloids and to the *-ides*; *ph* has come back to sulphur and *-al* to chemical; eyestrain and other ophthalmological terms are now defined, and many other improvements are evident. So now we have two dictionaries ostensibly by the same author—the "Practitioner's" with one spelling, the "Pocket Pronouncing" Dictionary with another—plainly a case of you pays your money and you takes your choice.

The present volume seems to be the former edition of "The Practitioner's Dictionary" with the addition of a large number of old words, apparently from Gould's "Illustrated Medical Dictionary," and a few words of more recent coinage. The claim is repeated in the preface of this edition that the book as regards its choice of words, is a *medio-tutissimus-ibis* dictionary, or in modern phrase a middle-of-the-road production; as the two editions are as unlike in this respect as two books can well be, it is difficult to see how the claim can hold for both; as a matter of fact this edition leans as far to the side of prolixity as the first did to that of incompleteness. The preface is also in other respects rather peculiar. The writers say, for example, that "if words exist and *are used*, they should be recorded," even if they are "obsolete"—that is to say if they *are not used*. They further state that more than one-third of a million copies of Gould's dictionaries are in the hands of the English-speaking practitioners of the world; as it is estimated that the English-speaking practitioners number about a quarter of a million, some 85,000 of them must be carrying a Gould dictionary in each hand. The book is well printed in clear but eyestrainingly small type and is externally quite pleasing to the eye, though the cloth binding does not look as though it would stand much hard use.

AUTOPLASTIC BONE SURGERY. By CHARLES DAVISON, M.D., Professor of Surgery and Clinical Surgery, University of Illinois, College of Medicine; Fellow of the American College of Surgeons; Surgeon to Cook County Hospital and University Hospital; and FRANKLIN D. SMITH, M.D., Clinical Pathologist to University Hospital. Price, \$3.50 net. Philadelphia and New York: Lea & Febiger, 1916.

IN this book we have a comprehensive study of the principles involved in the transplantation of bone with and without periosteum; a description of the process of bone regeneration and repair, including the rôles played by the different histological elements concerned in the process; a summary of the indications for autoplasmic bone surgery; a very convincing dissertation on the advantages of the autoplasmic bone graft and, conversely, on the disadvantages of metal plates and screws; a description of the instruments required and the technique of bone graft surgery under varying conditions and as applied in fractures in the different parts of the body; a chapter on autoplasmic immobilization in tuberculous spondylitis; chapters on autoplasmic repair of congenital and acquired defects and deformities of bone; and other matter germane to the subject. Not only the results of the authors' experiments and clinical studies are included, but when the experience and theories of others have differed from theirs the authors have impartially stated these facts and the reader is thus put in a position to weigh the evidence for himself and draw his own conclusions.

In view of this evident general willingness to give credit to others, it is a surprise to find the authors so apparently loath to give credit to Albee; for although one who is unprejudiced must concede that Albee has probably done more than any other one man in developing the technique of bonegraft surgery as it is practised to-day, we find but comparatively scant reference and attention paid to his work. It is true that Albee's method of spinal fixation is detailed by name and at length on page 305 et. seq., but there are certain points in technique referred to as "the author's" which we in the East have unhesitatingly credited to Albee. Doubtless each has worked independently and certain portions of the technique which each claims as "the author's method" happen practically to coincide.

While the book is unusually well written there are occasional inaccuracies of statement or nomenclature. For example, the author frequently speaks of obtaining grafts from the "spine" of the tibia when undoubtedly "crest" is meant. The illustrations are particularly good, but unnecessarily multiplied in many instances. However, the book presents perhaps the most comprehensive résumé of the theories and principles involved, as well as the technique in this branch of surgery, that we have seen; and while the importance of the intramedullary graft may be unduly emphasized and while we utterly disagree with the author as to the best method to be employed in certain special fractures, we have no hesitation in cordially approving the book as a whole.

HARVEY'S VIEWS ON THE USE OF THE CIRCULATION OF THE BLOOD. By JOHN G. CURTIS, M.D., LL.D., Formerly Professor of Physiology in Columbia University in the City of New York. Price, \$1.50 net. New York: Columbia University Press, 1915.

THIS book is based upon a lecture delivered in 1907 before the Johns Hopkins Hospital Historical Club at Baltimore and was uncompleted at the time of the author's death in 1913. The manuscript was arranged in form and the few omissions supplied by the author's successor, Professor Frederic S. Lee. Those who are familiar with the scholarly attainments of Professor Curtis will need no assurance of the depth of erudition displayed in the preparation of the book. He has discussed Harvey's writings on the subject and then shown how Harvey's ideas were developed and explained why he thought as he did. The work shows that Harvey was more a disciple of Aristotle than of Galen and was able to support his arguments creditably by his observation, limited as it was in his day by the lack of instruments of precision. To all those who are interested in the history of medicine the book will make exceedingly interesting reading and it will endure as certainly not the least of Professor Curtis' many contributions to medical literature.

NITRO BY HYPO. A Peptonized tonic for the Physician. By EDWIN P. HAWORTH, Superintendent of the Willows Maternity Sanitarium. Kansas City: The Willow Magazine Company.

THIS small book consists of some of the contributions to the Willow Magazine. They are humorous and instructive.

DIE PATHOLOGIE UND THERAPIE DES ILEUS. Von Professor W. KAUSCH, Direktor der chirurgischen Abteilung des städtischen Krankenhauses in Berlin-Schöneberg. Mit 6 Abbildungen im Text. Sammlung Albu, Band V, Heft 6. Price, M 1.40. Halle a. S.: Carl Marhold, 1915.

IN this brochure of about 50 pages Professor Kausch has given a very comprehensive discussion of the subject, starting with a differentiation of the various forms of ileus and their etiology, the pathogenesis of ileus, and so on through the symptomatology, diagnosis, differential diagnosis, prognosis, and treatment. Under this latter heading the medical treatment under certain conditions is discussed and approved; but the author takes pains to point out that a large percentage of the cases are surgical and that surgery, when indicated, should be resorted to early. About one-fifth of the article is devoted to the surgical aspects of the subject, and as a parting injunction he says: "At all events we can say this much, the earlier one afflicted with ileus, who can be cured through operation, is operated upon, so much the better are his chances; and many cases are lost because the attending physician calls in the surgeon too late."

This dissertation will well repay reading by internist and surgeon alike.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Tenth Triennial Session, Held in Washington, May 9 and 10, 1916.

(Special Report to the MEDICAL RECORD.)

(Concluded from page 931.)

Wednesday, May 10—Second Day.

THE PRESIDENT, DR. WILLIAM S. THAYER, IN THE CHAIR.

THE subject for discussion at this session was "Immunization and Its Practical Applications."

The Underlying Problems of Immunization.—Dr. THEOBALD SMITH of Princeton presented this communication, in which he said that the underlying principles of immunization were twofold. We had, in the first place, the plain practical problem to prevent or to check disease by applying the methods copied from nature and improving upon them in the interest of man, if possible. Secondly, we had before us the problem of discovering the *modus operandi* of resistance to disease, the sequence of events which were associated with recovery on the one hand and with complete resistance on the other. The object of immunization was to raise the resistance of the body from a lower to a higher level. The remarkable effectiveness of smallpox vaccination had left the impression that immunization against any disease always meant complete protection from that disease. We missed here the quantitative concept which was involved in all life processes. We must accept the fact that no kind of vaccination would be invariably and completely protective. We might, however, hope to convert a fatal into a non-fatal attack, a mild attack into one so mild as to remain unrecognized, or into complete protection. As long as the susceptibility of individuals varied toward the same infecting agent we could not expect the same treatment to bring all to the same level of resistance. Nor was it possible with the same treatment to protect equally well against agents of high and low virulence. To neglect the quantitative side of immunization was to bring the process into discredit, because our claims could not be justified. One of the problems bearing on this phase of the subject was a better study of spontaneous mild disease as a result of exposure in the vaccinated individual and of attacks which might not be recognized by older clinical methods and which even the patients themselves might overlook. For our present conception of acquired immunity we tacitly assumed that after every exposure there was some, however slight, multiplication of the virus necessary to wake up the immunizing mechanism. In working out such problems of immunity the essential factor to be kept in mind was to raise such resistance with the least injury to the subject. The direction which immunization was to take depended upon the etiological factors involved. There were primary and secondary infectious agents in most diseases. It was generally conceded that if we protected against the primary agent the others were thereby kept suppressed. The assumption underlying this view was that the secondary agents played no part in giving the primary agent an opportunity to infect, but that the reverse was true. This, however, had not been proved. When it came to an actual outbreak of diseases the situation was changed; the main or primary disease would run its course satisfactorily if the complications could be kept away. The question then at issue became a choice of vaccines toward possible secondary invaders. The general rule that a single attack of a disease protected for life was subject to many limitations. All acquired immunity was a perishable commodity. This question was complicated by several factors, among which were the following: (a) The human body became more resistant to infection with age; (b) there was a possibility of reinfection without clinical signs which would maintain and strengthen any immunity obtained in infancy and childhood. There was a clearly marked distinction between groups of microorganisms as to the capacity of the host to be immunized experimentally. With some the attempt was much more readily successful than with others. Those bacteria which acted only through their toxins were most easily kept in check by immunization. Next came the group of acute septicemic diseases, such as those due to bacteria which were quite perishable, including the group of pneumococci and bi-polar bac-

teria. Bacteria-producing diseases of longer duration appeared difficult to suppress in proportion to the chronicity of the affection. To these general rules there were, of course, exceptions. Endemic disease led to relatively heightened resistance. Since most of the diseases in question were due to parasites which survived and might persist in the blood during a lifetime—which, in other words, were able to subsist in an immune host—the most rational explanation of this immunity was that based on the transmission of immune bodies to the offspring. Among the established facts in immunology was the greater efficacy of living virus over any other; the practical application of this fact, however, encountered many obstacles. There was the degree of permanency of the attenuation, which must be carefully considered. Besides the attenuation of homologous viruses, the finding of naturally attenuated strains was a possibility to be considered. The preconception that strains of low virulence could not immunize toward highly virulent strains should not stand in the way of actual trials. Next to living virus, the bodies of bacteria killed by heat seemed to have the best chance of producing immunity. The success or failure of this method would depend theoretically on what was the important antigen. If the aggressive activity or virulence of microorganisms was rapidly lost after isolation from the tissues, the effectiveness of cultures killed by heat, or otherwise, would naturally depend upon the total age of the cultures used, provided the factor of virulence was not completely destroyed when the bacteria was killed. The evident success of this method in preventing an attack of typhoid fever was encouraging for this method of vaccination. The relative efficiency of sensitized vaccines probably depended upon a quantitative relationship between the antiserum and the bacilli. For diphtheria toxin and antitoxin this could be definitely controlled. It was difficult to see just how a similar accurate titration of immune serum and bacteria could be made in terms of any assignable units at present. The only way open was to inject series of mixtures of variously sensitized bacteria and await results. The explanation for the very effective immunizing power of sensitized toxins depended upon the greater penetrating power of such mixtures. The toxin appeared to travel farther in combination with the antitoxin than when free. Perhaps the last word in immunizing methods was the use not of living or dead virus but of distinctive parts thereof. Theoretically, the attempt to find the chief antigen of a microorganism and exclude all others as either unimportant or harmful was just as justifiable as the attempt to immunize the body toward the chief or primary infection, letting the secondary infection alone. Of a series of antigens there might be one which represented the primary, and therefore the most important, aggressive or protective agency of the virus, and which if introduced in abundance might produce that degree of resistance which later would interfere with the beginning of the infective process. The study of partial antigens opened up a wide field for speculation as well as for difficult and painstaking work. The recent developments in immunological research indicated that medical science was moving away from the doctrine that the toxins or poisons of bacteria were the chief substances against which immunization was to be directed. That they were responsible for most of the injury inflicted must be granted, but the inquiry might be a side issue not in line with the main events. The object of immunization was to suppress the invader; the problem underlying was to find the precise aggressive weapons which permitted the invader to multiply. The capacity of microorganisms to enter and multiply in the tissues of the host might or might not be due to the direct action of the toxins. If not, it would be useless to immunize them. However, when we came to treat disease in actual progress the neutralization of toxins might be a very important step.

Vaccine Treatment.—Dr. LUDWIG HEKTOEN of Chicago discussed the more recent developments in connection with vaccine treatment. He said that curative vaccine treatment was a direct outgrowth of the increasingly successful prevention of various infectious diseases by means of artificial immunization, and might be said to be a culmination of the efforts to combat infection with its own weapons, as it rested primarily on the assumption that under certain conditions the production of specific antibodies by the infected organism could be increased with curative results on injection of special preparations of the virus of the bacteria which caused the infection. Whether the practical results of vaccine treatment for curative purposes supported the

hypothesis as to the mode of infection on which it was based was even now a debatable question. Various practices had been introduced which were not in harmony either with the conditions demanded by the primary hypothesis or with the teachings of bacteriology and immunology, and which before long reduced vaccine treatment as generally practiced from a carefully controlled, essentially scientific procedure to one of guesswork and routine. The first departure from the course of safety and conservatism was the uncontrolled delegation of the making of vaccines to commercial concerns. According to fundamental principles, every consideration except that of expediency demanded that therapeutic vaccines should be composed of bacteria as little different and as little removed as possible from the strains causing the infections against which the vaccines were to be used. It was evident that in preparing vaccines on a large scale this condition could not be met, because the changes in virulence and affinities which took place in bacteria under artificial cultivation could not be avoided. Indeed, there was danger that with time the specific element on which the desired antigenic effect depended might be lost altogether. There was the further difficulty that the antibodies evoked might not act on the other strains of the same species. That this was not placing undue importance on some remote possibility was shown conclusively by the regular occurrence of fixed varieties according to immunogenic properties in certain species of pathogenic bacteria as illustrated by the pneumococcus. So far as was now known there were no all-inclusive strains of bacteria causing human infections which might be used to overcome this narrow specificity of immunizing action. In recognition of this drawback the polyvalent vaccine was evolved. This was an unsatisfactory substitute for the fresh autogenous vaccine which, it would seem, offered the best hope that the indication of each case at all times would be met in the most direct way. The principle of using autogenous vaccines, as a rule, had the further and great advantage that to secure it the definite etiology of the infection must be established. A true etiological diagnosis must be made and there was an end of guesswork. Undoubtedly the good results obtained by careful scientific physicians who used autogenous vaccines were due in no small degree to the careful study of the patient, whereby was disclosed not only the nature of the outstanding infection but in many cases also hidden bacterial foci that often perhaps were the primary source of the evident localizations and hence required removal before permanent cure could be established. As to the cultural filtrates, no reason could be found to warrant their use as vaccines; and their immune values had not yet been determined. At the same time the commercial vaccines contained no autogenous elements, and there was the further evident objection that there existed no such constancy of bacterial association in mixed infections as would permit the use of ready-made mixtures under the principles of specific vaccine treatment. Why not follow the simple and rational plan of mixing vaccines at the time of injection or of injecting them separately? With the readily available stock vaccines the vaccine treatment was extended to all forms of infection and even to conditions clearly not infectious in nature, regardless of whether there was any good reason to believe that benefit would result from efforts to stimulate the output of specific antibodies under all these circumstances. As would be expected, the interpretation of results often had lacked the discrimination and questioning which accompanied the efforts of critical intelligence. The simple fact was that we had no reliable evidence to show that vaccines, as commonly used, had the uniformly prompt and specific curative effects proclaimed by optimistic enthusiasts. While uncertainty and disappointment had developed in regard to the usefulness of vaccines, this must be ascribed rather more to the fault of exploitation than to the fault of the thing exploited. The original theory of vaccine treatment really furnished no basis for the application of vaccines to acute infectious diseases, and when, nevertheless, reports were made of good effects from vaccines in acute diseases, such as typhoid fever and pneumonia, we had no preconceived or readily available explanation to offer for the unexpected results. This brought us to the consideration of the remarkable development during the last year or two of the vaccine treatment of typhoid fever. After reviewing the history of the use of the vaccine treatment in typhoid fever, the essayist stated that at present it seemed to be the opinion of almost all who

had used the intravenous method of injection that by it the course might be modified and shortened and in a considerable number of cases a cure by crisis might be produced. The occurrence of recovery by crisis in from 30 to 40 per cent. after intravenous injection certainly could not be ascribed to any chance spontaneous cure. The subsequent course of the disease might be a permanent return to normal temperature and prompt recovery, or a rise of temperature to the previous level and then a gradual fall to normal in a few days; or the attack might be resumed, running an apparently unmodified course, or a milder course than before the injection. When the attack was resumed reinjections after a few days might cut it short. Crisis had also been produced in typhoid fever by the injection of colon vaccine, mouse typhoid vaccine, of meningococcus vaccine and even albumose. In infections other than typhoid, nonspecific products injected intravenously might cause acute reactions also; as, for example, typhoid vaccines in paratyphoid fever, colon vaccines in puerperal sepsis, etc. In short, it might be said that the injection of protein substances might produce a reaction which, at least in some respects, closely resembles the chill and fever which occurred naturally in the course of various infections. In subacute and chronic localized infections the results appeared to indicate that specific vaccines properly and skillfully used had value, most likely because they increased the production of specific antibodies, as demanded by the theory, but probably also because they stimulated leucocytic and other activities. In typhoid fever, and possibly in other infection diseases, the intravenous injection of specific vaccines and also of other substances might induce crisis and appeared to hasten recovery. The mechanism of this effect was not fully understood; but as it involved something more than, and different from, specific stimulation of the production of antibodies, it could not be interpreted wholly in terms of the current conception of the action of vaccines. It appeared that we were entering a new and interesting development in the study and treatment of infectious diseases.

Serum Therapy.—Dr. WILLIAM H. PARK of New York presented this paper. He said the advisability of using sera in any particular disease was influenced by a number of considerations. The primary one was whether a serum had been obtained and was available which contained antibodies of suitable kind and amount to neutralize the toxins or aid the body cells or ferments in destroying the microorganisms. Others almost equally important were whether the infections could be identified from clinical signs alone, or only after additional laboratory examinations, and whether the sera could be brought into contact with the toxin or organisms at the essential points, in the necessary concentration, and within the required time. In the light of these considerations he first considered pneumonia, reviewing the work of Dr. Rufus I. Cole, who, judging from the examinations he had made, believed 75 per cent. of all lobar pneumonia cases were caused by pneumococci of three strains, which he had called Type I, Type II, and Type III, and that the remaining 25 per cent were caused by a multitude of strains so numerous that in a moderate number of cases no repetition of the same type was likely to be encountered. About 30 per cent. of the cases of pneumonia and about one-third of the total deaths were caused by infections with Type I. At the present time the results of serum injection seemed favorable in Type I, doubtful in Type II, and absolutely negative in Type III and Type IV. In Type I large intravenous injections of specific serum in about 30 per cent. of the cases were followed by an almost immediate chill, with a considerable rise in temperature, which lasted for a short period. This occurred after the first but sometimes after later serum injections. If the blood contained pneumococcus they disappeared within twelve hours after the injection. The temperature usually rapidly fell after the initial rise to a point lower than before the rise, and the symptoms, as a rule, improved sooner than the average untreated case of equal severity. The mortality up to the present time had been much less than in the untreated cases. Serum sickness occurred in about 50 per cent. of the cases, and while very annoying was not dangerous. The serum should be standardized so that 0.2 c.c. of a recent serum would protect against 100,000 f.d. of a very virulent type of pneumococcus, and no serum should be put out that contained less than half that strength. Cole advised 80 c.c. of serum diluted with 80 c.c. of salt solution injected intravenously and repeated about every twelve hours until permanent improvement was noted.

Usually he gave three to five doses. Cole recommended that the serum be given only after the bacteriological test had shown the type, while Dr. Park said he believed in a severe case a first dose of Type I serum should be given as soon as possible and the later injections only after a bacteriological report. The treatment of cases should be considered from two points, one the good of the patient, the other the advance of knowledge. The severe cases that received an injection of Type I serum were considered only from the first standpoint. With the antistreptococcic sera the same reasoning applied as with the pneumococcic sera and the same dosage and method of administration. If it was suspected that the infection was with the hemolytic type we could rightly give this type of serum with the hope of some good results. If we suspected the viridans type a polyvalent serum of this type might be given with slightly less prospect of help. Before giving further injections the organisms should be identified. In epidemic meningitis the spinal fluid from every case should be examined microscopically, for in this way only could a correct diagnosis be made. Here, too, the strains differed; they had group relationships, and intravenous injection of suitably selected strains caused the horse to produce a serum capable of affecting almost all strains. The reports from England of failure to get good results under the serum treatment of meningitis might be explained by the great demand for the serum which led to the attempt to replenish the stock of serum by a too frequent bleeding of the horses; this resulted in a serum which was found at a later date to be poor in antibody content. Dr. Park then referred to the favorable results obtained in the treatment of early toxic cases of scarlet fever with convalescent serum or whole convalescent blood, and stated that 100 to 300 c.c. of fresh whole blood injected intramuscularly could also be used in acute and chronic exhausting diseases where the nutritive and bactericidal value of homologous protein was distinctly indicated. He then described the Schick reaction, and discussed the dosage of antitoxin in diphtheria. A single large dose of antitoxin had been shown to be more effective than a larger amount of antitoxin administered in several successive doses. If it were not for the disadvantages inherent in the intravenous method there would be no question that it would be the method of choice. It was necessary to weigh the indication for and against the method. There was no doubt that in cases that had been sick for twenty-four to seventy-two hours, and which showed a great extent of disease and symptoms of toxic absorption, 3,000 to 10,000 units of antitoxin intravenously was imperative. On the other hand, the mild or moderate cases might better be treated by a subcutaneous or, better, intramuscular injection. In discussing the methods of administering tetanus antitoxin Dr. Park stated that animal experiments had been conducted by Dr. Nicoll to determine the relative advantages of the intraspinal and intravenous methods. The results of these experiments demonstrated conclusively the superiority of the intraspinal method. Only those animals receiving the antitoxin in the spine were able to survive. This result was the more striking since the amount of antitoxin given them was only a fractional part of that given in the circulation. An attempt had been made to give the antitoxin intraneurally in four animals, but they lived no longer than those receiving the injections subcutaneously.

Dr. FRANK BILLINGS of Chicago said he would not discuss any of the problems brought up except those in connection with vaccines; he would not attempt to discuss provocative vaccination, since that was practically settled and proven, nor would he say much with reference to the employment of vaccines in acute disorders, but would speak of his experience with vaccines in chronic and local diseases. In the work they were doing they had the advantage of the guidance and criticism of such men as Dr. Hektoen, Dr. Rosenow, Dr. Davis, and others. They had used the autogenous vaccines along the lines laid down by immunologists in such conditions as chronic infectious arthritis, furunculosis, alveolar abscesses, pyelitis, cystitis, etc. They had tried to study the results on the basis of the opsonic index and the phagocytic index, and to study the local, focal, or constitutional reactions. They had tried, by injecting animals with the various strains of bacteria from man, to find where those strains would localize in the animals, to study their selective action with respect to the different tissues of the body; they had immunized horses with polyvalent strains of streptococci and had used the resulting vaccines to raise the defenses of the indi-

vidual. They had kept very careful records of all the work. They had used these vaccines on some 500 cases of chronic infective arthritis and chronic infective endocarditis, and had tried to draw conclusions from these. They had observed the same class of patients without vaccines so that they might have controls. As a result of it all there was much doubt in his mind as to the beneficial influence of vaccines in these chronic processes. When one considered how large a part starvation, fatigue, age, and many other factors played in the regeneration of tissues, it was a question how much of the improvement attributed to vaccines might be attributed to hygienic factors. It seemed quite evident that if these hygienic factors were not given due attention one did not accomplish much with the vaccines. Furthermore, many times a few minutes of history were worth more than months of vaccine treatment because by it one might be able to relieve a local process. It was a question whether the vaccines gained access to some local processes, as, for instance, an abscess at the bottom of the socket of a tooth. Dr. Billings said that in his experience the benefits to be derived from vaccines in both local and general chronic processes was so limited that they did not justify the labor and laboratory equipment necessary to carry on that form of treatment. Vaccines might be useful in acute diseases, but the reaction was often so alarming that a physician hesitated to use them. The way to determine their value in acute infectious diseases would be to make properly controlled observations. For instance, in typhoid fever in a hospital where one had perfect control of the patients, one might treat a group in one ward with a specific antigen, a second group in a second ward with an antigen that was not specific, and in a third ward a group might be treated by ordinary methods. By such a procedure one might come to a definite conclusion as to the value of vaccines in typhoid fever. In closing Dr. Billings commented on the widespread use of commercial vaccines, and considered their employment a disgrace to the medical profession.

Dr. RUFUS I. COLE of New York said he believed that the way to arrive at a solution of the problems of immunity was to take one disease and study that by applying to it the principles of immunity. This he had done with pneumonia. As to the production of immunity in acute infections, the recent work of Gay and Jobling justified further investigations, but as clinicians we should go slow in making practical application of newly discovered principles and make sure that we were on firm ground. It was quite justifiable for certain observers to carry out these tests on the patient, but for the general practitioner or the consultant to use them when they were not in a position to draw conclusions was wrong. Dr. Cole said that from his study of the literature and from what he knew of immunity there was no justification in acute lobar pneumonia in trying to produce active immunity when in animals they could not produce it in six or seven days. He took exception to Dr. Park's statement that a patient with pneumonia should be given a dose of serum of Type I before the type of bacillus present had been isolated. Under favorable circumstances such as they had at Rockefeller Institute, and in every good hospital in the country, it was not difficult to make a differentiation of the type of organism within twenty-four or forty-eight hours after the patient came into the hospital. The greatest danger was that serum would be applied indiscriminately in all cases of pneumonia and the type of organism would not be determined. The serum therapy of pneumonia should be applied with caution and care, and all the details should be carried out with attention to the principles concerned. Personally he felt that the use of the serum in Type I of pneumonia was efficacious. While he would not say much as to the clinical results, he had found that the organisms disappeared from the blood after the serum was given. The differences between the various types of pneumococci were as great as the difference between the typhoid and paratyphoid bacilli.

Dr. THOMAS W. HASTINGS of New York also expressed the opinion that specific therapy had been abused in this country, and said that sufficient care was not taken to determine the specific factor involved. This was the important point in both serum and vaccine therapy. This could be said more particularly of streptococcus infections. There were differences in strains of streptococci, as there were in those of pneumococci. It was useless to employ specific therapy when a surgeon was needed. In chronic infections, even when vaccines were employed carefully and judiciously

it was difficult to say whether good results were brought about by the specific therapy or by other factors. He did not think the physician should resort to serum therapy when he could get results with other measures known to be reliable, since the practical application of serum and vaccine therapy were extremely complicated and required a large amount of knowledge, caution, and judgment. The problems involved were at present beyond the comprehension of the average physician. The use of polyvalent vaccines should be absolutely discontinued.

Dr. THEODORE C. JANEWAY of Baltimore said there were just four points to make after this discussion. The first was that progress came from conflict and not by agreement. We needed both the enthusiast and the critic. It was even better to be both enthusiast and critic, to be able, after having used a method of treatment for a number of years, to have the courage to say that there was nothing in it. From the debauch of the indiscriminate use of vaccines through which we had passed good would come because of the stimulation of criticism to further work on these problems. The second point we might learn was that what one put into his premises he would get out afterwards, but that was not necessarily a scientific fact. If one made a culture from the tonsils or teeth, in some disorder of as yet obscure origin, got an organism, made vaccines, and after injecting them got improvement, and then thought that with that one procedure he has demonstrated the cause of the disease and provided the remedy, he was not advancing the cause of scientific medicine. The third point was with reference to the specificity and non-specificity of the vaccine or serum. When one was confronted by a reaction which he believed to be due to a specific agent he must be able to demonstrate that it would not be possible to produce the same reaction by some other non-specific agent. The fourth point to be emphasized was the importance, in cases of acute sepsis, of making a search for the primary focus of infection and of metastatic foci and, having found them, making an immediate surgical evacuation.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16-18, 1916.

(Special Report to the MEDICAL RECORD.)

(Continued from page 934.)

HOUSE OF DELEGATES.

THE PRESIDENT, DR. D. W. STANTON GLEASON OF NEWBURGH, IN THE CHAIR.

Report of Committee as to What Constitutes Eligibility to Membership.—The committee appointed by President Wendt to prepare an exact and clear definition of what should constitute eligibility to membership in the Medical Society of the State of New York, presented the following as an amendment to Chapter X of the By-Laws, Section 3: "All legally qualified graduates in medicine, licensed to practice in the State of New York in conformity with the law and the requirements of the Board of Regents, are eligible to membership, except those admitted by special enactment of the Legislature, with evasion of the educational requirements either preliminary or professional."

Report of the Counsel.—Dr. JAMES TAYLOR LEWIS, counsel of the Medical Society of the State of New York, presented this report. He reviewed the list of cases that had been conducted during the year calling special attention to two cases of more than ordinary interest. There was continuing and increasing application to the counsel for advice on various subjects by members throughout the State. Opinions had been written and the law examined on various topics connected with the practice of medicine, demonstrating the great influence of this malpractice defence on collateral matters. The influence of the State Society was broadening in many directions. State societies were organizing malpractice defence plans by various methods, either exactly as their defence was conducted in New York State, or upon some plan fundamentally like it with modifications which would make it more adaptable to a particular locality.

Report of Committee on Constitutional Convention.—This Committee reported that its efforts put forth in the securing of a recognition of a State Department of

Health in the proposed new constitution, and the preventing of unfavorable amendments affecting the interests of the medical profession of the State of New York, were highly successful, as would appear in referring to the text of the new constitution.

Reports of District Branches.—The various district branches presented reports, all of which were adopted by the House of Delegates.

New Business: Amendment to Public Health Law.—Dr. NATHAN E. BRILL of New York stated that inasmuch as only 85 per cent. of the graduates of medical schools in this State obtained hospital internships, and that whereas no graduate of a medical school was fit to practise medicine without clinical experience, he wished to propose an amendment to the Public Health Law for presentation at the next session of the Legislature. This amendment required twelve months satisfactory clinical work in a hospital having an average of not less than 30 patients daily and not less than 50 beds, including a medical and surgical service, and maintaining the recognized clinical and laboratory standards.

Resolution for Medical Preparedness.—Dr. HAROLD HAYES of New York presented a resolution similar to those recently adopted by the New York Academy of Medicine recommending that in the plans for National preparedness proper provision should be made for the care of the health and lives of those who offered themselves in the service of their country. These resolutions stated that it was the sense of this Society that in its plans Congress should make provision for the appointment of seven medical officers per 1,000 men in times of peace, this number to be increased to ten in event of war and that this should apply equally to the Army and the Navy. The resolutions further provided that copies of these resolutions be sent to the Surgeon-General, the House of Representatives, and the Senate.

Resolutions Favoring Forest Preservation.—The Erie County Medical Society presented resolutions putting the Society on record as interested in and favoring all efforts to further forestry and forest preservation and recommending that this resolution be presented to the American Medical Association at its next meeting.

Invitation to American Medical Association.—Dr. FLOYD M. CRANDALL read resolutions which had been framed by the Comitia Minora of the Medical Society of the County of New York stating that the question of inviting the American Medical Association to meet in New York had been considered, and it had been decided to ask the State Society to join in invitation with the Medical Society of the County of New York to hold the meeting in 1917 in New York City.

SECTION ON MEDICINE.

Tuesday, May 16—First Day.

THE CHAIRMAN, DR. JOHN L. HEFFRON OF SYRACUSE IN THE CHAIR.

THIS was a joint meeting with the Sections on Public Health and Pediatrics.

Vision of the School Child.—Dr. F. PARK LEWIS of Buffalo said that increased deficiency of the individual was one of the most important features in the problem of preparedness. A physical defect such as imperfect sight or defective eyes might be a sufficient handicap to place those who would otherwise be self-supporting in the dependent class. For the protection of the State the citizen must be raised to the highest efficiency. This would be found to be economically profitable. In order that individual data might be secured the eyes of every school child should be properly examined. To do this standardized methods were essential. Where it was impossible for the individual to pay for the relief of difficulties that impeded his usefulness the assistance of the State must be required. All preliminary examinations should be made in the schools and by the teachers. Boards of Health should have on them those trained in ophthalmology. To these should be assigned the examination and the relief of corrigible defects. To meet these requirements place and time must be given in the schools themselves. The cooperation must be secured of both the teachers and the parents. This could be done by giving illustrative lectures in the schools on the nature of the defects, the importance of their correction, and those responsible for the correction should be urged to see that this was done. Such records might have great value in the case that compensation was claimed for injury to sight. If it then could be shown that defects

existed while the claimant was still a child, or if it could be shown that good vision was present, which the defendant denied, these school records, which should be available, would aid in securing more equitable results. Graphic illustrations were shown by lantern slides of the way objects appear to those having myopia of different degrees, astigmatia, corneal scars, tubular sight, color blindness, etc.

Some Practical Experiences in Medical Inspection in Rural Sections.—Dr. WILLIAM A. HOWE of Albany said that during the first year of the administration of the medical inspection law, many impressive and varied experiences have arisen throughout the State. Those to which he wished to call attention were taken from the rural sections where many of their most difficult problems in this phase of the work were to be found. Many grateful parents had written the Department of the wonderful relief extended to their children. Thousands of children had been placed on a higher plane of physical fitness, thus enabling them to make normal progress in school. While most of these cases belonged to those commonly seen, many had been most impressive and a report of several such cases was presented. In conclusion and in view of such experiences as well as many others which might be given, he offered the following suggestions: That, only physicians interested or willing to take an interest in the work be utilized as medical inspectors; that, the utmost care be exercised in all examinations and that definite care should be shown in giving information to parents regarding the nature of the defects found; that, physicians should receive a fee commensurate with the services rendered, which on all occasions should be his best; that, physician, teacher, parent, pupil, and nurse should cooperate in the entire system of school inspection; that, the real success of school inspection would be measured by the thoroughness with which the examinations were made and the results accomplished.

Dr. JOHN HEFFRON of Syracuse said the question asked in regard to Hutchinson's teeth was important. These cases came under his observation frequently and he felt that the condition found in these children that resembled the sign known as Hutchinson's teeth was sometimes due to a delay in the eruption of the teeth. He had not been able to discover that anyone had made accurate observations on this point.

Dr. HOWE said he just wished to say that the State Department of Health stood ready to make the Wassermann tests. They had found a reasonable number of children with syphilis and treated them in a very satisfactory manner.

Dr. WHITEBECK said that in reference to the examination of the teeth, the importance of such examination was very evident. In orthopedic work all cases of arthritis were examined by the x-ray to find the condition of the teeth. Where a focus of infection was found in the mouth or the sockets of the teeth the patient was put under treatment until this condition was cleared up. A goodly percentage of cases with acute arthritis, if the focus of infection was not removed, developed into chronic rheumatism. Frequently when there was an abscess at the root of a tooth the dentist wanted to save the tooth. In such cases it was better to pull out the tooth since if the source of infection was not thoroughly removed the condition might progress and lead to permanent disability.

Dr. L. DUNCAN BULKLEY of New York said nothing had been said as to the importance of thorough mastication. Mothers should be instructed to teach children to chew their food properly and should insist on their staying at the table for fifteen or twenty minutes, or even half an hour. Some device as aluminum or celluloid balls or a cardboard cuff fastened on the upper arm might be used so that the child could not get its thumb to its mouth.

Scope of Practical Examination in Routine School Medical Inspection.—Dr. CLINTON P. McCORD of Albany, N. Y., read this paper. The most essential thing to determine in a given district was the size of the working staff. Any district with 3,000 children should employ its school medical inspector for "full time." The working unit was one doctor and two nurses for each 3,000 children. An examination of the character indicated in the health certificate referred to in the New York State law was practicable only in a physician's office and could not be properly accomplished in less than a half hour. In most school buildings the only examining room available was the kindergarten in the afternoon or the principal's office. Under such conditions the

removal of the clothing was not practicable and besides, a competent examiner would be able to ascertain all facts required for purposes of school medical inspection without removing any clothing except in a relatively small number of cases. This last group included the poorly nourished children, those with cervical nodes that showed a tendency to break down, those with chronic coughs or digestive disturbances, those that were extremely nervous or those that suffered from dizziness and shortness of breath. In considering routine examination they must consider the question of school medical inspection records. Some difference of opinion here existed. Discussion fell under two possibilities: (1) A suggested standard card plus supplementary cards for various records, etc., or (2), suggested data essential for scientific work, leaving the actual form of the cards to the local executives. A card system should include the following: physical record card; parental notification card; miscellaneous care card; report of sanitary survey; medical inspector's report blank; school nurse's report; dental record cards; physical training card; open air school records; and special class records. In most places to-day the working unit was too small to give all the children adequate care. Proper standardization of the working staff and scope of the work should be their first thought. It was of little good to require an examination involving a chest examination when one "part time" man was appointed to 4,000 or 5,000 children. Where conditions were such that a "part time" man had more than 1,000 children a chest examination should not be considered except in the case of the relatively few anemic, nervous children and those with suspicious lymph nodes, or those that brought to them evident signs and symptoms of organic heart disease. Working two hours a day, five days weekly, for thirty-six weeks, an inspector might examine approximately 1,000 children. Working one hour a day for the school year he would examine approximately 450 children. Certain standards should be suggested to govern the reporting of defects. An analysis of examinations of several thousand children by 167 different general practitioners showed a wide range in standards of judgments as to the existence of physical defects. The routine examination should cover the following. *Eyes.* The Snellen card test plus a card for near vision and astigmatic chart in some cases. These tests must be given with an appreciation of the possibilities of error in handling children. *Ears.* The watch test is perhaps the most practicable. There was considerable variation in the response of children at different ages. Discharging ears were serious. *Tonsils.* Enlarged and cryptic tonsils with a history of frequent sore throat were perhaps pathologic. *Nose.* The medical inspector diagnosed nasal obstruction, leaving it to the family physician to determine the cause of the obstruction. *Teeth.* The decay of the "six year" molars was the most important thing to look for. It was poor economy to employ a dentist to inspect mouths of school children; he had better be employed in the actual treatment of the most urgent cases. *Nutrition.* The judgment of nutrition was based on pinched, pallid features, arrested development, the lack of spontaneous activity, weak and flabby tissues and the signs of nervous exhaustion. *Skin and Glandular.* The enlarged cervical nodes associated with poor nutrition, those that became acutely inflamed and those that underwent softening were the ones that merited attention. *Eczemas* and any contagious or parasitic skin disorder should also be looked for. Simple home treatment for pediculosis was indicated. *Orthopedic and Nervous.* Stoop shoulders and flat chest, lateral curvature, "general nervousness," chorea, psychic disturbances of adolescence, epilepsy, mental deficiency, etc., should be kept in mind under this heading. *Acute Contagious Diseases.* This was a very important though relatively small part of the work of school medical inspection. The highest co-operation should exist between the inspector and the local health officer. Physicians new to the work of medical inspection and desirous of obtaining good results frequently asked for direction. They should read a few good books on the subject. They should visit some city where a system of recognized efficiency was in operation and observe the actual routine work. They should keep in touch with the expert examiner of school children for some months. They should be familiar with the latest advancements in educational hygiene. They should keep an open mind. The medical profession as well as the parents should be awakened to the wisdom of health supervision prior to the school age. School health

work was more than putting glasses on children who could not see well, removing adenoids, tonsils and filling decayed teeth; it involved a wide understanding of the various social, educational and economic problems that were closely bound up with the physical condition of the children.

The Neuropathic Child.—Dr. EDWARD B. ANGELL of Rochester presented this contribution. He said he thought the best description of the neuropathic child was that given by Dr. Francis Warner of London who had examined 100,000 school children. That authority described the characteristic manifestations of the neuropathic condition as headache, difficulty in getting to sleep, grinding of the teeth, delicate physical condition without actual disease, lack of appetite, and tendency to be easily fatigued. These children were generally well made in body and had good heads; they had well cut features, fine skins and usually light complexions. There was a weakness and an overspontaneity. There were uncontrolled movements without co-ordination yet they early gave pleasure to the babe. Later impressionability and imitativeness showed that the child's mind was impressed by what it saw. With growth developed the power to arrest the motor concept and to modify or even deny its inhibition. Thus developed a control over the senses by which the mind gradually acquired desire and volition, the relative value of sensory impressions and motor action. Another quality developed was retentiveness and co-ordination action which was the result of many past impressions, desires and resulting movements. The normally constructed brain of the healthy child in its motor action presented well balanced muscular movements. The relationship between the muscle activity and the brain activity was very direct. Basing his test on these facts, Dr. Warner had found that requiring the child to raise his arms and hold them straight out in front in a horizontal position was a test of the nervous condition and the degree of fatigue. If the latter were present the child did not hold both arms parallel, or dropped one arm, or one hand but in the very neurotic the knuckles of the hand were pointed directly backward. The normally constructed brain of the healthy child in its motor action presented well balanced muscular movements. The relationship between muscle activity and brain activity was very direct. Hence it was that military training not only developed the muscles but the brain as well, while the habit of instant obedience did much to establish healthy brain activity and normal self-control. Self-control could not be too thoroughly established for the growing child, since without self-control there was an unstable equilibrium which later gave rise to the vagaries of neurasthenia and hysteria. If one studied the nervous child he would find that his position might be one of erectness, of assurance or defiance, or it might be drooping and self-conscious, or one of weariness, or fatigue, the latter being more common in girls. Another habit easily acquired by the nervous child was that of introspection and this led later to unstable equilibrium and self-consciousness to the detriment of efficient mental activity. Dr. Angell said he had observed 75 or 80 cases of typical nervous children and had found that alcoholism and insanity had entered in as factors in about one-third of the cases, while the arthritic diathesis was present in about 30 per cent. In only one case did he find tuberculosis in the family, but tuberculosis probably played a more important part than this indicated in the transmission of an unstable nervous constitution. In about 25 per cent of these cases the condition could be traced to abnormalities in pregnancy or delivery. Faulty metabolism, such as constipation, headaches, mental depression, irritability and a poor circulation were characteristic evidences of disturbed nutrition. There was defective nutrition in about two-thirds of the cases and nearly one-third were the victims of night terrors. He believed that protein entered too much into the diet. Fresh air was a most important factor in the treatment of this type of child. The Boy Scout movement was an excellent thing in developing the correlation of muscular and physical activities, teaching the boy self-control and how to adjust himself to life.

The Open Air School Child as a Type.—Dr. EDWARD DUNEY of Buffalo presented this paper. He said there was a type of children that were being segregated and were regarded as suitable for treatment in fresh air schools. They were the children that were living under wrong conditions of life, the children with a heredity of alcoholism or epilepsy, those who were the subjects of faulty nutrition, children of abnormal nervous activities, who thus dissipated their powers. Next in import-

ance to the nutritional defects were the distinctly nervous conditions. Some of these children were the spoiled children of the so-called better families. The nervous conditions in these children ranged anywhere from chorea to partial recovery from infantile paralysis. The defects brought out by present methods of school inspection, such as defects of vision, adenoids, enlarged tonsils, etc., must be corrected if the children were to receive the full benefit of the fresh air treatment. The attitude of the children themselves toward these schools was the best argument in their favor. Records of the weight of these children had been kept and the gain in weight that had been shown was a positive index of the improvement in their condition. The change from the ordinary school to the fresh air school was frequently accompanied by an increased interest in both work and play. There was often a mental deficiency accompanying the physical defects, and with the methods used in the open air schools these defects were sometimes benefited or removed. Among the children that would be improved by the open air school might be included a large number of children in the ordinary schools.

The Effect of Malformation and Infection of the Oral Cavity of the Child upon Its Future Health.—STEPHEN PALMER, D.D.S., of Poughkeepsie read this paper by invitation. He said that the fact that a man belonging to the dental profession had been asked to address this society was very significant of the change that had come to pass. It meant a recognition of the vital relationship of medicine and dentistry. He quoted from the writings of Victor C. Vaughan to show the relations existing between mouth infections and various constitutional conditions. These made it evident that nothing was so important as the hygiene of the mouth of our boys and girls for upon that depended the health of the men and women of to-morrow. Evidence in support of this statement might be brought forward from many authorities. Medicine to-day recognized the importance of prophylaxis and in dentistry it found the prophylaxis of many conditions that had been puzzling to the physician. Malformations were of the utmost importance and were so common that one rarely saw a normal conformation of the mouth and teeth. This he attributed to the mixing of the races and the fact that enough time had not elapsed to evolve a definite type. To the proper moulding of the human face a full complement of teeth was requisite. Where there was malformation, there was malocclusion, and this latter condition was the rule rather than the exception. The anatomy of the mouth and teeth was such that the loss of one tooth ultimately disturbed the balance of the whole. Therefore one cause of dental deformity was the loss of one tooth. Thumb, lip and tongue sucking were another cause of deformity causing malocclusion and a narrowing of the palatal arch, and nasal obstruction. It was therefore important for the rhinologist to work with the dental surgeon when it came to the treatment of mouth deformities involving the palatal arch, for such deformities retarded the function of the tongue, lips, and nasal passages. Mayo and Hunter had emphasized the importance of oral sepsis as a source of infection. In the demonstration of alveolar abscesses the x-ray had been a great help to the dentist as it had to the physician. The value of oral prophylaxis had been amply proved by the establishment of dental dispensaries and in every city and town there should be a dental clinic. Pyorrhea alveolaris was not a disease of childhood, but with proper prophylaxis and the correction of malocclusions it could be prevented. One might put it down as an axiom that a clean tooth never decayed, that teeth in good occlusion were easy to keep clean, and therefore teeth in good occlusion never decayed. The value of oral prophylaxis had been amply demonstrated in the German army. Attention had been given to this matter among the school children of Germany and as a consequence few of the German soldiers required dental care, while on the other hand such prophylactic work had not been carried on to the same extent in England and there was a great deal of dental work to be done among the soldiers of the English army. In September there would be a legalization of dental hygienists, which would make it possible to have a trained corps of dental assistants who would bring the importance of dental hygiene before the public. By the concerted action of physicians and dentists the coming generation would be healthier than the present one.

Economic Foundations for Health.—BENJAMIN C. MARSH, Executive Secretary of the New York Con-

gestion Committee, presented this paper in which he cited statistics showing that the wealth of the country had gradually been accumulated in the hands of a few. Two-thirds of the population were earning less than \$750 per year and almost one-third less than \$500. This was below the standard of decent subsistence. Among this class of the population 30 per cent. of the families took boarders or lodgers, and the statistics of infant mortality showed that 256 infants out of every 1000 born died during the first year of life. On the other hand, it had been shown that among families in which the father earned over \$125 per month the infant mortality was 84 per 1000. We looked with horror on the loss of life in the European war, yet in this country 300,000 lives were lost annually from preventable diseases. Land monopoly was largely responsible for shifting the burden of taxation upon the consumer. The wealthy were taxed to not more than 14 per cent. of their incomes, while the poor bore a tax equal to one-third to one-seventh of their earnings. The remedy, he believed, was in taxing all vacant land and exempting all improved property. Such a system of taxation was approved by the American Federation of Labor, the New York State Federation of Labor and two federations in New York City. He then made a plea for the municipal control of public utilities, such as transit facilities, gas and electric light. Private corporations were making annual dividends of from 16 to 20 per cent., which were paid by the poor and went into the hands of the land owners, who constituted only a small proportion of the people. This was then an ethical as well as a health question and as such should be of interest to all physicians.

Dr. JOHN L. HEFFRON of Syracuse said it might be of interest to Dr. Lewis and some others to know how they were taking care of refraction work in their town. The work was done by a volunteer staff of dispensary doctors. This year the Department of Education of the city had undertaken to employ these doctors from the dispensary at the nominal salary of part time medical inspectors to care for the eyes of the school children. These men had had good training in the dispensary and as a consequence the school board got good service.

Dr. KASCHNER of New York said he was glad that Dr. Angell had called attention to the neuropathic child. As a rule the general practitioner gave this type of child scant attention. When the mother brought such a child to him complaining of night terrors, bed-wetting, and nervous symptoms, he usually prescribed bromides and Fowler's solution and let it go at that. In this class of children one often had a greater problem to solve than in actual organic disease. The many details of environment and economics must be taken into consideration. These were the children that later filled the asylums, homes for epileptics and reformatories, and their treatment should be regarded as an important and serious problem.

Dr. B. W. WHITBECK of New York said that with reference to the examination of children there was one point that he would like to bring out at this time and that was the importance of the influence of flat foot upon the general condition of the child. The records of the New York schools showed that about 60 per cent. of the children presented a condition of weak or flat feet, and it was his opinion that 75 per cent. would be more nearly correct. He had inquired at Washington as to the disabling effects of flat foot in the United States Army and Navy and found that they were throwing out many candidates because of this defect. Children with this defect were often backward in school, tired, would not play or eat. They were placed on tonics, sent to the oculist because of headaches, when it was a correction of the flat foot that was required. Dr. Whitbeck cited such a case. The boy was finally sent to his family physician, who found he had a hollow back and flat feet. The boy was treated with proper orthopedic appliances and his general condition improved and he took off his glasses. Unless one had seen these cases it was hard to believe that such a defect could have such far-reaching results.

Dr. WILLIAM A. HOWE of Albany asked Dr. Whitbeck what he considered the cause of flat feet, and asked if he would recommend that school children be examined for flat foot.

Dr. WHITBECK replied that he believed it was one of the conditions incident to civilization, probably standing with the toes out had something to do with it. Some children never had good feet, they were flat-footed from babyhood, but the condition was frequently not noticed until the child grew older and suffered pain. It was

not merely a question of whether the feet were flat, but of whether they were functioning; not so much a question as to whether they were flat as it was whether they were weak. Many persons had flat feet and yet went through life without symptoms; it all depended upon whether the feet functioned or not.

Dr. FRANK OVERTON of Patchogue said in hearing the papers he had been interested in the references to instances in which private physicians failed to detect the defects of school children. He said in his town there was efficient cooperation between the private physicians and the school inspectors. This was true in many towns, but he understood that there were places where there was not this cooperation. It was one of the functions of this medical society to bring about such cooperation, and he believed it was doing this more and more.

Dr. EDWARD B. ANGELL of Rochester said he wished to go on record as being in accord with what Dr. Karschner had said. One should call the attention of the general practitioner to these cases. There were many conditions that he had not referred to in his paper, and one was dementia praecox. It was sometimes very difficult to tell whether one was dealing with a neurasthenia or a dementia praecox. He had had a case of dispituitarism, in a boy who presented feminine characteristics and an utter lack of any sense of responsibility. In this case treatment with pituitary extract had brought about great improvement both physically and mentally. Such cases showed that something could be done by a careful study of these cases in youth. The points brought out as to the relation between flat foot and hollow back and their effect on the general health were very important. Dr. Warner of London, to whom reference was made in the speaker's paper, stated that he had found many cases of hollow back and had observed that it bore some relation to flat foot but he had not attempted to explain it.

Dr. T. DE WITT SHERMAN of Buffalo said that those who had had experience with fresh air schools had observed that infections, especially influenza, were spread less rapidly in fresh air schools. They had had experience with whooping cough and chicken pox and had found that the fresh air school did not seem to have any influence in delaying or preventing the spread of these infections. He said he had not seen this point referred to before, and wondered whether others had had the same experience.

Dr. SCHILLER of Amsterdam said it seemed to him that they were just drifting in medicine and surgery. Many eloquent papers had been read, and they showed that physicians knew what should be done for these children, but they were unable to do the things that ought to be done because they did not have the means. The medical inspector knew the children in his schools that needed glasses or needed to have other defects corrected, but the parents did not have the means to have the work done. They could not do much until basic economic conditions in the home were improved.

Dr. A. P. SQUIRE of Rotterdam said he was interested in the significance of Hutchinson's teeth. He asked if anyone had tested for the Wassermann reaction in children having Hutchinson's teeth, and if any one had found out just what this sign signified in school children.

Dr. HOWE said no one had called attention to the effect of coffee and tea drinking in relation to the nervous conditions that had been discussed. In his work he had found that a very large proportion of children were given tea and coffee even in families that were fairly intelligent.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held April 18, 1916.

DR. NELLIS B. FOSTER IN THE CHAIR.

The Retention of Nitrogenous Waste Products in the Blood and Tissues in Nephritis.—Dr. V. C. MYERS said the nitrogenous waste products, urea, creatinine, and uric acid, were quite uniformly distributed in the fluids and tissues of the body, both normally and in conditions of retention, this being especially true in the case of urea. The degree of retention of the various waste products, as indicated by the examination of the blood, afforded an excellent index of the severity of the condition, and probably a fair index of the extent of the retention in the later stages of the disease. By comparing the concentration of the uric acid, urea and

creatinine in blood and urine, it would be observed that the kidney was able to concentrate the creatinine 100 times, the urea 80 times, but the uric acid only 20 times. In other words, it would appear that, normally, creatinine was the most readily and uric acid the least readily eliminated by the kidney, with urea standing in an intermediate position. From this it was logical to expect that the excretion of uric acid would be the first to be impaired. In nephritis our blood studies appeared to indicate that a retention of uric acid was generally the first to become evident. In harmony with this hypothesis they should next expect a retention of urea and lastly that of creatinine. Many early cases of nephritis, probably of the interstitial type, gave blood pictures in which the essential feature was the high uric acid. The urea and creatinine were frequently normal, though sometimes appreciably increased. As the condition of the cases of this type became more severe, the retention of urea increased until they had high values for urea as well as uric acid. If improvement took place, the concentration of urea gradually fell until the picture was that of the preceding group. If, on the other hand, the case went on to a fatal termination, the retention of uric acid and urea was followed by that of creatinine, the concentration of which might reach twenty times the normal.

The Relation of Gout to Nephritis.—Dr. MORRIS S. FINE said the blood picture, high uric acid, normal urea and creatinine, hitherto regarded as characteristic of gout, had been frequently found in early interstitial nephritis as well. This raised the much debated question as to the relation between gout and nephritis, and the practical problem as to how far a diagnosis of gout might be based upon a high concentration of blood uric acid in the absence of the typical symptoms of this disease.

Acidosis of Nephritis.—Dr. EDWARD QUINTARD and Dr. MORRIS S. FINE presented this communication. As a measure of the approach to the condition of acidosis they now had available Van Slyke's ingeniously devised apparatus for determining the CO_2 -combining power of the blood plasma. The apparatus had been in almost continuous use in their laboratory for over eight months and they were glad of an opportunity to express their appreciation to Dr. Van Slyke and Dr. Cullen for their suggestions and advice freely given concerning the method. In their studies on nephritis they had endeavored to determine (1) the common variations in the CO_2 -combining power of the plasma; (2) the possibility of determining the dyspnea due to acidosis by the lowering of the CO_2 -combining power; and (3) the efficiency of treatment in the acidosis of nephritis. They had found, in agreement with Van Slyke, that the CO_2 -combining power normally varied from 53 to 77 c.c. per 100 c.c. of plasma. In nephritis this was generally 40 to 50, and might fall to as low as 25 shortly preceding death. A lowered CO_2 -combining power was found to be a valuable index for detecting the dyspnea due to nephritis. The determination proved useful also as a measure of the efficacy of treatment of the acidosis of nephritis.

Practical Application of the Newer Laboratory Tests in Nephritis with Special Reference to Blood Chemistry.

—Dr. A. F. CHACE said that although considerable attention had been given by a number of workers to the urea and non-protein nitrogen of the blood in nephritis, scant consideration had been accorded the uric acid and creatinine. It was true that the greater part of the waste nitrogen was eliminated in the form of urea, but it did not necessarily follow from this that data on uric acid and creatinine were unimportant and uninteresting. The scheme of blood analysis now employed in the medical wards at the Post-Graduate entailed the determination of the uric acid, urea, creatinine, and blood sugar as a routine, with estimation of the CO_2 -combining power in cases where this appeared to be indicated. The determination of the blood urea was regarded of more value than the non-protein nitrogen for the reason that it represented the retention of a definite compound and, further, was more easily and accurately determined. Where good laboratory facilities were available, the chemical examination of the blood required less of the physician's time and gave him more definite information than the quantitative work on urine. The rise in the concentration of the uric acid of the blood appeared to be an excellent early diagnostic sign of incipient interstitial nephritis. The blood creatinine had been found of very great prognostic value. In severe cases it was superior to the phthalein test, since changes in the patient's condition were clearly shown,

while the phthalein test was continuously negative. All cases which had been followed for any length of time, with over 5 mg. creatinine to 100 c.c. of blood, had died.

An Unusual Case of Chronic Interstitial Nephritis with Findings in Blood and Urine.—Dr. R. H. HALSEY reported this case which occurred in a man, 39 years of age, whose previous history was negative and whose health had always been good until the beginning of his present illness. This began in March, 1915, when he consulted an oculist because he noticed that his vision was becoming dim. In June, 1915, his family physician diagnosed Bright's disease, and prescribed a diet free from meat and salt and two grains of nitrite three times a day. Upon the advice of his physician, he started to spend the winter in Florida, but stopped to consult the writer on November 30, 1915, at which time his symptoms were so slight as not to impress him that he was seriously ill. At this time the arteriosclerosis, retinal changes, and high blood pressure were extreme; there was only the slightest physical evidence of hypertrophy of the heart. The deep reflexes were greatly exaggerated and a fine tremor of the muscles could be felt when the extremities were held. The blood examination revealed a secondary anemia. The urine excreted in 24 hours was 2200 c.c. with specific gravity 1.010, no albumin and no casts. The percentage of chloride and nitrogen was not determined. The chemical examination of the blood revealed a retention of the nitrogen constituents; urea nitrogen, 97, uric acid, 6.6, and creatinine, 17.5. Because of these findings the patient was continued on a protein-free diet. Subsequent blood examinations showed that the nitrogen and blood sugar retention increased progressively while the carbon dioxide combining power of the blood plasma decreased. There was complete absence of phenolsulphonphthalein excretion. On December 23, two days before death, a profuse epistaxis occurred and was followed by edema of the uvula and palate, and the development of fibrinous pericarditis. Respirations were usually 18 to 20, except during the periods of sleep, when they rose to 30 to 36, and were accompanied by vigorous twitching of the legs and arms, but at no time was there Cheyne-Stokes phenomena. It was of particular interest to note that during the time the patient was on a nitrogen poor diet, the creatinine jumped from the figure 17.5 to 21.5, and remained at that figure for six days, subsequent to which it made a further increase to 28.9, at which point it remained until the day before death. The same temporary cessation of retention was shown in the urea figures, which for a week subsequent to the nitrogen-free diet remained almost stationary, but subsequently increased very rapidly, reaching the high point of 200 the day before death. The ratio between the urea in the blood and the urea in the urine, as suggested by Ambard, gave a figure of 1.58, while with McLean's index the figure of 0.27 was obtained, both showing very strikingly the impaired secretory power of the kidney. Dr. Halsey concluded that the phenolsulphonphthalein excretion test was of value to indicate the present status of the patient, but the amount of urea and creatinine in the blood, particularly the latter, gave a definite clew to the progress and prognosis.

Practical Application of the Newer Laboratory Tests in Nephritis.—Dr. ARTHUR F. CHACE said that the introduction of the phenolsulphonphthalein kidney test by Rowntree and Geraghty in 1910, not only supplied them with a most valuable diagnostic and prognostic test but furnished the impetus in this country to numerous investigations on the functional activity of the kidney. With the introduction, three years later, of simple methods of blood analysis, especially at the hands of Folin and his co-workers, the possibilities of these new methods as practical diagnostic tests were quickly appreciated. In some quarters the non-protein or incoagulable nitrogen alone had been employed as a test of kidney activity, while in others the urea had been utilized. McLean, in particular, had emphasized the value of a comparison of the urea of both the blood and urine, somewhat after the method employed by Ambard. So far as he was aware, in institutions other than their own, the uric acid had been used chiefly in connection with the diagnosis of gout. Although considerable attention had been given to the urea and non-protein nitrogen of the blood in nephritis, scant consideration had been accorded the uric acid and creatinine. It was true that the greater part of the waste nitrogen was eliminated in the form of urea, but it did not necessarily follow from this that data on uric acid

and creatinine were unimportant and uninteresting. In fact, from what had already been said, it would appear that the reverse might be true. They did not believe that it was possible to make entirely satisfactory deductions regarding nitrogen retention from the urea or non-protein terminations alone. The scheme they now employed entailed the determination of the uric acid, urea, creatinine, and blood sugar as a routine, with estimation of the CO_2 -combining power in cases where this appeared to be indicated. They originally determined the non-protein nitrogen and creatine, but had discontinued these tests for diagnostic purposes. The determination of the urea concentration of the blood was, they believed, of more value than that of the non-protein nitrogen for the reason that it represented the retention of a definite compound, and, further, was more easily and accurately determined. The phenol-sulphonaphthalein test was so far superior to any other general functional kidney tests that one scarcely need mention any other test in a brief discussion. In comparison with the chemical examination of the blood, it was believed that the latter method gave much more definite information in many cases. In their own work, however, they had almost invariably employed the phthalein test, either previous to or in conjunction with the blood examination. Another very important element in favor of the chemical examination of the blood, compared with the urine, was the difficulty and time required in the collection of urine specimens. It was their opinion that the chemical examination of the blood, when good laboratory facilities were available, required less of the physician's time and gave him more definite information than the quantitative work on urine. As had already been pointed out, the rise in the concentration of the uric acid of the blood appeared to be an excellent early diagnostic sign of chronic interstitial nephritis. The value of the uric acid in comparison with other tests was well brought out in a chart which was shown. The blood creatinine had been found of very great prognostic value. It was superior to the phthalein test, since changes in the patient's condition were clearly shown, while the phthalein test was continuously negative. All the cases which they had been able to follow for any length of time, with over 5 mgs. creatinine to 100 c.c. of blood, had died. The observations which had been made in these cases were shown in tabular form.

Remarks on the Correlation of Nephritis to the Digestive System.—Dr. LUDWIG KAST analyzed the relation of the different symptoms of indigestion to nephritis and emphasized the fact that they were in most cases toxic manifestations, through irritations of the brain centers, particularly the vagus. He stated that indefinite attacks of indigestion had a value as premonitory symptoms of uremia. Investigations on patients with chronic nephritis and uric acid retention, as well as creatinine retention, showed a very suggestive parallelism between abnormal blood chemistry and the occurrence of indigestion. The fact that patients might have uncontrolled vomiting without any other or very little disturbance, and might die within a short time with an attack of uremia, was perhaps not sufficiently appreciated in general practice, since one often heard of such patients having succumbed to an attack of indigestion. An interesting group of cases were those with high blood pressure and gastric ulcer symptoms in which apparently the changed tone and motility of the stomach produced ulcer symptoms which were dependent upon the retention of urotoxic substances in the blood. This group of cases did not respond to ulcer treatment but did respond to treatment of the vascular hypertension. The effect of nephritis upon the intestines showed itself often in severe forms of diarrhea with ulcerative enteritis and also in the occurrence of meteorism apparently of a toxic nature. In some instances patients who had suffered in early years with migraine showed a recurrence of the headaches in the more atypical form with a good deal of indigestion. In a large number of these cases it was possible to demonstrate a latent nephritis as the cause of the toxemia.

Dr. WILDER TILESTON, of New Haven, said the very interesting and important papers which had been presented showed the great and growing importance of blood analysis in clinical medicine, and what great care was necessary in the interpretation of results. At first they were told that a marked increase of uric acid in the blood meant gout, if a few rare conditions like leucemia could be excluded. Dr. Myers had shown that the same degree of increase could be found in the early stages of nephritis, in the absence of gout. Again,

in the case of non-protein nitrogen, a very marked increase was supposed to be indicative of uremia with severe disease of the kidneys, but he had found just as great an increase in some cases of acute intestinal obstruction, and in a case of hemolytic anemia. In the diagnosis of uremia the newer methods of blood analysis had proved of the greatest value, a marked increase in the non-protein nitrogen, urea, or, as Dr. Myers had shown, the creatinine, indicating, with certain exceptions, a more or less corresponding impairment of renal function.

While it had long been known that uremia was practically never encountered without a well-marked hypertension, it was not until the recent methods of blood analysis were introduced that the separation of cases of hypertension into two types became possible, viz., (1) those with normal or nearly normal nitrogenous waste products in the blood, and (2) those with retention of these substances. This distinction was of the greatest practical importance, for the patients in the first group stood in no danger of uremia and did not need very active treatment; they were more likely to succumb to cardiac decompensation or cerebral hemorrhage. Those with a marked increase of nitrogenous waste products, or azotemia as Widal had very aptly called it, required, on the other hand, restriction of the protein intake and eliminative measures. The patients in the group of hypertension without azotemia were usually well past middle life, were subjects of arteriosclerosis and complained chiefly of symptoms of hypertension and circulatory failure, viz., dizziness, headache, and shortness of breath. The subject of hypertension with azotemia also suffered from headache, but in addition there was usually nausea and vomiting, loss of appetite and failing weight and strength. The patient with simple hypertension, however, not infrequently suffered from digestive disturbances, acute or chronic, and here blood analysis gave them very precious information. The presence of a high degree of albuminuric retinitis had been in his experience always associated with retention, and was therefore of bad prognosis, at least in chronic nephritis. But he had seen mild grades of retinitis without azotemia. With regard to the prognosis of chronic nephritis, cases showing 100 mg. or more non-protein nitrogen seldom lived more than a month or two. But a high degree of azotemia, if transitory, was not inconsistent with recovery. Thus in acute intestinal obstruction without nephritis, he had found as much as 150 mg. in a case terminating favorably. In closing, he repeated the words of Widal concerning the prognosis of nephritis: "If I had to choose, I had rather know the results of the blood analysis than those of the examination of the urine."

Dr. FENTON B. TURCK said that the excellent report made on the chemical findings in the blood in nephritis was of very great diagnostic value especially in the late manifestations. The determination of the etiological factors, of course, would be of greater diagnostic scientific and practical importance. Some form of infection was now regarded as the cause in most cases of nephritis and the alimentary tract as the principal foci was becoming more apparent especially in the light of experimental research.

In their experiments of feeding animals with intestinal bacteria, lesions of the kidney were produced showing various stages of nephritis with changes in the blood that seemed to parallel the observations made in man. Reduction in the alkalinity of the blood was noted, and of special interest were the studies in metabolism during the feeding experiments with certain strains of colon bacilli. They found that bacteria migrated into the intestinal wall and the bacteria passed between the cells into the submucosa where bacteriolysis occurred and indicated that the "Split products" of the disintegrated bacteria were significant in causing the toxic effect upon the kidney. The escape of intestinal bacteria by diffusion through the tissue and filtering through the kidneys was so subtle as to pass unnoticed because of the absence of acute and violent reactions. The pathological process appeared as an autolysis of the tissue cells with secondary replacement of connective tissue cells in chronic conditions. By similar feeding experiments Ashford fed animals with cultures of *Monilia* taken from patients suffering from sprue producing in the animals kidney and other lesions found in sprue. A study of the condition of the intestinal tract was of paramount importance in the early diagnosis of kidney disease, and such a study would lead to prophylactic measures and cure in the earlier stages of nephritis.

IMMUNITY, NATURAL AND ACQUIRED.*

BY WILLIAM H. PORTER, M.D.,

NEW YORK.

PROFESSOR EMERITUS IN PATHOLOGY AND GENERAL MEDICINE AT
THE NEW YORK POST-GRADUATE MEDICAL SCHOOL
AND HOSPITAL, ETC.

IN the short time at my disposal it is impossible to consider in full all the theoretic and practical details connected with immunity. All that can be done is to call attention very briefly to some of the more conspicuous facts.

Throughout the many centuries that have passed, the medical mind has been cognizant of certain facts connected with this important subject. *First*, that certain diseases were transferrable, directly or indirectly, from one individual to another. *Second*, that as the result of a specific infection, coupled with nature's efforts to combat and expel the poison, a definite train of symptoms followed, thus giving rise to the differently named diseases. *Third*, that the natural tendency of these phenomena was, in a large percentage of the cases, to terminate in complete recovery; in a smaller percentage, in death; while in some instances, neither recovery nor death resulted, but a more or less prolonged or chronic train of symptoms ensued. *Fourth*, that in a large percentage of the cases where recovery occurred, the individual was in large measure safeguarded against a second attack of the same disease, the animal organism being so changed that it is said to be immune to that specific poison.

In the early centuries the pest and smallpox were highly destructive to human life. The frequently recurring epidemics of the latter destroying many lives and badly disfiguring many who were fortunate enough to recover from the much dreaded disease.

Acting upon these facts, Mithradates the VI (120 B. C.) was known to take daily small quantities of certain poisons in order to render himself immune. In like manner, the hunters in some wild tribes inoculated themselves with snake venom in order to guard against snake bites. Long before the above facts were known, the Chinese were in the habit of placing the smallpox virus in the nasal cavities of healthy individuals, thus inducing smallpox in the individual who might be and was highly resistant to the infection. When this was the case, the disease pursued a much milder course, but it did not prevent the spread of the disease from those so inoculated, and often in a highly virulent form. The Persians were more scientific in their use of the same principle, vaccinating much as we now do with the cowpox virus.

The first real scientific attempt to control and limit the spread of disease was at the suggestion of Dr. Mead of London, in 1719, who was instrumental in having a law passed by parliament by which cases of the pest could be moved from their homes and isolated. Two years later, in 1721, Lady Montague returned to England from Constantinople and introduced the Eastern custom of direct inoculation with the smallpox virus. This, as in the East, decreased the intensity of the disease in the person inoculated. It did not, however, control the spread of the disease nor modify the virulence in those who had the misfortune to contract the disease from those so inoculated. On the contrary, it spread rather than decreased the number of cases. For this reason the practice was prohibited by law.

Thus matters stood until the illustrious Jenner in 1796 inoculated a boy with the virus of cowpox, and later with the virus of smallpox, and proved him to be absolutely immune to the latter. Two years later he gave his wonderful discovery to the world and proved beyond a question of doubt that nature has an absolute law of immunity, so complete in this particular instance that if pushed to the full scientific limit it would result in the complete eradication of smallpox.

Immunity is defined as the power on the part of the animal economy to resist, destroy, and expel from the system the toxic effects of microorganisms and their products or other foreign proteins, after which the system in many instances is not liable to react again to the same poison. The ability to react naturally presupposes susceptibility, for if it were possible to maintain continuously the highest grade of nutritive activity the effects of any antigen would stimulate the formation of antibodies to such an extent that no profound symptoms could be produced and universal immunity would be established.

With smallpox this has been accomplished, the antigen, in all probability, being a foreign protein. This being the case, immunity is largely the play of the protein molecule, the same as it is in normal metabolism; therefore, a clear conception of the rôle played by the protein compound in normal metabolism will aid in the elucidation of its part in producing immunity.

The starches, sugars, and fats are directly oxidized into carbon dioxide and water, yielding heat with which to energize the animal economy; hence the constructive and recuperative work falls entirely upon the protein substances and the inorganic elements with which they combine—the latter, however, playing simply a mechanical part. Hence, the great question is: what changes may occur in the protein molecule?

The pure proteins, as we all know, are derived from both the vegetable and the animal kingdoms. After the proteins from either kingdom are reduced to albuminoses and peptones in the alimentary canal

*Read before the New York Medico-Surgical Society, March 18, 1916.

they are drawn into the protoplasm of the epithelial cells lining this canal (Fig. 1). From the protoplasm of these cells lining the intestinal tract the proteins are discharged into the enterohepatic blood stream. As a rule, however, they do not enter the blood stream as albuminoses or peptones, for the blood normally contains neither of these substances; in fact, the latter is a highly toxic form of protein.

FIG. 1.—Schematic drawing of highly magnified intestinal epithelial cell; open intestinal canal on one side with glucose, protein, fat, and salts passing from the lumen into the cell. Glucose passing through the cell to the blood stream. Protein splitting into three well-known types. Globulins splitting into serum, globulin, and fibrinogen. Fats passing to lymphatics. Salts passing to the blood. (From the Reference Handbook of the Medical Sciences, Vol. VI.)

In view of these two facts—its ready absorbability and toxicity—nature provided by some transmuting process in these cells, either by isomerism or by decomposition, oxidation reduction, and re-synthesis, a process by which the peptone loses its identity. The protein, represented by the easily absorbable peptone, on the one side of the cell, appears on the other, as it drops into the bloodstream, under several distinct forms, recognized by all physiologists—certainly four, if we include hemoglobin and lecithin producers. In fact, there may be many more. One is already known to be composed of three distinct subdivisions. The three which are commonly mentioned, however, are: (1) Serum albumins; (2) globulins; (3) nucleoproteins, or proteins. Serum albumin is not a single substance, but is the one known to be composed of two or more allied proteins, three having already been isolated. In like manner, the globulins yield serum globulin and fibrinogen (See Fig. 1).

Regarding the exact method by which metabolism and the biotic processes of the animal economy are effected, there have been almost endless speculation, theorization, and experimental research work, to enter into the pros and cons of which is beyond the scope of this paper. The process may be one of isomeric transmutation and mechanical multiplication of molecules, which are ultimately split into less complex substances; or it may be by a process of cleavage oxidation reduction and resynthesis of simple molecules—amino bodies—which are built up into more complex ones which constitute the various structures, with a final reduction into less complex substances.

Whatever the process, the important point to be kept in mind is that the proteins are the essential factors; that the main function of animal life is to utilize these complex bodies and reduce them to simpler forms, and that it can be accomplished most easily and with the least strain upon the digestion

and assimilative forces when the animal proteins are used.

The proteins, like sugars and fats, have a heat-producing power, each gram requiring for its complete combustion 1.3786 grams of oxygen, and each gram so consumed yielding 4.1 large calories. Thus we find that the heat energy or caloric force for the maintenance of animal life is produced by all three of these essential compounds.

The most pronounced function of the protein substances, however, is to enter into the composition, construction, maintenance, and repair of all the fluids and structures of the animal economy. For this reason, in the study of metabolism and its disturbances, they must be considered chiefly as constructive elements and for the maintenance of the nitrogen elements or nitrogen balance, rather than for their caloric value. The same is true in their relation to immunity. The amount required to maintain this daily balance is variously estimated and must necessarily vary under varying conditions.

Table I gives the main catabolic elements containing nitrogen, and the average amount excreted normally during twenty-four hours, and Table II indicates the route by which it leaves the body.

TABLE I.—SUBSTANCES ELIMINATED AND AMOUNT OF NITROGEN IN EACH.

	Grams of Nitrogen
35.00 grams of urea contain.	16.331
2.18 grams of urates contain.	0.642
0.80 grams of uric acid contain.	0.266
1.00 grams of keratin contain.	0.371
0.35 grams of hypauric acid contain.	0.054
73.12 grams of sodium taurocholate contain.	2.068
18.28 grams of sodium glycocholate contain.	0.446
14.60 grams of bilirubin contain.	1.267
14.60 grams of biliverdin contain.	1.430
900.00 grams of perspiration contain.	0.380
0.02 grams NH_3 in respiration contain.	0.016
In desquamated epithelium, ferment, etc., contain.	0.779
1059.95	24.000

Upon analyzing this table of composition a little more closely it is clearly apparent that a large part of the nitrogen is excreted through the kidneys and a considerable amount through the liver, while the balance escapes through the desquamated epithelium, through the mucus secreted by the various mucous membranes, and in the unorganized ferments secreted by the various digestive organs. In this manner the total amount of nitrogen—24 grams—is eliminated from the system and is distributed as follows:

TABLE II.—ILLUSTRATING ROUTE BY WHICH NITROGEN IS ELIMINATED.

	Grams	Per Cent
Through the kidneys	17.634	73.475
Through the liver	5.241	21.837
By perspiration and respiration	.346	1.441
By other organs and membranes	.779	3.245
	24.000	99.998

To produce this amount of nitrogen in the excreta, it is absolutely necessary to take into the system through the food ingested not less than 150 grams of protein daily. Not only must this amount be absorbed into the circulation, but it must be utilized perfectly if the animal economy is to be maintained at its full and normal working capacity.

With a clear understanding of the form in which foods are introduced into the system, and the known excretory products, we are in a position to speculate with considerable accuracy as to how and where these oxidation reductions occur.

At one time they were supposed to take place in the blood and fluids of the body. This theory has long since been abandoned, with the introduction of the cellular theory and the knowledge of the fact that a very small percentage of any of the catabolins are ever found in the blood, these chemical

transformations were transferred to the protoplasm constituting the cellular structures. Some are inclined to place these transmutations largely in the muscular structures; while others place them almost exclusively in the cells of the secretory and excretory glands. The latter seems to accord more accurately with known facts. This includes the action of the ductless glands, which unquestionably play a large part in protein utilization.

The excretory products, however, are always abundant on what may be called the outside of the glands or in the ducts leading therefrom—that is, when speaking of glands having ducts, while those products are found in very limited amounts only on the opposite or internal side, or that in direct contact with the blood vessels, or in the blood.

Some are not found there at all under normal conditions. Therefore, it seems logical to assume that the proteins are transmuted in the cells into the various types and forms of proteins that enter into the construction and function of the animal economy.

That the enzymes that go to make up the various digestive ferments thus become both secretory and excretory products—secretory in the fact that they have a physiological function to perform after leaving the cell structures; excretory, in the fact that they carry nitrogen out of the body just as much as urea does.

The same holds true for the pure catabolins, for they are found abundantly on the outside, or duct side, of the cell, and in very minute quantities, if

FIG. 2.—Schematic drawing of normal liver, highly magnified. a, Lumen of bile ducts and radicals; b¹ to b⁴, hepatic cells very highly magnified, illustrating chemical transmutations within them; c, lumen of lymphatic channels; d, basement substance between bile radicals and lymphatic spaces; e, blood vessels of the portal system; f, hepatic artery; g, hepatic vein. (From the Reference Hand Book of the Medical Sciences, Vol. VI.)

at all, upon the opposite side or in the blood. The leucomaine product out of which some of the catabolins are produced must be contained in the blood, but not necessarily the finished product.

This naturally brings up the question: What changes may occur in the protein molecule in connection with the hepatic cells? It certainly undergoes a much more complex transmutation than occurs in connection with the glucose or glycogen-like molecule, yet both yield heat and energy.

But out of the protein substances, in their passage through the liver, there must be produced normally the bile acids and pigments, and possibly some, if not all, of the glycogen. To produce the bile acids, pigments, etc., as found in the bile, the protein substance must undergo oxidation reduction. The protein and the oxygen must meet in the cell, coming, as they both do, from the portal blood adjacent to the hepatic cells. Within these cells, some of which have the special function of effecting certain reductions, the various catabolins found in the bile as a secretion and as an excretion are produced.

With each form of transmutation a given quantity of oxygen is required, and a certain amount of heat is produced for each gram so transmuted.

In Fig. 2 are shown a few hepatic cells of the acinus very highly magnified, in which are found chemical equations representing some of the normal oxidation reduction processes. It graphically illustrates how and where these reductions are effected. It shows also that the protein bodies can be split up in various manners, with similar end products resulting therefrom. Certain of these mutations are what occur when the system is working normally, while when less perfectly transformed they represent disturbances in metabolism.

In cell b^1 , for instance, we find the glucose-like molecule losing by cleavage one molecule of water, with the formation of glycogen, in accord with the older glycogenic theory of the liver—or it may be then and there completely oxidized, as noted.

In cell b^2 we find the protein element splitting into taurocholic acid, bilirubin, a leucomaine product, carbon dioxide, and water. In this instance the sulphur atom of the protein is eliminated in the taurocholic acid, which acid usually appears in the bile under normal conditions as a soda salt of this acid.

In cell b^3 we find the protein body splitting into glycocholic acid, bilirubin, a leucomaine product, carbon dioxide, and water. In this instance, the sulphur atom has to be eliminated, theoretically, as sulphuric acid, the acid, however, joining with soda to form a sulphate, which is the form in which it is found in the secretions and excretions.

In cell b^4 we find the protein body splitting into bilirubin, biliverdin, taurocholic, and glycocholic acid, a leucomaine product, carbon dioxide, and water. In this instance the sulphur atom, as in cell b^2 , is eliminated in the taurocholic acid, and there is no resulting sulphate.

In cell b^5 we find illustrated what may be called the new glycogen theory. Here we find the protein body splitting up into a leucomaine product, glycogen, carbon dioxide, water, and sulphuric acid, ultimately eliminated as a sulphate.

In cell b^6 we have illustrated what may be called the new glucose theory. Here we find the protein body splitting into a leucomaine product, a glucose element, carbon dioxide, water, and the theoretic sulphuric acid. In both these instances (cells b^5

and b^6) the sulphur atom is accounted for as in cell b^3 .

Thus we find that this schematic drawing well illustrates the formation of both glycogen and glucose-like elements out of the protein substances; the former representing a normal process, while the latter is probably an abnormal one. It shows how the constituents of the bile are formed. As some of these substances are essential to a perfect digestion, these products found in the bile are both secretory and excretory. It is not until the bile has served its full purpose in the digestive act that its constituents can be classed as excretory. The presumption is that the leucomaine products so formed normally pass into the lymphatic or blood channels, and finally reach the renal cells, from which they are

FIG. 3.—Schematic drawing of a highly enlarged renal epithelial cell showing leucomaine products and oxygen passing from the blood stream into the protoplasm of the cell to be split into urea, creatinine, uric acid, carbon dioxide, and water; the urea, creatinine, uric acid, and water passing out of the cell into the lumen of the uriniferous tubules; the carbon dioxide and some of the water passing back from the cell into the blood and lymph stream. (From the Reference Hand Book of the Medical Sciences, Vol. VI.)

discharged into the lumen of the uriniferous tubules as urea, creatinine, uric acid, carbon dioxide, and water, as illustrated in Fig. 3, thus accounting for the so-called urea-nitrogen, or urea of hepatic origin—coming from the liver, however, as a leucomaine product rather than as fully formed urea, uric acid, etc.

What part this leucomaine product may play, if any, in the processes of metabolism, is one of the unsettled questions. As only 21.8 per cent. of the nitrogen is eliminated from the system by these chemical mutations in the hepatic cells, while 73.4 per cent. escape through the kidneys, it seems like a very small amount of work to be accomplished by so large a glandular organ, besides being an organ that has the power or function of reproducing itself.

The presumption, however, is that this large organ and its multitude of cells is very largely concerned in partially transmuting all the protein food elements, so that they become more available for nutritive purposes, and are made more easily reducible when they have served their full purpose throughout the body and reach the kidneys for final oxidation reduction and elimination.

We know that peptone is transmuted by the action of the hepatic cells from a toxic to a non-toxic condition. In like manner many other toxic substances are so transmuted. We take advantage of this fact in the management of metabolism and its disturbances when we administer toxic medicinal substances, substances which when they reach the

hepatic cells are taken up by the protoplasm and oxidized in the cell or excreted with the bile, thus protecting the system in general from their toxic effects, yet at the same time stimulating sluggish and inactive protoplasm to increased activity. By the intelligent application of these principles much can be accomplished in the management of all forms of metabolic disturbances.

Viewed in this light, we find the hepatic gland one of the most important in the animal economy; one that cannot be neglected if we hope to succeed fully in the management of metabolism and its disturbances. One reason for introducing this hepatic problem into the discussion is the fact that when nature acts without artificial aid in producing immunity, the explanation must be in keeping with the utilization and transmutations of the protein substance under normal circumstances. Whatever the antigen may be, it must excite, through the activity of the hepatic cells the chemical mutations of the protein substances, thus forming the various antibodies, such as agglutinins, lysins, opsonins, precipitins, etc., etc., the continued activity of which finally brings about the destruction and liquefaction of the bacteria and their toxins.

It seems highly probable, from what normally occurs in this great organ, the liver, that, either directly or indirectly, its cells are largely concerned in the production of the innumerable substances that are said to enter into the production of immunity, active or passive, substances that not only destroy the microorganism and its toxins but also stimulate the phagocytes to increased activity and finally bring all the foreign substances to the various excretory glands for their final elimination from the system. When all this has occurred, the integral body is so changed that it is in large measure safeguarded from the effects of the same infection. Thus immunity may be acquired by inoculation with virulent living bacteria, by attenuated or relatively virulent microorganisms, by the use of dead bacteria, and by excreted bacterial products.

When the antibodies are produced within the animal, or intrinsically, it constitutes active immunity. When they are introduced by injection from another animal in which they were produced, it constitutes the passive type.

The second reason for introducing this hepatic problem is the well-known clinical fact that when the functional activity of the liver is kept at its highest point, in connection with all infectious diseases, the symptoms are the least intense, their duration shortened, and recovery made more certain.

16 WEST EIGHTY-THIRD STREET.

THE DIETETIC TREATMENT OF DIABETES COMPLICATED BY NEPHRITIS.*

BY HENRY S. STARK, A.M., M.D.,

NEW YORK.

THE question of the dietetic treatment of persons suffering simultaneously from diabetes and nephritis has always been a matter of deep concern to the clinician. So far as intensive practical study is concerned, this class of patients has been so woefully neglected that we cannot point to any definite plan which would govern the physician in the choice of a diet. Texts have been a closed book, while the subject itself has been a sort of *nole me tangere*.

*Read at a meeting of the Harlem Medical Society, April, 1916.

While the literature of diabetes has grown to enormous proportions, it remains a conspicuous fact that little has been devoted to that phase of it which forms the subject of this paper. It would be difficult, indeed, to account for this lack of concentration of the medical mind on a topic which from its frequency alone should invite constant investigation. Were the physician to adhere religiously to the teachings of his elders, or to tradition, such patients would be consigned, *ipso facto*, to a slow process of starvation. For carbohydrates would be eschewed on account of the diabetes, proteins on account of the nephritis, and fats because they might provoke a ketonuria. He would thus be left in a sea of speculation as to the probable method of treatment of this large and growing class of patients. I say growing class for the reason that diabetes has trebled itself in frequency within thirty years, while its death rate is steadily increasing.

Chronic nephritis occurs as a complication of diabetes in a large but undetermined proportion of cases. My records in both public and private practice make it appear that after the fifth year of frank diabetes nephritis occurs in about 35 per cent. to 40 per cent. I know that some observers place the figure lower. It occurs also as an antecedent or as a terminal factor. Whichever sequence prevails the diet problem always stands in the foreground, for we now have a factor introduced which more seriously influences the prognosis. This complication of diseases usually means a grave prognosis, and this gravity is estimated in terms of the albuminuria, the quantity of casts, and the hyperglycemia, the patients standing midway between the Scylla of death from diabetic coma or gangrene and the Charybdis of death from uremia, apoplexy, or cardiovascular conditions.

Some authors actually believe that the kidneys of a confirmed diabetic are never normal and that this abnormality is a consequence of a hyperfunctioning of the kidneys, causing disturbances of their excreting powers, or that this abnormality was to be assigned to the almost constant presence of fugitive toxic acids in the tissues, or to the glucose in the blood; in both instances giving rise to a toxic nephritis. While such nephritides frequently accompany diabetes, I could not personally subscribe to so sweeping a statement that the kidneys of a confirmed diabetic are always involved.

These authors probably base their observations on the ill-founded conception that albuminuria always means nephritis, when as a matter of fact there may be no anatomical basis in the kidneys for this symptom. Conversely, we may meet with diabetics who have a nephritis, usually the chronic interstitial variety, with a temporary absence of an albuminuria. I have under treatment many diabetics for years who have never given any evidences clinically or objectively of a complicating nephritis. It becomes, therefore, apparent that the observer who wishes to estimate the frequency of nephritis as a complication of diabetes will fall into error if he looks upon an albuminuria as the cardinal diagnostic feature.

In dealing with chronic nephritis as a complication of diabetes, of course, I refer to true nephritis, in contradistinction to certain kidney lesions which we frequently find concurrently with diabetes, namely, fatty degeneration, hypertrophy, or persistent hyperemia or disturbed permeability of the kidneys, all of which are really different expressions of the hyperfunctioning of the kidneys or are evi-

dences of the constant presence in the circulation of such toxic elements as glucose or urea. Of course, in many instances, these renal disturbances eventually are precursors of chronic renal changes.

The advent of a complicating nephritis is usually unheralded, for the reason that its presence contributes few new subjective symptoms to the original clinical picture of the diabetes. The patient is usually past middle life, with weakened functions and organs, due to long-standing disturbances of metabolism. Along with this state of impaired health go a variety of symptoms which can be variously interpreted, such as headaches, pale countenance, loss of energy, and tired feeling after slight exertion. In fact, were it not for the objective urinary findings, the clinical picture of the complicating disease would oftentimes be so masked as to escape detection.

The sequence of these diseases is interesting. Either there is no relationship of cause and effect between them or else the diabetes is the cause of the nephritis. There seems to be at times a reciprocal or alternating effect manifested between these diseases. That is to say, the renal disease seems occasionally to exercise a benign influence upon the diabetes to such a degree that the glucose disappears from the urine for a period covering months and sometimes I've seen it remain away two years, while the albuminuria persisted. These are the cases which have passed as cured diabetes, a claim which, of course, is open to criticism. In a previous article¹ I offered a possible explanation for the disappearance of a primary disease upon the appearance of another of a different type. The explanation I offered was that there existed a well-defined pathological antagonism between certain diseases to such an extent that the pathological effects of a secondary disease may completely neutralize the pathological effects of a parent disease.

This brief survey of the intimate association of diabetes and chronic nephritis must impress one with the conviction that in the treatment of this particular combination of diseases the question of diet transcends that of drugs. In the selection of a diet to suit the various exigencies that arise in the course in these diseases we must bear in mind these salient facts, namely, that diabetes means a defective carbohydrate metabolism, while nephritis means a defective protein metabolism; secondly, that diabetes means a tendency to general emaciation and debility, to coma or gangrene, while nephritis means the probability of an arteriosclerosis, cardiac involvement, uremia, and apoplexy; thirdly, that diabetes means a glycosuria which is crippling several organs, while nephritis means an albuminuria which is constantly weakening the patient and making him less capable of performing muscular work. And we must bear in mind that both diseases mean chronicity, the danger of dietary errors, the loss of energy, and of the power to repair loss of flesh. It is natural, therefore, to expect that such marked contrasts as exist between these diseases must call for various and diverse measures of dietetic treatment.

The general dietetic principles involved are the following on the part of the diabetes to suppress the excretion of glucose and acetones, to maintain weight and conserve strength; on the part of the nephritis to prevent loss of flesh to ward off edema, to arrest or control arteriosclerosis and the high blood pressure that accompanies it, to effect the elimination of urea and other end products of pro-

tein metabolism. Here we should bear in mind that while these diseases differ so materially in their degree of severity, it is yet quite possible to group patients into classes for purposes of treatment. Thus one class of patients will suffer severely from both diseases, another class will suffer mildly from both diseases, in a third class one or other disease predominates in severity, and, finally, a set of cases in which the advent of one disease exerts a benign influence upon the primary disorder. Naturally the dietary measure must vary to suit the requirements of each group.

The prognosis of this combination of diseases is estimated in various terms. For example, it will depend, on the part of the diabetes, on age, upon the degree of tolerance for carbohydrates, the presence of an acidosis, evidences of malnutrition, the presence of bacterial infections or intoxications, and the state of the vascular system; while the prognosis on the part of the nephritis must depend upon, firstly, how far the renal lesion is advanced, the permeability of the renal epithelium, the state of the vascular system, the integrity of the general renal functions, the presence of arteriosclerosis and hypertension, and the degree of cardiac hypertrophy. From the facts here set forth it is easy to understand that the dietetic treatment of these diseases calls for study and individualization. For, while the radical cure of these patients is beyond hope, their alleviation is often entirely within our reach. If we can prevent an acidosis or cause its disappearance, can reduce the hyperglycemia, control blood pressure, conserve cardiac compensation, and preserve the functions of the kidneys, we are doing a great deal to lengthen the patients tenure of life and to make him comfortable. As one writer aptly put it, we must treat the man, not the disease, for the latter is incurable. The intelligent management of these cases calls for a measure of technical knowledge. I can think of no other diseases which approach the ones under consideration in this particular. The following data is essential, a qualitative analysis of the urinary excretions, a knowledge of the physiological functions of the elements of nutrition, a familiarity with the nutritive values of the common foods, a knowledge of the carbohydrate, fat, and protein content of special articles of diet, a knowledge of the patient's power of assimilation, not only of the carbohydrates but of fats and proteins, and finally a knowledge of the renal function. Without such a mental equipment it is out of the question to construct, with any hope of success, a ration which shall meet the requirements of individual cases.

In prescribing a diet, we must bear in mind that there are clear limitations to dietotherapy beyond which it is not safe to venture. Among such the following stand out prominently:

1. The danger involved in a continuous one-sided diet.
2. The natural requirements and cravings of the economy for all proximate food elements, not excepting water and salts.
3. The danger of a strictly starch-free diet, continued over long periods.
4. The menace involved in strictly scientific feeding based upon ingenious and partisan theories.

A due regard for these limitations will go a long way to simplify the problem of diet and make it possible to standardize various methods of treatment.

Dangers of a One-Sided Diet.—I refer to the fre-

quency with which an acidosis or coma can follow in the wake of a long starch-free diet, or to the symptoms of intestinal intoxication which often follows a continuous protein diet. How often we find diabetics whose symptoms are referable to over-indulgence in animal foods rather than a failure to burn up sugars. These patients display a marked susceptibility to proteins forming sugar more liberally from the latter than from starches. It may be stated as an aphorism that a diabetic who assimilates meat poorly is worse off than one who assimilates starches poorly. His vicarious metabolism shows that a number of his organs are crippled to the verge of complete loss of function. Usually this class of patients will run low sugar percentages and show marked symptoms of prostration, muscular weakness, especially in the calves, and evidences of intestinal disturbances. Such patients require at once physiological rest for their protein-digesting organs besides an exhibition of sugars to the point of tolerance. The proteins should be reduced by one-half beginning with the animal kind, while cheese, milk, and eggs should form their only protein food, if it be deemed advisable to allow proteins at all. Flesh, fish, and fowl should be barred.

The error involved in an over-indulgence in fats must not be overlooked. Many diabetics suffering from nephritis are swamped with foods containing fats, fatty acids, butter, cream, nuts, and cheese, with a view of balancing loss of weight. Soon it is found that these patients do not increase in weight, that emaciation progresses, toxic fatty acids appear in the urine and fats in the stool, while intestinal symptoms due to this faulty fatty metabolism become marked. It is soon realized that it is not a question of how much is eaten, but how much is digested or assimilated, and that an excessive indulgence in fats may become a serious menace to health.

The Natural Cravings of the Human Economy, etc.—In a state of health there is a normal craving for all food elements. There may be individual and natural predilections, varying between total abstinence from one of the food elements, as seen in vegetarians and fructucarians, to the insatiable appetite for sweets or the carnivorous longings seen in others. Hence, a mixed or so-called balanced ration has been found to furnish all natural food requirements. Directly we depart from such a ration for any reason, disturbances of metabolism eventually arise. That is why an acidosis follows in the wake of an exacting starch-free diet, and that is why a prolonged protein diet often leads to disaster. There is also a pathological craving, which may be so strong as to frequently tempt patients to deviate from the straight and narrow diabetic path and indulge their appetites in sweets.

The influence of age upon a choice of diet and upon food requirements, is of importance here. For in a sense the latter are directly proportionate to our bodily activities. Infancy, manhood, middle age, and old age each has its own level of food necessities; persons engaged in sedentary occupations have food requirements quite apart from those employed at manual labor, likewise males differ very materially from females in this respect.

The influence of salts, as an element of nutrition, upon diabetonephritis is of considerable importance in the light of recent investigations. Taking into consideration the fact that diabetics consume large quantities of mineral salts and water,

we have before us a problem which presses with double weight when a true nephritis is associated with the diabetes. It is acknowledged that sodium chloride has a baneful influence on the metabolism of water, which becomes very pronounced after a long administration of sodium bicarbonate, which latter is given for the purpose of warding off coma. A number of investigators, Staubli and Blum,² have furnished clinical evidence of this phenomenon that mineral salts can cause a chloride retention and, as a sequela, a marked or a masked edema. This sequence of pathological events is not uncommon in the wake of diabetes. We have all met with diabetics, who appear to take on flesh and weight, following a long administration of sodium bicarbonate, who on a more critical examination are found to be suffering from a water retention or marked edema. The lesson derived from this observation teaches that we cannot, with immunity, allow salts *ad libitum* in diabetes associated with nephritis, and that it is incumbent that the administration of such salts should be so regulated that there is not placed too much strain on the organs involved in nutrition. Therefore, directly signs of edema appear in this group of cases or the urine becomes diminished or the chlorides disappear, we must assume that these patients are being crowded with foods too rich in extractives, *e.g.* certain fruits, vegetables, meats, etc. Such offensive foods should at once be restricted, and milk, potatoes, cereals, yolks of eggs, butter, and other articles with low salt contents substituted. The presence of an albuminuria with casts pointing to a true nephritis is always an admonition that proteins and mineral salts must be allowed in measured quantities and their elimination carefully guarded.

The Dangers of a Strictly Starch-Free Diet.—In the group of cases under consideration the matter of the glycosuria is often of secondary importance, especially is this true of old persons in whom starchy foods, even slightly beyond the point of toleration, do little harm, always provided that a marked acidosis be prevented. We are on the wrong track, if we allow ourselves to believe that a glycemia is the greatest source of danger, or that the gravity of a given case can be measured in terms of sugar excreted. Many diabetics with high sugar percentages remain in better condition than do those with low percentages. It was formerly the rule to regulate the quantity of starch-free food by the degree of glycemia or the glycosuria and to estimate the progress of the disease by their amount, but to-day we believe that the amount of sugar excreted is a deceptive guide in passing judgment upon these cases. The tolerance for carbohydrates is a very variable term; it fluctuates within wide ranges in the same individual. Likewise the degree of tolerance for different carbohydrates is a relative term. Some diabetics have a greater tolerance for oatmeal, others for starch, or rice, or potatoes. In persons suffering from diabetes and nephritis it is necessary to establish this index of tolerance, for there may come a time, depending upon the state of the renal or cardiac functions, when proteins must be discarded to a certain extent in favor of starches. When such patients show evidence of cardiac decompensation or of edema or cerebral symptoms, it is time that most animal foods be abandoned, and milk and cereals substituted.

A method that I frequently adopt, especially if the edema be marked and be an expression of a

chronic interstitial nephritis, is to place the patient upon the so-called Karel treatment. This method of treatment has been employed for many years for the relief of edema due to renal or circulatory disturbances. It consists in the exclusive administration of milk in small quantities daily, for a number of weeks, say two hundred c.c. four times daily. The principle involved in this treatment is the reduction of all foods with a view of bringing about a draining or dehydration of the system. I usually modify Karel's method in order to satisfy the want of the patient, by allowing two or three eggs each day. This is also an ideal method of treatment where the blood pressure continues high and uremic symptoms are manifest. For such a diet allows just enough proteins necessary for the repair of tissues, for the conservation of energy, and the performance of muscular work, besides which it takes away the strain on kidney, heart, and arteries, at the same time promoting the elimination of toxic elements from the blood.

The danger of a strictly starch-free diet as an element in the production of acidosis has already been alluded to. A question of much interest in this connection is, How long may a patient safely continue on a starch-free diet? I should say about four weeks. Often at the end of this period, both the albuminuria and glycosuria will have disappeared, or perhaps one will alternate with the other. Another question that may arise is, How much carbohydrate food may a patient have? The answer to this is, as much as he can assimilate. Usually it will be whole milk a pint a day, two or three potatoes daily, two or three slices of ordinary wheat bread. This, of course, is in addition to the quantity of protein food allowable by reason of his nephritis.

The Theory Involved in Strictly Scientific Feeding and in Partisan Theories.—There are few diseases whose treatment has gone through so many vicissitudes as has diabetes. Ever since this disease was recognized as a disorder of metabolism, one dietetic method after another has had a "try-out." Each of these methods in its day was hopefully received by a gullible profession, had a meteoric run, and then was relegated to the category of therapeutic failures. It seems to be the acknowledged order of things in medicine that new methods of treatment are always hailed with enthusiasm, and, of course, furnish wonderful results. But often there comes a period of doubt and suspicion, and then the new method shares the fate of many others that have gone before it. Many of them seemed plausible enough at the time, and had the merit of being ingenious as far as the dietetic necessities of the patient were concerned, for they were constructed upon theories based on chemical formula and equations and other physiological data derived from laboratory studies, but unfortunately for the patient clinical experience did not bear out these theories nor harmonize with the chemical formula. Scientific feeding based on laboratory findings has in many instances proven to be a therapeutic fallacy. It has not solved the problem of diet for the sick, for the reason that the laws of nature are quite apart from the laws of the laboratory. That is why caloric feeding has not netted satisfactory results in the individual, although it has proven useful among large bodies of men, as in camps, hospitals, and prisons. The stomach refuses to act as a test tube, while human metabolism is itself so complex a phenomenon as not to permit

of generalization of food values nor to admit of the framing of positive rules of food disposal.

Recently a dietetic method, which has been widely heralded and favorably received as a great advance in treatment, has come into vogue, and is known as the prolonged fasting or starvation treatment of Allen. Fasting as a dietetic measure has been advocated and practised under various guises by Falta, Magnus-Levy, von Noorden, and Guelpa, each of whom in his day reported flattering results as far as his efforts to make the urine sugar and acid free were concerned. And yet, with the exception of von Norden's oatmeal and vegetable régime none of these fasting methods had inspired confidence enough on the medical mind to survive the test of time and experience. The fundamentals of Allen's³ method may be briefly summarized in the following three postulates: (1) Diabetes is the weakness of a metabolic function; (2) increase of weight and metabolism increase the strain on pancreatic function; (3) patients should be kept under weight and under reduced metabolism. This conception of the nature of diabetes is fortified at length by Allen with clinical and experimental studies of great value. My own experience with this treatment is limited to twelve cases of the classical type, of which five were complicated by nephritis; although my patients were not institutional but home ones, nevertheless I was enabled with their intelligent co-operation to conduct the treatment with due regard for details as advocated by Allen. Of course, I am aware that on the basis of such a limited experience, generalizations and deductions as to the value of this method are barely possible, and I do not hesitate to make this acknowledgment. The record of my dozen cases show that seven cases became sugar free at the end of an initial fast of four to seven days; the others resisted all efforts in this direction. Nine of these cases showed well-marked acidoses, of which six became acid free after the initial fast; in the other three, the acidosis persisted to my chagrin with the same intensity. Of the cases improved, that is the seven that became sugar free, five lapsed into their former state of glycosuria. A point of interest here is that a number of cases cited above had been sugar free temporarily, under other dietetic measures and several became sugar free even under reduced feeding and rest in bed. From a study of these cases we may reasonably infer that there is an honest difference of opinion as to the permanent value of this method.

Allen lays great stress on the factor that diabetes is the simple weakening of a metabolic function, which can by proper training be strengthened. This conception is open to the serious objection that we cannot logically devise a line of treatment purely on the basis of a disturbed physiological function; we must go one step further and find a pathological basis. This is the elementary principle of rational treatment. If unfortunately, as is the case with diabetes, we cannot point to any acknowledged pathology, but one that vacillates with each decade, we must expect that treatment will do the same. Human metabolism is one complex system of checks and balances, involving different and distant organs, and chains of organs, and this complex incidence makes it impossible to localize this metabolic disturbance, nor can we dignify any organ, the pancreas not excepted, as the one uniformly involved in diabetes. Hyperchlorhydria is a weakening also of a metabolic function in a sense, but we do not treat this disturbance by constantly re-

stricting acid foods, or endeavor by dietetic measures to strengthen it; the logical procedure is to look for a pathological basis on the principle, that this gastric symptom must proceed from the operation of a diseased organ. We are advised that diabetes is due to a disturbance of carbohydrate metabolism, which is true, but how can we reconcile with this statement the recent discovery that glycosuria often is produced from amino-acids, which are the end-products of protein metabolism. This opens up the question, Is the fasting treatment applicable to this type of diabetes?

We are told this treatment causes the glycosuria and acetonuria to disappear in a few days, but we are not advised as to the *modus operandi* by which these changes are effected. I believe it is natural to expect that fasting will make the urine sugar and acid free; fasting probably has the same effect on other foreign elements found in the urine during disease, *e. g.*, peptones, albumoses indican, fats, glycourinates, and ethereal sulphates. During the process of fasting, whether voluntary or therapeutic, the body is self-consuming to such a degree that it sheds itself, so to speak, of much extraneous matter, supporting itself meanwhile on its own protein and fats. As an illustration of this, I cite the fact that several of my cases showed complete absence of albuminuria after the initial fast. But though the albumin disappeared from the urine, I could not convince myself that the chronic nephritis had come to an end. And so it is with the glucose, though we may succeed in eliminating it, the pathological factors that produced it are still in operation, and the patient still has diabetes.

Regarding the aim of Allen to keep the patient below weight and under reduced metabolism, it would appear that this effect is automatically accomplished by the natural ravages of the disease itself, without subjecting the patient to the heroic treatment of fasting. My experience has been, that a confirmed diabetic before he comes under treatment will lose weight at a rapid pace, and while he may improve materially under observation he rarely reaches the level of weight that marked his era of health. This rapid emaciation and failure to regain his original highest weight admonishes us that there is a real danger in under feeding patients who are naturally disposed to emaciation and denutrition. The inclination of diabetics to overfeed and thus to overload their digestive organs and overcharge their organs of metabolism must be combatted. Feeding is not so much a question how much is ingested, but how much is digested.

The suggestion that increase of weight and of metabolism increase the strain of the function of the pancreas presupposes that this organ is the real pathological site of diabetes; this, however, is a question which still lacks full confirmation, for we know that diabetes occurs without evidence of pancreatic disease, and conversely pancreatic disease occurs without diabetes. Pathology has not yet solved this discrepancy. Efforts have recently been made to place the pancreatic origin of diabetes in the background and to ascribe its etiology to disease of one or more of the ductless glands.

The influence of diet upon this association of diseases is very changeable. The renal and cardiac function require constant watching. The amount of urine voided is no longer a reliable index, since the natural course of the nephritis may produce a diminished amount, which will be masked by the increased amount due to the diabetes. In the same

way the specific gravity is unreliable. The blood-pressure curve is valuable in determining the relative importance of the two diseases. When a diabetic voids less than he usually did, has headaches or is drowsy, has an increasing blood-pressure, an accentuated aortic second, an increasing albuminuria, his nephritis will require more attention than the glycosuria. On the contrary, if the patient show no steady rise of blood-pressure, no cardiac hypertrophy, no evidence of arteriosclerosis, the glycosuria will require attention. The ideal to be sought in this form of cases is avoidance of a ketonuria. In a patient advanced in years, in whom an acidosis can be kept in abeyance, the glycosuria need not be regarded seriously.

1309 MADISON AVENUE

THE X-RAY TREATMENT OF UTERINE MYOMATA.

A WARNING BASED ON A STUDY OF THE LITERATURE.

BY ARTHUR STEIN, M.D., F.A.C.S.,

NEW YORK.

ADJUNCT VISITING GYNECOLOGIST, GERMAN HOSPITAL ADJUNCT VISITING OBSTETRICIAN, HARLEM HOSPITAL.

THE announcement that x-ray treatment had been so unusually successful in cases of myoma of the uterus aroused the interest of all the men who had been relying on the knife only in these cases. A new and powerful method seemed to be waiting for a trial. Certainly the first reports were astonishing, to say the least, and even now, when the first enthusiasm has subsided, we hear of excellent results. However, I feel that this is a good time to look over the field and to see just what good and what harm lies in the treatment, the more so as I had the opportunity to observe and finally operate in a case for a supposed myoma of the uterus where the x-ray treatment was considered, but for some reason or other fortunately not adopted. The case was that of a young unmarried girl, 27 years of age, where I performed a total extirpation for multiple myoma weighing about 16 pounds. Microscopical examination of sections taken from the various portions of the tumor (made by Dr. Humphreys, chief of the German Hospital laboratory) showed it to be a fibromyoma undergoing sarcomatous changes. This young woman could be discharged cured less than three weeks after the operation, and it is somewhat painful to reflect on what might have been her fate had she been subjected to x-ray treatment. The risk is too serious, for surely no gynecologist will claim an ability to recognize the malignant degeneration of a myoma in the uterus.

As one cannot draw conclusions from one case (which did not even receive x-ray treatment) I looked through the literature and herewith present the following cases which substantiate my claim.

In the treatment of uterine myoma the most important consideration of all is probably that of sarcomatous degeneration. In view of the danger of delay in the presence of malignancy the enthusi-

astic claims in favor of *x*-ray treatment of these cases call for very close investigation of the actual facts. The question has been raised among leading gynecologists whether the operative treatment of myoma has not been rendered superfluous by *x*-ray treatment. After making careful inquiry as to the remote results in radiated patients it will be realized that much harm may be done to the patient through irreparable loss of time and also to the surgeon who finds himself confronted in certain cases with a condition that has become inoperable. It is very instructive to learn of Klein's¹ experience with malignant degeneration of uterine myoma established by microscopical examination, for his findings show that at a conservative estimate the figure of 7.7 per cent. represents the minimum of malignancy. (Among 491 operative cases of myoma 38, or 7.7 per cent., showed malignant degeneration or a combination with cancer or sarcoma.) While opinions vary as to the liability of myoma to sarcomatous change, discretion is indicated in the avoidance of the extreme attitude that sarcoma never develops in a radiated uterus.

The difficulty of the early diagnosis of malignant tumors, especially sarcoma, is generally admitted, but there seems to be some danger of underestimating it in this particular connection. In view of the notorious fallacy of statistics there is a deplorable tendency to minimize the incidence of malignant degeneration in untreated tumors. Nor have we the right at the present state of radiological knowledge to take it for granted that the *x*-rays may not set up proliferative changes of a degenerative character in those cell areas of a radiated myoma which are not destroyed by the treatment. Although young women in the child-bearing age are not usually considered fit candidates for *x*-ray treatment, it is well to point out in this connection the possible danger to later offspring through changes of the germ-plasm brought about by exposure of the maternal tissue to *x*-rays. Stunted and malformed young have been noted in the litters of animals which had served for *x*-ray experimentation. As pointed out by Fiessler,² gynecological *x*-ray treatment affects all the germinal cells which may still become fertilized and develop in the lifetime of the individual. The question naturally arises if a radiated germ cell will recover so as to be in the same state as before the radiation or if the cell is irreparably damaged and able to produce only a low-grade fetus. Singer³ believes that *x*-ray treatment, aside from many other dangers, may induce miscarriage in subsequent pregnancies. Fraenkel⁴ cautions against the radiation of functioning ovaries, as we do not know whether or not the ova and germinal tissue may be permanently damaged. In this connection it is of interest to note that in the opinion of v. Herff⁵ the effect of *x*-ray radiation upon the retrogression of myomas is exclusively indirect and due to damage to the ovaries. Destruction of ovarian tissue through the *x*-rays is unjustifiable in the treatment of uterine myoma in young women—aside from the possible effects upon the offspring—on account of the detrimental influence upon the general metabolism through the loss of an important internal secretion. In addition, the *x*-ray treatment of myoma patients involves the danger of very profuse hemorrhage which may actually threaten life. In a case reported by Weisswange⁶ timely operation was prevented by the long-continued *x*-ray radiations, and the patient became so weak through profuse hemorrhage that operation

came too late. Sometimes the *x*-ray exerts an action opposite to the desired effect of reducing the myoma. An illustrative case in which the myoma greatly increased in size under the influence of *x*-ray radiations was reported by Rübsamen and Kehrer.⁷ In the experience of Füh,⁸ with eleven cases of myoma, two patients with large tumors had to be operated upon finally after *x*-ray treatment had failed. In one of these cases the tumor (size of child's head), after twenty separate radiations, applied in the course of five months, not only had failed to decrease in size, but was actually a little larger than before, while the very profuse hemorrhage still persisted. The other patient's tumor likewise increased in size under *x*-ray treatment, but here general condition fortunately improved so as to permit the surgical interference which should have been resorted to in the first place.

Doederlein,⁹ at a recent meeting of the Munich Gynecological Society, presented a myomatous uterus which had not ceased to bleed in spite of *x*-ray radiation and insertion of mesothorium. An operation was performed and the microscopical examination of the specimen showed a large cellular sarcoma. The inquiry was raised in the assembly as to the medico-legal aspect of the matter, and Doederlein stated that in his opinion a physician is justified in declining radiotherapy altogether in the treatment of myoma.

A very instructive case was reported by Lacaille¹⁰ concerning a patient who refused operation, although the tumor had recently grown so rapidly and her general condition had deteriorated so markedly as to suggest sarcoma. Under radiotherapy her general condition improved, and the tumor diminished in size, rendering operative interference possible: The myoma was found to have undergone sarcomatous degeneration. An equally serious revelation was furnished by the late operation in Strassman's¹¹ case, illustrating the great responsibility incurred with long-continued radiation treatment. The patient was a woman, 53 years of age, with a large myoma which had previously been radiated and then had given rise to pressure symptoms. Laparotomy was performed and showed the presence of a large parovarian cystoma, a myomatous uterus, and malignant degeneration of both ovaries.

Halban's case adds its weight to the unreliability of *x*-ray treatment when the condition is not positively known to be an uncomplicated myoma. He demonstrated before the Vienna Obsteric and Gynecological Society, in January, 1914, a carcinoma of the lowest coil of the small intestine which was adherent to the myomatous uterus. The patient, a woman 35 years of age, who menstruated regularly, was to receive *x*-ray treatment, but fortunately an operation was performed instead, and the true condition was discovered.

The difficulty of selecting suitable cases for radiotherapy is shown very strikingly in Kaufmann's¹² case of interstitial pregnancy and uterine hemorrhage in a woman of 30 years with a tumor (the size of a plum) of the fundus, apparently a myoma, but shown on operation to be a fetal sac containing a fetus 1 cm. in length. As the diagnosis was uterine myoma, the choice between radiation and operation had been left to the patient, who fortunately decided in favor of the latter. Other than operative treatment might have resulted in her death through rupture of the interstitial pregnancy, whereas instead she made an uninterrupted recovery.

The *x*-ray treatment of myoma is not universally regarded as a progress, and this fact, resting as it does on the experience of authorities, must be emphasized again and again in view of the wave of injudicious enthusiasm which threatens to sweep away in untimely death a number of cases originally amenable to surgical measures. The exaggerated and indiscriminating employment of radiation was, for example, criticized by Kaiser,¹³ who confirmed his views by the demonstration of two fresh specimens, one a submucous myoma which could not be diagnosed as such, the other a myomatous uterus with malignant degeneration of the endometrium. Upon the basis of a wide experience Bretschneider¹⁴ is not convinced of the superiority of *x*-ray treatment of uterine myoma, especially in view of the fact that his 108 cases include no less than eight cases of malignant degeneration. The danger of radiating an unrecognized malignant tumor, notably a sarcoma, cannot be entirely eliminated in any case, and the possibility of a connection between the formation of a malignant tumor and exposure to *x*-rays can hardly be denied in the following observation of Hedinger.¹⁵ The patient, a woman 55 years of age, was treated with prolonged and intense *x*-ray radiations for myoma of the uterus the size of a fist. Two years later she began to suffer from profuse hemorrhages, requiring operative interference at the end of a few months. Hysterectomy was performed and the corpus uteri was found to contain a partly ulcerated nodule, measuring 2 to 3 cm. Microscopically this was shown to be in part a round and spindle cell sarcoma and in part pure cylinder cell sarcoma. Myomatous tissue was no longer demonstrable. A very interesting and instructive counterpart to this observation was recently reported by Shoemaker,¹⁶ whose patient gave a complete and readily verified history of *x*-ray treatment for a large fibroma of the uterus. The patient, at the time of the report a woman 56 years of age, developed sarcoma in her fibroid tumor about seven years after Roentgen-ray treatment was begun and five years after it was discontinued. The comparatively brief past of *x*-ray treatment of uterine myoma is emphasized by Shoemaker, who points out that it will be many years yet before the final outcome of these treated cases can be known. Carcinoma was demonstrated after two and a half months' *x*-ray treatment in a case reported by Haenisch.¹⁷ In two patients radiation proved useless, and an operation became necessary. Repeatedly profuse hemorrhage followed upon the first radiation requiring surgical interference. Malignant degeneration of uterine myoma was found in 7 per cent. in a material of over five hundred myoma cases by Klein,¹⁸ who emphasizes that the indications and contraindications for the radiation of uterine myoma cannot yet be positively outlined. All *x*-ray treatment is tentative, and must be followed by operation if necessary. The frequently observed *x*-ray peritonitis, with acute swelling, redness, and even deposits on the peritoneum, is probably due to exacerbation of chronic inflammatory processes. Operative treatment of myoma, in his opinion, is still in part justified, in part necessary, in suspected malignant changes of the myoma, or in myoma combined with malignant degeneration of the uterine mucosa, in necrotic and gangrenous myoma as well as in submucous tumors with profuse hemorrhage, and in polypoid myoma; finally in cases with a doubtful diagnosis of the existing tumor, or where there is reason to suspect a combination of myoma with some other more dangerous tumor,

such as malignant neoplasm of the ovary. Among 491 myoma patients who were operated upon 38 showed malignant degeneration, or combination with malignant tumors, including 13 sarcomata, 16 carcinoma of the corpus uteri, 9 carcinoma of the cervix. In Klein's experience 6 supposed cases of myoma which were unsuccessfully radiated proved to be solid ovarian tumors requiring operation. Among 418 operative cases observed by Mackenrodt¹⁹ a combination with carcinoma was noted in 6 per cent., with sarcoma in 4 per cent., with ovarian tumor in 20.8 per cent., with suppurative oophoritis and pyosalpinx in 4.3 per cent. In addition there was one case of combination with tuberculosis, four with appendicitis, two with pyometra and suppuration. There remained only twenty-one cases which after careful examination entered into consideration for *x*-ray treatment with prospects of a fairly successful outcome.

Radiotherapy, although only recently inaugurated, already has a mortality which is due not only to accidental factors, such as embolism, but principally to inaccurate and faulty diagnosis. In view of the difficulty of recognizing the complications of myoma, if present, *x*-ray treatment is not indicated in all cases.

Opitz²⁰ speaks of severe disturbances due to loss of internal secretions of the ovary, as well as disturbances of the bowel and peritoneum. He disposes of a consecutive series of 83 myoma operations, mostly total abdominal extirpations, without a death, and thinks that surgical interference should be advocated in many cases, especially as the primary and permanent curative results leave nothing to be desired. The effects of surgical myoma therapy are among the most brilliant achievements of the operating gynecologist. The frequency of sarcomatous degeneration and the occurrence of carcinoma in a myomatous uterus are regarded as contraindications against *x*-ray treatment by Koblanck.²¹ Kuntzoch²² reports three cases, in one of which the *x*-ray treatment led to the patient's death, and in the two others would inevitably have caused death if it had been employed. The first case concerned a mistaken diagnosis in a case of ovarian cancer; in the second case the myoma was found to contain in its interior a cancer the size of an apple; in the third case torsion of the pedicle, necrotic changes and adhesions had occurred, and considerable peritonitis was present without clinical evidence. Among twenty myoma cases which were operated upon on account of rapid growth of the tumor, Walthard²³ observed five which had not been previously recognized as sarcomata. The diagnosis was confirmed through recurrence of the tumor and death of three of these patients. v. Franqué assumes a percentage of 3.6 per cent. of sarcomatous denegeration of uterine myoma, and is inclined to question the alleged clinical harmlessness of myoma in the menopause, also in the artificial menopause through radiation. The difficulty of diagnosis in not so very rare cases of myoma combined with carcinoma of the corpus mucosa is emphasized by Küstner,²⁴ together with the scantiness of available information concerning the effect of the *x*-rays upon the myoma tissue.

On account of the overwhelming importance and ever-present danger of malignant degeneration, the liability to aggravated bleeding and loss of strength in consequence of *x*-ray treatment in certain myoma cases is often regarded as relatively insignificant. However, such patients may be seriously weakened by the recurrent hemorrhages, sometimes with

actual danger to their lives. A myomatous uterus of this type which had been unsuccessfully treated with x -rays and was finally removed for vital indications was demonstrated by Flatau at a meeting of the Nuremberg Medical Society, April 18, 1912, and Falk, at a meeting of the Berlin Medical Society, February 28, 1912, showed three cases of uterine myoma in which the x -ray treatment had to be stopped and an operation performed on account of increased bleeding after the first radiation. In the experience of Bégouin²⁵ weekly radiations of about twenty to thirty minutes in two patients of 56 years were followed in the fourth week of the treatment by general unfavorable manifestations, anemia, emaciation, rise of temperature, abdominal pains, a slimy discharge, and edema of the legs. One of these two patients died six days after the fourth radiation, the other's life was saved through arrest of radiation and rest. Five of six cases treated with x -rays reported by Zoellner²⁶ became worse after a brief primary improvement, and the hemorrhages were seriously aggravated. The initial congestion of the genital organs at the beginning of the radiations may cause a reversal of the effect of the x -rays so that the bleeding is increased instead of diminished. Moreover, in spite of the undeniable influence of the x -rays, the source of the hemorrhage is not apparently always reached. More general causes, such as hemophilia or leucemia are sometimes responsible for uterine hemorrhage. No matter what the ultimate reason in a given case may be profuse hemorrhage has been repeatedly observed in connection with the first radiation, requiring surgical interference.

Injuries directly due to x -ray treatment are practically unavoidable, even with the present improved technic. From the surgeon's viewpoint the newly formed adhesions are a very important obstacle in the performance of subsequently needed operations. Abel⁴ noted extensive adhesions in operating upon patients who had received large doses of x -rays. Multiple peritoneal adhesions were found by v. Haberer⁴ at the time of extirpation of a carcinoma of the abdominal skin which had originated after three weeks of x -ray treatment. Deep ulcers of the abdominal skin are by no means rare in obese radiated patients on account of poor nutritional conditions, and these ulcers heal very slowly. (Desplats.²⁷) Well marked reaction on the part of the skin, and even dermatitis is frequently mentioned. (Haenisch.¹⁷) A sclerotic change of the pelvic connective tissue is described by Henkel as an undesirable associated phenomenon after x -ray radiation.

The absence of reaction is not a guarantee against subsequent damage, which is occasionally delayed for a considerable time, up to eighteen months, according to Iselin,⁴ who calls attention to the cumulation of x -ray effects even with conscientious dosage and filtration. The cause is presumably a primary damage of the cutaneous blood vessels. The onset of deep, very obstinate, and extremely painful ulcers of the abdominal skin six to ten months after beginning of x -ray treatment is mentioned as a late reaction by Klymens.²⁸

The occurrence of intestinal lesions in particular seems to have been definitely established as a sequel of radiation. As pointed out by Bumm,²⁹ who observed a case of progressive emaciation with uncontrollable diarrhea due to x -ray treatment, there is no reason why, if the uterus and hard tumors like

myomas are directly influenced, the ganglion cells of the abdomen in the vicinity of the radiated zone should not be equally influenced and exposed to serious damage. Irritative conditions on the part of the bowel and bladder are mentioned among the associated phenomena of radiation by Eymer and Menge.³⁰ Haendly³¹ observed loss of weight amounting in one case to eleven pounds, and uncontrollable diarrhea in two others. Mackenrodt¹⁹ described a case of progressive emaciation in spite of all remedies not arrested after vaginal extirpation of the uterus, suggesting a possible obliteration of the intestinal glands. The necessity of care in radiations of the abdomen for the avoidance of injury to the digestive tract is emphasized by Wetterer.³² The intestine in some cases reacts very strongly to the radiation and symptoms such as nausea, vomiting, diarrhea, mucoid discharges and pain often persist for several days, suggesting intestinal lesions through the x -ray treatment. A number of French investigators³³ produced intestinal lesions through radiations in experiments upon dogs whose gastrointestinal mucosa closely resembles the human digestive tract. Rapid damage resulted, especially well marked in the villi of the small intestine, the glands of Lieberkühn and the lymphoid elements of the mucosa. Large doses of x -rays were found capable of causing the entire disappearance of the glands of Lieberkühn within a few days, the glandular elements undergoing destruction through the necrotic changes and absorption of the epithelial cells. Moderate and even weak doses caused a diminution in the size of these glands through destruction of part of the cells and reduction in volume of the remaining cells. Perforation is apt to occur in the most seriously damaged portions of the intestine.

As a sequel of long-continued x -ray treatment, atrophy of the gastrointestinal glands is therefore not an uncommon occurrence and these atrophic changes may moreover extend to the blood-forming organs so that caution is recommended by Albers-Schönberg.³⁴ Radiation, in the opinion of Matthei,³⁵ gives rise to considerable leucocytosis, causing an alteration in the blood. The grave damage done to the heart and the circulatory apparatus must not be underestimated. At the end of years remote changes may still appear suggesting very insidious damage of the blood vessels.

The fact that x -ray treatment is not a panacea, as some are inclined to believe, was emphasized by Runge⁴ at the Sixth International Congress for Obstetrics and Gynecology. By parallel experimentation, moreover, Wetterer³² was enabled to show that the rapid sterilization of women suffering from myoma and metrorrhagia is not desirable because the symptoms of lost function are much more marked than in those cases in which the artificial climacteric is induced more gradually.

Summarizing the contraindications of x -ray treatment of uterine myoma, de Bovis³⁶ enumerates the development of carcinoma or sarcoma, gangrene, submucous seat of the tumor, grave anemia after profuse hemorrhage, complications with inflammatory conditions of the adnexa. Aside from the actual dangers of this mode of treatment it also involves the disadvantages of long duration and considerable expense. The limitations of x -ray treatment are emphasized by Mackenrodt¹⁹ as follows. The radiation acts through the obliteration of the ovaries; where this is not desired such treatment can never be indicated. In many cases

radiation does not arrest the development of the myoma but merely improves some symptoms. Not only are errors unavoidable in the selection of the cases, but radiation is probably always associated with more or less undesirable side effects. By Matthei,³³ x-ray treatment is advocated exclusively for climacteric and preclimacteric hemorrhages of known benign character as shown by exploratory curettage. In young women, recurrences of radiated and apparently cured myomas are not uncommon, an additional reason why x-ray treatment is contraindicated in these cases. It must also be kept in mind that the persistence of a myoma in the uterus is undesirable even in the absence of hemorrhage.

In a recent contribution to the x-ray treatment of myoma by Birdsall³⁷ the following paragraph appears: "The question of subsequent malignant degeneration of the fibroid has been raised. The answer to date is that no such sequel has as yet been reported. The percentage of cases undergoing malignant degeneration with no treatment at all is but from 1 to 2 per cent., thus giving another good reason for the selection of the Roentgen treatment."

The facts arraigned above are so eloquent as to render superfluous any further comments on the contraindications of x-ray treatment for uterine myoma. Judiciously restrained, its indications are very limited, including besides the myoma patients who have reached the climacteric, those suffering in addition from diabetes, obesity, advanced arteriosclerosis or hemophilia, in whom surgical interference involves danger to life.

NITROUS OXIDE ANALGESIA IN OBSTETRICS.

BY N. SPROAT HEANEY, M.D.,

CHICAGO.

THE use of nitrous oxide in obstetrics is not new. Klikowitz of Petrograd in 1880 gave a mixture of 80 parts of nitrous oxide and 20 parts of oxygen in a series of twenty-five labor cases with gratifying results. He began the administration early and continued its use intermittently throughout the entire labor. He gave only sufficient to allay pain, but not enough to obliterate consciousness. He reported that the contractions were frequently increased in intensity, but never diminished, and that the fetal and maternal pulse were not much altered.

In 1881 von Winckel used nitrous oxide and oxygen analgesia in fifty cases, and in his textbook of midwifery (translated by Edgar in 1890) makes the following statement: "Narcosis by means of laughing gas is not dangerous, and may be discontinued at the will of the parturient woman; it mitigates the pain in proportion to the intelligence of the person, as stupid persons often withstand its influence for a long time before its favorable effect is felt. In most persons its inhalation produces a state of intoxication for a short time with a tendency to laughter. Women to whom it is not administered until the stage of expulsion can seldom be induced to inhale in quietly, while when it is administered in the first stage of labor its beneficial action is at once felt, and extends to the second stage. It is especially useful in primiparæ."

In speaking of the clinical results Winckel says: "The pulse of the parturient woman is usually slowed considerably by laughing gas, but finally reaches its original rate again. The child's pulse is also slower in 8 per cent, but usually it seems to be more frequent. The woman's temperature rises often several tenths of a degree. At first the pupils are somewhat contracted. The pains are not the same in strength or duration, but are often more frequent and stronger, and existing vomiting frequently ceases. Klikowitz and I have both observed aphasia, and once in fifty cases a hysterio-epileptic attack was caused, and in one a real epileptic seizure followed its use, but otherwise no bad effects were observed, either as regards the mother or the child. The oxygen of the blood remains in normal combination, while the nitrous oxid probably circulates in much looser chemical combination in the blood, absorbed by the plasma. (Doederlein.) These researches should be supplemented by the observations of others, and were by no means thought conclusive by us, as Doederlein believes. It seems to me most practical to get the mixture from the apothecary, as was formerly the

case, and that he should be provided with rubber bags, which he may fill and furnish the physician when needed. In this manner the gas might be introduced into private practice and would not be monopolized by the clinics. A number of interesting problems attach to its use, but we refrain from discussing them. The apparatus, which consists of a rubber bag like a pillow, is inconvenient, it must be confessed, but this is entirely subordinate; in abnormally painful labor it is at any rate an extremely important remedy."

Since nitrous oxide is so extensively used in surgery, it is but natural to believe that many obstetricians since Klikowitz and von Winckel must have made use of it in the conduct of labor cases.

The routine use of nitrous oxide and oxygen in normal labor is, however, of rather recent origin, and dates from the time of perfected gas machines and pure nitrous oxide, which permitted accurate dosage, safe and cheap administration. While in 1913 and 1914 in Chicago nitrous oxide and oxygen analgesia was being employed as a regular means of relieving the pains of labor only in the Presbyterian Hospital, it is now used extensively in every Chicago hospital, with possibly one exception, and in several is administered as a routine to every case which can pay for the gas used.

With a proper machine nitrous oxide may be so given that a patient is oblivious to pain yet maintains consciousness and coordination. The quantity of gas necessary to produce this state varies with the individual; some require much, others quickly pass from the equilibrium of analgesia into anesthesia. In order to produce a more stable equilibrium, oxygen is mixed with the gas so that the concentration of the nitrous oxide may be varied to suit the individual as well as the changing character of her pains. The more susceptible the individual, the more apt she is to become cyanotic and unconscious, the greater the percentage of oxygen necessary in the mixture.

A few pains will show what mixture is best for a given case. When the mixture is right, two to three quick inhalations at the beginning of a contraction are sufficient to prevent the contraction being felt, and the patient's normal color and consciousness are preserved; she can bear down when directed and can follow every command of the attending physician. If the mixture is too rich, the patient becomes cyanotic or anesthetized and has confusing dreams. No physical harm results from slight excursions into anesthesia except that if the expulsive stage is on, the patient cannot give the very necessary help which is so characteristic of the proper stage of analgesia. When giving gas for the first time, the tendency is to give more than necessary; with familiarity, much less gas is used.

The administration may be begun at any time. Usually this is left to the inclination of the patient. As soon as she feels inconvenienced by the strength of her pains she makes the fact known, and the analgesia is started. It is rarely asked for before the first stage is well advanced; oftentimes not until dilatation is complete. The A. C. Clark Company has placed a trigger valve next to the inhaler, and since their gas machine is equipped with automatic regulators controlling the gas pressure, the patient may administer her own analgesia during the early stages of labor, the indicators being set for a constant mixture of gas and oxygen. In the event that she should pass beyond the analgesic zone the hand relaxes and the valve closes. With the approach of

her next pain she applies the inhaler, presses down the valve, inhales, and the gas flow is started again. As labor advances it is necessary that the physician be in attendance.

Normally the uterus begins to contract several seconds before the patient perceives pain. If, when the attendant palpates the approaching uterine contraction, he places the inhaler in position and directs the patient to take the necessary number of inhalations determined as necessary in her case, she is well within the analgesic zone by the time the contraction would ordinarily be producing pain. If the labor is in the second stage, the patient is then directed to hold her breath and to bear down, and to pull upon the straps provided for the purpose. After the maximum effort is expended, she is directed to take another deep breath or two and to again bear down. The usual second-degree pain is such that it is divided into three or four expulsive efforts. The first inhalations are usually pure nitrous oxide, while each subsequent inhalation is of a more diluted mixture, the degree of dilution varying in each case and at different periods during the same labor. When the uterus is felt in beginning relaxation, the mask is removed, and the hand is placed upon the abdomen to anticipate the next pain. If the administration of the gas is delayed each time until the patient herself feels the pain, the result will be decreased pain instead of painlessness.

High-strung individuals with keen perceptive qualities sometimes suffer pain before the attendant can detect that the uterus is contracting. In such cases occasionally we have to administer a light continuous analgesia, if the patient is in the second stage, or administer a dose of chloral, if in the first stage, to decrease the keenness of perception.

Nitrous oxide analgesia does not lessen the frequency or the intensity of the uterine contractions, so that if for any reason it is deemed that the birth is advancing too rapidly, ether may be mixed with the gas or substituted for it. When the pains are again satisfactory, the ether is stopped and nitrous oxide resumed. As the head passes over the perineum occasionally the gas must be administered to the anesthetic degree, though usually analgesia is entirely sufficient.

The heart tones of the mother and child are unaltered by nitrous oxide analgesia, so that the criteria to the well being of the child are uninfluenced by the fact that the mother is receiving nitrous oxide.

The child cries immediately upon birth, since its dose of gas is as evanescent in its action as is the mother's. The mother is in full control of her faculties within a minute or two after delivery, and suffers no inconvenience from her analgesia.

There is no relaxation of the uterus, and, providing ether has not been used, the third stage terminates as promptly and as satisfactorily as when no anesthetic is given. The perineum may be repaired under analgesia or in a deeper stage of anesthesia, as the occasion demands.

The course of labor is followed by rectal examination. In this way the physician can administer the analgesia himself until it is necessary for him to prepare for delivery, after which time it may be given under his guidance by someone else, not necessarily skilled in its administration. Should vaginal examinations be necessary, these are made while the patient is analgesic. The whole hand may, when necessary, be introduced into the vagina,

and at that time, if advisable, the cervix may be manually dilated, or a malposition may be converted, not only without pain, but without stopping the progress of labor as is usually the case when these manipulations are performed under the influence of ether.

In hospital use the gases are secured in large cylinders, which markedly reduces the cost. With gas-saving appliances, careful administration, and large cylinders we can give the analgesia at a cost of from fifty cents to one dollar an hour. With a portable apparatus and small cylinders the cost is increased, but not beyond the desire of the patient to pay for its use rather than to do without it.

The percentage of entirely successful administrations is very high. When the pains are natural in character, *i.e.*, where the normal interval exists between the beginning of a uterine contraction and the perception of the pain by the patient, we can with a great deal of assurance promise a painless labor. In abnormal pains, such as are more liable to be found in abnormal presentations the first part of the pain may be felt unless chloral is given in the first stage or a continuous analgesia in the second stage. Even in such cases the pains are reduced by the ordinary analgesia alone to a minimum that is satisfactory to the patient; though such a one may complain of her suffering at the time she afterward expresses herself as satisfied with the experience.

In order to determine whether we were securing for our patients anything in addition to painlessness Dr. C. H. Davis of our staff, in September last, studied a series of 104 consecutive cases delivered in our wards within a certain period and learned the following facts:

A group of 44 primiparæ who had nitrous oxide analgesia had an average labor of 13.5 hours, while 18 primiparæ, who had nothing, or a little ether during the last few pains, had an average labor of 17.9 hours, *i.e.*, 4½ hours longer, even though the average of their babies was 5 ounces less. The 15 multiparæ who had analgesia had an average labor of 7.3 hours, while the 27 multiparæ who had nothing or a little ether had an average labor of 10 hours, *i.e.* 2.7 hours longer, yet their babies averaged 10 ounces less than those in the first group. Those who took gas were able to leave the hospital on an average of 1½ days earlier than those who did not; not being so fatigued by labor their convalescence was more rapid.

The babies of the nitrous oxide primiparæ lost 4 per cent less of their body weight than did the babies of the unaided primiparæ. This difference is so slight as to prove nothing except that nitrous oxide certainly does not interfere with milk production. There were no cases of hemorrhage among the nitrous oxide patients, while there was one case in the group receiving no nitrous oxide. There were many other interesting particulars learned to the advantage of nitrous oxide in this study.

Though this series is small yet the same parallelism is found in a larger group reported by Davis in his recent booklet, "Painless Childbirth, Eutocia and Nitrous Oxide—Oxygen Analgesia." Though we have carefully observed, we have not been able to ascertain a single danger to mother or child in nitrous-oxide analgesia. We have during the last few months received many communications from all parts of the country and have yet to receive word from a physician who has tried analgesia and does not get pleasing results.

We believe that nitrous oxide analgesia is an efficient means of relieving the pain of childbirth; that its use makes more efficient the expulsive powers during the second stage and thereby shortens the labor; that by decreasing fatigue it hastens the convalescence in the puerperium; that it is devoid of all demonstrable danger to both mother and child, and that the gas can be given efficiently in the home and is within the reach of even those of limited means.

920 MONROE BUILDING.

CONTROLLING THE SPREAD OF SPUTUM.*

TESTS AND SUGGESTIONS.

BY WALLACE A. MANHEIMER, PH.D.,

NEW YORK.

THE recent campaign in New York City against spitting in public places undoubtedly had the effect of reducing, to some extent, this pernicious practice. The cooperation of the police, who arrested several hundred people, was likewise salutary in its effect. It must be admitted, however, that campaigns of this kind have only temporary results, and that when vigilance relaxes, as relax it must, the former conditions rapidly return.

Far better results could be obtained by controlling the spitting habit, than by making the futile attempt to suppress it. It appears to the writer, furthermore, that the legal definition of spitting should be somewhat amplified. The delicatessen store clerk who moistens his finger with saliva to pick up the piece of paper in which to wrap the butter, is spitting on the paper and therefore on the butter; the street car conductor who wets his fingers and then gives you a transfer is spitting on the transfer and therefore on your hand, etc. A general campaign against spitting, thus broadly conceived, would undoubtedly result in a reduction of disease from this source.

In passing it might be well to state that the discharges from the mouth are responsible for almost as many diseases as are contracted from all other sources put together. Tubercle bacilli transmitted in wet saliva are far more virulent than when dried and blown in the air. Wet or fresh sputum, when we consider the frequency with which it is spread about, represents the most dangerous material discharged by human beings. The pneumococcus, the diphtheria bacillus, the germs of measles, scarlet fever, smallpox, whooping cough, epidemic meningitis, mumps, influenza, common colds, and others are more frequently transmitted through fresh sputum than in any other way. A recent case of syphilis contracted through counting paper money with fingers wetted with saliva, emphasizes the caution which should be observed from this source of infection.

Some very simple steps could be taken which would have a far more important educational and controlling value than the attempted suppression of such pernicious habits through the police power.

Non-spore-bearing Bacteria on Envelopes.—The common habit of moistening the gum of stamps and envelopes with saliva, has suggested the possibility of the transmission of disease through letters infected in that way. The recent work of Zinsser and Hopkins on the viability of *Spirochæta pallida* showed that the organism of syphilis can survive

*The bacteriological tests were conducted at the Research Laboratory of the New York Department of Health, through the courtesy of Dr. Park.

under laboratory conditions for a period in excess of twenty-four hours. It is commonly accepted, though by no means proved, that dried tubercle bacilli in sputum retain sufficient virulence to produce tuberculosis. The evident contamination of letters while sealing them, and while sticking on the stamp, and the frequent spreading of the saliva by the fingers and hand to other parts of the envelope suggest the importance of determining what the danger from this source really is.

Letters are handled by the carriers and postal clerks almost immediately after mailing, and are delivered to the addresses sometimes within a few hours and often within twelve to eighteen hours after posting.

Immediate contact of the hands with saliva and the subsequent introduction of the fingers into the mouth, represents a much more dangerous mode of infection than, for example, the inhalation of dried sputum. An attempt was made in the following experiment to estimate the danger from infection through bacteria dried in sputum.

Experiments.—Five c.c. of a culture of colon bacilli were mixed with saliva and water, making a bulk of 25 c.c. Quantities of 0.2 c.c. were spread over equal areas on each of eight envelopes, and allowed to dry. In order to determine the number of bacteria added at the beginning of the experiment, two envelopes were tested immediately after drying. Two were placed in a glass closet, and thus subjected to diffuse light at laboratory temperature and four were sent through the mail. The envelopes were tested sixteen hours later.

Envelope No.	Remarks	Colon Bacilli Count	Averages
A. 1	Tested immediately after drying	300,000	300,000
2		300,000	
B. 3	Left over night in glass closet	10,240	9,900
4		9,600	
C. 5	Sent through mail	11,500	15,300
6		12,800	
7		25,000	
8		12,000	

A. It is evident from the data that immediate contact with the letters would result in contact with active living germs. The letter-carriers and postal-clerks are subjected to just such contact.

B. Only 3 per cent. of the germs that were originally added to the letter kept in the laboratory remained alive. The warm temperature in the laboratory and the diffuse light probably assisted in the destruction. Enough bacteria were alive (over 9,000) after sixteen hours, however, to constitute a danger, had they been pathogenic.

C. Of the bacteria sent through the mail, 5 per cent. remained alive. The night the letters were mailed was one of the coldest of the winter (February 18, 1916), and this condition being favorable to the viability of the organism probably explains the somewhat larger number of bacteria remaining alive here as compared with those left in the laboratory.

Diphtheria Tests.—In addition to the above experiments, an attempt was made to isolate diphtheria bacilli from envelopes upon which saliva of diphtheria patients was allowed to dry. Five convalescents, still having positive throat cultures, were selected to lick two envelopes apiece. One envelope from each case was tested immediately, the

other being enclosed in an additional envelope, so as to preclude infection, and sent through the mail.

So far no diphtheria bacilli have been isolated from any of the envelopes. There are a number of difficulties met with in an experiment of this kind which make positive results difficult to obtain. A sufficient number of trials on a number of patients would undoubtedly produce some positive results. The well known resistance of diphtheria bacilli to drying, cold, etc., would indicate a possible danger from this source, which this experiment surely does not rule out.

The conclusions to be drawn from these experiments are very simple:

1. Post-office employees who handle letters should be cautioned to wash their hands before eating, and to avoid putting the fingers into the mouth. They should be particularly careful not to moisten their fingers to facilitate the handling of letters.

2. The Post-office Department should provide all stations and sub-stations with wet sponges so that the gum on stamps and envelopes could be moistened without the use of saliva. Probably a weak antiseptic solution could be used in connection with this. On the container holding the sponge some statement should be made such as this: "Wet your stamps and envelopes here; don't send your sputum through the mail." This would encourage the use of water instead of saliva even in the home. In fact, an ordinance concerning this would have educational value. Stationers could easily manufacture and sell a small and inexpensive device for the desk, containing a wet sponge for this purpose.

Additional Suggestions.—1. Places should be selected in busy thoroughfares where people may spit.

While efforts might be continued to abate the spitting nuisance, the writer believes that such efforts are futile. Even during the height of the recent campaign, the busy streets of New York were dotted with sputum, suggesting, therefore, the importance of other methods of control.

If definite spaces around sewer inlets were designated for spitting and signs placed there stating, "Spit here and nowhere else," many people who now spit on the sidewalks and crosswalks would refrain from so doing. Lime could be placed over such areas, and at definite times washed together with the sputum, into the sewers. The street-cleaner would then be doing a greater public health service than in the removal of manure, or in the cleaning up of refuse, although neither of these should be neglected.

In the subway the road-bed in front of station platforms should be thickly sprinkled with heavy lime. While spitting onto the road-bed is comparatively harmless, the lime would direct attention to the proper place to spit.

Large receptacles for sputum containing lime, to be placed where occasion demands, are far more important than receptacles for refuse. Of course, we need both. It would probably be less costly and of far more educational value to place such receptacles about, than to arrest hundreds of citizens yearly during such transitory campaigns.

2. Street car conductors should be provided with rubber covers for the index finger so that saliva will not be used for separating transfers.

3. If no ordinance exists at the present time controlling the habit of moistening the finger with saliva when picking up wrapping paper for food and other kinds of merchandise, such an ordinance

should be enacted and given wide publicity. This habit is quite prevalent among store keepers, and a little publicity and other pressure would have a very salutary effect.

No attempt has been made here to cover all the ways by means of which sputum is transmitted from person to person. Many other methods of transfer will undoubtedly occur to the reader, all worthy of control. In fact very valuable work has already been done. The posters against unguarded coughing and sneezing sent out by the Association to Improve Condition of the Poor, and the recent article in the Weekly Bulletin of the Department of Health against common cigar-cutters are very commendable movements in this direction. The campaign, however, should be broadened until even blowing into a bag and blowing into cigar wrappers to open them will come under the ban. Who knows, we may eventually adopt the European form of kissing both cheeks, instead of continuing our American way of swapping sputum.

The marked reduction in intestinal diseases which resulted from proper disposal of sewage and from safeguarding the water supply should encourage a campaign for controlling the spread of sputum. If one fiftieth of the amount of money spent for sewage disposal were spent on sputum disposal, marked reduction in diseases from this source could be expected.

Sputum is universally recognized as a most dangerous human discharge and serious efforts to control its spread should be one of the next steps in Public Health.

THE EPIFASCIAL METHOD OF INJECTING MERCURY AND SALVARSAN DERIVATIVES.

By ABR. L. WOLBARST, M.D.,

NEW YORK.

IN July, 1914, while in Berlin, I had the opportunity of observing the epifascial method of injection as practised by Prof. Wilhelm Wechselmann at the Rudolf Virchow Krankenhaus. At that time Wechselmann had already administered some fifteen hundred epifascial injections of neosalvarsan and was just beginning his experimental work with salvarsannatrium (sodium salvarsan), the last of Ehrlich's salvarsan products.

This method of administration was of special interest to me in view of the possibility which it afforded of diminishing the painfulness while retaining the greater effectiveness of the intramuscular injection, as compared with the intravenous. I am still of the opinion previously expressed,¹ and held also by Ehrlich and Wechselmann, that the intramuscular injection of salvarsan or its successors, is by far the more effective of the two methods of administration. Unfortunately, we are not yet possessed of the technique by which pain may be eliminated entirely, and until this is discovered, we must content ourselves with the painless, but less effective intravenous method.

It was my observation, however, that many of Wechselmann's patients suffered little if any pain after a large dose of neosalvarsan administered by his new method; some of them evidently suffered considerable pain, notwithstanding Wechselmann's doubts that such was the case. Some patients left the injection table smiling and apparently unconcerned, while others writhed and moaned with pain.

Wechselmann himself at that time felt that he had at last devised a painless injection technique. Perhaps 50 per cent. of his patients differed with him, more or less, on that score.

In the two years that have elapsed, I have had the opportunity of using the epifascial method of injection in several hundred cases, in the administration both of neosalvarsan and of mercury. Owing to the scarcity and the high price of neosalvarsan, I have given but fifteen epifascial injections experimentally, as against a little over two hundred injections of the various salts of mercury. I am therefore hardly able to express any definite opinion as to the merits of the method as regards neosalvarsan, though Wechselmann in several interesting papers^{2,3} speaks of it in enthusiastic terms.

As regards the epifascial injection of mercury, it is my belief that this method has a distinct field of usefulness and is a decided improvement over the purely intramuscular method of administration. First, as regards absorption: It would appear that the solution or suspension (depending on which form of mercury is being used) is absorbed with the same readiness in this method, as in the intramuscular injection. If there has been any failure of absorption resulting in encapsulation and infiltration, I have not observed a single evidence of that occurrence. In not a single instance has infiltration or necrosis developed, nor has there been any evidence of localized inflammation at any time.

From the standpoint of pain, the matter cannot be dismissed so readily, for the personal equation enters so largely into this subject. Some injections have been absolutely painless—about 20 per cent.; many have been painful for a day or a part of a day—about 60 per cent.; the remainder, about 20 per cent., have suffered more or less severe pain for periods varying from one day to one or two weeks, the pain increasing for about two days and gradually diminishing.

The medium employed for the injection seems to have no bearing on the element of pain in these cases. In some cases mercury salicylate administered epifascially gave no pain whatever; in other cases, pain was severe and lasted several days. The soluble preparations reacted to pain in the same uncertain way; one can never tell whether a particular patient is going to suffer pain or have no pain at all. Nor is there any way of telling where the pain is going to be felt. Most patients feel the pain about two inches below the point of injection. This gives the impression that the injected fluid does not remain at the site of injection, but as the patient assumes the erect position in walking about, the fluid seeks its lowest level and thereby causes the pain at that point and not at the immediate site of the injection. One of my patients, a rather fleshy woman, never felt the pain in the buttock at all; four or five hours after an epifascial injection, when the effect of the local anesthetic had passed off, she began to feel a more or less severe pain running down the thigh along the course of the sciatic nerve, the pain sometimes extending down to the toes and making it uncomfortable, and even impossible, to wear a tight shoe. Whatever spot was chosen for the injection in this patient, the pain was sure to be felt along the course of the nerve, but never at the immediate site of injection. In quite a large proportion of cases, the pain was felt in the thigh at some point distant from the site of injection, and in most of these the pain apparently ran along the course of the sciatic nerve.

The technique of the epifascial injection is not difficult once it is mastered. It is peculiarly difficult to describe. It is based on the theory that medication fluid injected in proximity to the layers of the fascia lata will be less painful and cause less inflammation with equal absorption, than when deposited in and between the muscle fibers. The success of the technique depends on the surgeon's ability to determine whether the point of his needle is in proximity with the deep fascia or simply in the muscle proper of the buttock. Experience with the method gives an amount of information which cannot be imparted in words. The needle is plunged into the gluteal muscle as in the intramuscular method; it is then manipulated until the hand feels that the needle point is moving freely from side to side, and is not being impeded by muscle fiber. When that sense of free motion of the needle point is felt, the surgeon may be certain that the point is in proximity with the deep fascia. Any doubts on this score may be cleared up easily by the simple expedient of injecting ten to fifteen drops of sterile water, saline solution or, better still, a local anesthetic solution, and withdrawing the syringe but not the needle. If the eye of the needle is epifascial, there will be a steady flow of the injected fluid, drop by drop, from the needle; if, however, the needle point is in the muscle tissue, there will be no flow of fluid. In that event the needle is manipulated, *i.e.* pushed in deeper or pulled out further, until such a point is reached where the injected fluid issues steadily from the needle. We then proceed with the injection.

Recalling the anatomy of the buttock with reference to the fascia lata, we find that the fascia passes down from its attachment to the iliac crest over the gluteus medius to the upper border of the gluteus maximus, where it splits into two layers, one passing above and the other passing below the fibers of the latter muscle. At its lower border the two layers unite to form one layer again. It is, therefore, evident that any point on the side of the buttock, the patient lying flat on the table, face downwards, will bring the injected fluid in contact with the fascia. The needle is plunged in horizontally, that is, at right angles to the side of the buttock. I find a needle about $1\frac{1}{4}$ to $1\frac{1}{2}$ inches long is most suitable for this purpose.

As previously stated, a local anesthetic fluid may be used to determine whether the point of the needle is epifascial or intramuscular. This serves the double purpose of giving us the information that the needle is properly placed, and also of making the injection proper absolutely painless. I have injected neosalvarsan and mercury epifascially without the slightest sensation of discomfort or pain, by the employment in this manner of a local anesthetic, such as 2 per cent. alypin or novocain. Not more than ten to fifteen drops are needed to anesthetize the site of the injection. This freedom from pain is, of course, but temporary, like all local anesthetic effects, but the step has the double advantages already indicated above.

The epifascial technique requires the employment of a needle and two syringes for its best results, though one is sufficient for practical purposes. The needle having been plunged into the buttock, the first syringe, holding ten to fifteen minims of the anesthetic solution, is attached and the fluid deposited epifascially; this syringe is now detached from the needle, which is meanwhile held steadily in place so as to prevent its moving, and the second

syringe containing the medication fluid is now attached and the process completed.

I think this method is one that offers a distinct improvement on the intramuscular method and is worthy of further study and attention.

113 EAST NINETEENTH STREET

A FURTHER NOTE ON THE THERAPEUTIC VALUE OF SPLEEN EXTRACT.

By HENRY R. HARROWER, M.D., F.R.S.M. (Lond.).

LOS ANGELES, CAL.

SOME years ago while making a rather extended stay in Europe I prepared a somewhat comprehensive paper on the therapeutic possibilities of spleen extract with special reference to its availability as an adjunct remedy in the treatment of tuberculosis.¹ This paper was originally published in *The Lancet* and was prepared at the instance of Sir Lauder Brunton who had become somewhat interested in the possibilities of this method of treatment.

During the past three years I have had occasion to verify a number of the statements made in this paper and the correspondence which it initiated has brought me into contact with a number of physicians who have also put the suggestions collated in the above paper to very good clinical use.

There is always a fairly well-marked element of skepticism evident amongst those who listen to an address or a paper on some phase of organotherapy, and a number of times reference to the prospective value of spleen extract has caused a smile by some who seemingly were pitying me for my belief that such medication as spleen substance could possibly have any therapeutic effect, much less in a disease as complex as tuberculosis.

Aside from the experiences which have time and again verified my position, two circumstances have established my confidence in this method of treatment, and for the benefit of those who are not aware that the extract of spleen not only has an effect when given by mouth, but that this effect is quite often a salutary one in conditions of anemia, splenic disease, and tuberculosis, it has occurred to me to detail these experiences.

Some months ago I was invited to address the San Diego County Medical Society, and took as my subject, "The Diagnosis of the Obscure Internal Secretory Disorders." During the interesting discussion which developed a physician directed attention to the value of spleen extract, and asked if I had any information upon its utility. In the answer reference was made to the paper mentioned above and to the work of one C. R. Carpenter² some years previously. A ripple of laughter greeted this statement, and the explanation was quickly forthcoming when it was learned that the gentleman was none other than Dr. Carpenter himself.

Naturally he was pleased that I had noticed his work and referred to it in my recent book,³ and we had a pleasant visit which has later been rendered more profitable by an extended correspondence. It appears that for over fifteen years Carpenter has been using spleen extract in various conditions, and has accumulated quite a fund of information which certainly should be published. His confidence in

this remedy has not been shaken by the passage of time, nor by the remarks of some of his colleagues, and it has become a routine procedure to use this preparation when it is necessary to enhance the resistance to infection, increase leucocytosis, or augment the activity of the spleen, particularly in definite disease of this organ and in malaria, especially the chronic forms.

The philosophy of this procedure has been very fully outlined in my previous article,¹ and cannot conveniently be repeated here. The fact remains, however, that spleen organotherapy is a decidedly useful and much-neglected phase of treatment, and deserves to be considered and used much more frequently.

The other coincidence was the receipt from Sir Leonard Rogers, professor of pathology at Calcutta University, of a reprint telling of his clinical experiences with spleen medication.⁴ The results obtained in his work, coupled with the fact that Sir Leonard is responsible for the remarkable vogue of emetine at present (he was the first to suggest the use of this alkaloid in the treatment of tropical dysenteries of amebic origin in 1912), make his remarks regarding the value of spleen extract of more than usual interest.

While the particular application of this method was made by Sir Leonard Rogers in kala-azar,* and this disease is not found in the United States, the fundamental deductions from this report are applicable in a number of other conditions which are more commonly met in general practice here.

Rogers has shown that the most important controllable factor in kala-azar is a chronic infection which, after prolonged illness, predisposes to secondary infections and permits them to become rapidly fatal. From a laboratory standpoint there is a pronounced leucopenia, and the resistance to the common infections is unusually low, and when they are present there is no response by the body evidenced by leucocytosis and the usual reaction to bacterial invasion.

Careful study showed that this absence of leucocytosis was the factor which might be combated with hope of controlling the extremely high mortality, and Rogers made a large series of attempts to accomplish this by various methods, including arsenic in various combinations (including salvarsan), iodine, sodium nucleinate (one of our best leucocytic stimulants among the drugs), alkalies and various forms of bacterial vaccines (living, killed, sensitized, etc.). The results from several of these methods were practically negative; it is clear, however, that vaccines are useful and that alkalies are indicated.

Results with spleen substance are referred to by Rogers in the following words: "As early as 1905 I recorded the use of bone marrow in kala-azar with apparently beneficial results. Early in 1913 a paper by H. R. Harrower appeared in the *Lancet* on the therapeutic action of spleen extract, in which he gave references to Goldschneider and Jacob⁵ on the

effects of splenic and other extracts in producing leucocytosis, and of Carpenter on the value of spleen extracts in the treatment of malarial fever. I obtained these papers through the kindness of the Royal Society of Medicine and purchased all the spleen tabloids to be obtained in India, and used them in a series of cases of kala-azar in the European General Hospital. In several cases the temperatures soon began to decline and the weight and leucocytes increased, while the spleen became considerably smaller. I hoped that at last I had found a specific, but further trials soon showed that this view was too sanguine, as in some cases four to six tabloids a day failed to maintain or produce improvement, although no harm ever appeared to follow their use."

Ten patients were treated in this manner; one was apparently cured, three were much improved (though one relapsed later), three were slightly improved, and three became worse, of which two eventually died, one from pneumonia. It must be recalled that kala-azar is, according to all authorities, "an extremely fatal disease," yet Rogers concludes that, "on the whole, spleen may be regarded as of distinct use in the treatment of kala-azar, which it may readily be given in combination with other treatment."

I am convinced that there is a greater field for spleen organotherapy in many conditions of anemia, malnutrition, poor resistance to infection, with or without a marked leucopenia, malaria and, possibly, typhoid fever. It is indeed of "distinct use," and may advantageously be added to the present treatment of many cases of tuberculosis, malnutrition and other diseases in which the physiological effects of this extract are likely to be of service.

715 BAKER-DETWEEN BUILDING

The Advantages of Pyelotomy in Renal Calculus.—Henri Moyrand contends that, contrary to the general opinion, coral-shaped calculi can be removed by pyelotomy, but not large aborescent stones fitting snugly into the calyces when the body of the calculus does not come into the renal pelvis. To justify this operation we must be sure the stone is seated in the pelvis. He thinks the danger of hemorrhage following pyelotomy has been exaggerated and that pyelotomy possesses the great advantage over nephrotomy in the fact that there is no danger of secondary hemorrhage. Pyelotomy, Maynard maintains, does not in any way impair the renal function. The writer produces numerous data to show that incision of the kidney is far from so inoffensive as many urologists have claimed and that it should be resorted to with extreme reserve and only in those cases in which pyelotomy is found to be absolutely impossible.—*New York Medical Journal*.

*For convenience it may be well to state that kala-azar, sometimes also called febrile tropical splenomegaly, is a fatal epidemic fever, resembling quite definitely chronic estivo-autumnal malaria. It is endemic in Assam and is supposed to be due to infection with a parasite named the *Herpetomonas donovani*. Our interest in this, to us, rare disease is due to the fact that it is marked by chronic and progressive anemia, wasting, enlargement of the spleen and sometimes the liver, conditions which are not infrequently met in practice in this country though their etiologic origin may be quite dissimilar.

MAGNESIUM SULPHATE IN THE TREATMENT OF TETANUS.

WE had occasion recently (May 20, 1916) to comment in these columns on the efficiency of tetanus antitoxin in the prophylactic treatment of this disease. When the affection has once developed, antitoxin is not nearly so valuable a remedy, though it cannot by any means be dispensed with. One reason for this is that the convulsive attacks so use up the patient's strength that he succumbs before the antitoxin is able to neutralize the toxin already in combination with the body cells. Various drugs have been used to combat these seizures and thus protect the patient while the antitoxin is allowed to act, but most of them carry with them the disadvantage of their own toxic action.

Ten years ago Meltzer and Auer introduced magnesium sulphate for this purpose after a series of experiments on animals, in which they were able to demonstrate the depressant effects of the magnesium ion. Robertson has continued his work on the study of tetanus with a résumé (*Archives Int. Med.*, 1916, xvii, 677) of the results which have been obtained by the use of this drug. Used at first only by intraspinal injection there was reported a mortality of 44.4 per cent., among which were many cases in whom the drug produced a marked amelioration of the symptoms. Later it was administered subcutaneously, and in the twenty-nine cases which he finds reported in the literature there was but one death. He admits that the number of cases is small and that they are obviously selected but nevertheless insists upon the importance of the results obtained. The drug is also given intravenously, but this method of administration is not so practical, for its action is apparently dependent upon the concentration of the salt in the blood, and as it disappears rapidly from the blood stream it is necessary to inject it either continuously over long periods of time or repeatedly at rather short intervals. The intramuscular injection is not used because of its painfulness.

There are, of course, certain dangers attendant upon the use of magnesium salts in this way. These dangers have been carefully studied by Meltzer, and quite recently Auer and Meltzer have reported (*Jour. Exper. Med.*, 1916, xxiii, 641) a number of experiments in which they produced anesthesia in animals by the intravenous injection

of magnesium sulphate. They were able to produce a very satisfactory surgical anesthesia in dogs, but found that there was a distinct effect upon the respiratory center, so that it was necessary to continue respiration by means of Meltzer's method of intratracheal insufflation. Moreover, they showed that the effects of the magnesium could be neutralized by the injection of calcium chloride or sodium sulphate, preferably the former. In a very few minutes after the injection of a comparatively small amount of calcium chloride the animal recovered consciousness and rapidly became apparently normal again. There was one important exception. A dog which had an irregular heart before the experiment began did not recover but died after an anesthesia lasting about one hour, in spite of the use of calcium. Robertson mentions apparent cardiac deaths from the intraperitoneal use of magnesium, so that the drug should probably not be used, at least for anesthesia, in the presence of cardiac insufficiency. In a case of tetanus the physician would have to use his best judgment after a study of the case.

Since the salt is excreted by the kidneys, it is apt to cause a certain amount of renal irritation, and the presence of albumin and casts has often been reported after its use. There is no evidence to show that this constitutes a dangerous or even severe injury to the kidney. In connection with this subject, it is worth while to mention the work of Gates and Meltzer (*Jour. Exper. Med.*, 1916, xxiii, 655), who recognized the antagonistic action of magnesium and calcium and showed that if the calcium of the body were removed by the injection of a small amount of sodium oxalate, anesthesia could be produced by the use of a much smaller amount of magnesium sulphate than was otherwise required. The action of the magnesium salt is apparently limited, when given in subtoxic doses, to the motor nerve endings, and it is therefore well suited for the treatment of tetanus. The patient should be watched carefully as in any other serious condition, and there should be a solution of calcium chloride on hand in case of need. The possibility of renal injury may safely be neglected in the presence of the greater need. In the presence of cardiac disease the problem is complicated, but it is probable that even here magnesium sulphate offers more chances of benefit than of injury. The subcutaneous method of administration is perhaps better in the majority of cases since it requires less apparatus and technical skill. Whether magnesium sulphate will ever be widely used as a means of inducing anesthesia is a question which demands much more time and experience for its reply.

NAUHEIM TREATMENT IN SARATOGA.

IN *The Saratogian* of May 26 we find some resolutions passed by the local medical society endorsing the very proper attitude of Conservation Commissioner George B. Pratt, in disapproving the addition of any chemicals to the natural CO₂ waters of the Springs, unless prescribed by a physician. Commissioner Pratt is to be commended for this positive stand to avoid a repetition of the stigma

cast, many years ago, upon the fair fame of these waters, by reason of their adulteration. We thought, however, that this stigma had been finally and definitely removed. It is true that in the paper on "The Nauheim Method" read before the State Society, which will be published in an early issue of the MEDICAL RECORD, Dr. Simon Baruch, dwelling upon the importance of exactly following the Nauheim method in order to obtain the results which have made that spa famous, suggests the addition of certain salines which are deficient in the Hathorn water, when Nauheim baths are prescribed in cardiac cases. He advises that a carefully calculated quantity of calcium and sodium chloride be held in readiness at the bath houses, to fill any prescription that may be received from physicians desiring to follow the Nauheim method. This, it appears to us, is exactly what the resolutions of our Saratoga colleagues very properly demand, viz., that such additions should be "plainly and explicitly ordered in a prescription of the physician."

If it is against this modification of the natural Saratoga water that the new commissioner has set his face, he is, we believe, making a mistake. An effort is being made to spread abroad the fact that the Saratoga waters are radioactive; this is very commendable, for the waters are certainly radioactive and are most beneficial in those cases in which the magical action of radium is called for. But these waters also lend themselves admirably to the carrying out of the Nauheim method, for which, however, they must be modified by the addition of salts, as above stated. Unless, therefore, the physician can be sure that a supply of these salines in weighed packages is in readiness when the prescription is presented, it will be impossible to carry out the Nauheim method in Saratoga. We cannot believe that Commissioner Pratt would fail to see the absolute propriety and necessity of having the proper chemicals supplied, since such a course would in no wise violate the resolutions of the Saratoga Medical Society, nor his own idea that "if any individual physician wishes to prescribe them (the baths) in altered form, for an individual patient, this will be entirely upon his own responsibility and will affect no other than his own individual patient." This open and avowed practice would be eminently ethical, and could in no sense be regarded as an adulteration such as was the secret addition of purgative salts. If the effort to establish the Nauheim method at Saratoga fails through a mistake of this sort, the Spa will never attain the popularity which its friends are working to secure for it.

OUT OF THE PAST THE PRESENT.

"THE thing that hath been, it is that which shall be," said Solomon the wise, and to him this seemed to make all further endeavor but folly and vexation of spirit. To the productive spirit of to-day this but acts as a stimulant. The past may not be despised, for it is the rich soil from which the present grows, nor need the repetition of experience which history furnishes be other than an incentive

to greater creative effort to discover and express reality. Various writers remind us of previsions of truths which scientific investigation succeeds in explaining and establishing upon a more exact basis. Humors in the blood were once made to account for pathological conditions of the body. To-day science is learning to understand the presence of the internal secretions, hormones, and their activity under control of the nervous system, psychical as well as vegetative, which is of the utmost importance for health, and the disturbance of which is of equal significance in disease. Again, cerebral location of function was vaguely guessed in a theoretical attempt to assign definite bodily location to the various human characteristics.

The historical value of the past in this relation to the present has found especial emphasis in White's review of Reil's *Rhapsodien* (*Journal of Nervous and Mental Disease*, Vol. XLIII, No. 1, January, 1915). White not only recalls us to the deferential spirit of understanding which alone will rightly appraise the past; he presents besides significant examples of Reil's apprehension of truth won, however partially, through the latter's true contact with the reality of things and expressed pragmatically in accordance with his breadth of conception. He recognized the psychopathological manifestations of daily life, which Freud has traced to unconscious complexes. He felt the limitation of consciousness as but a small part of the great whole which is ourselves. Mental disease is marked by a lack of this unity, and consciousness recedes before an advancing flood of phantasy beyond its control. White points out other conceptions which strikingly anticipated, even though incompletely, the working theories of present-day neurology and psychiatry. Reil's intuition of the interaction between two opposing forces, which he seems to have applied to the several levels of activity, nervous and psychic, White notes, is attained by man at an immeasurably earlier period, for the Australian "black fellow doctors" preconceived through the philosophy of magic the importance of the fat above the kidney, which science has been so late to confirm in its discoveries in regard to the adrenals.

What is the significance of all this? It is perhaps not that man has had supernatural glimpses into reality, or that there is an overshadowing of absolute truth which occasionally breaks through. It may be rather the pragmatic attempt to express in workable terms contact with the stream of dynamic reality. The intuitive plunge into the ceaseless flux of duration belongs to every age of man, to the primitive Australian as to the profound thinker at Halle in the beginning of the last century. There is only a difference in degree of tension. Out of this repeated immersion in duration man arises with fresh knowledge of reality to be fixed in working concepts which shall serve and, in their turn, be replaced. Thus Bergson has expressed it, and this would seem the testimony of history. Reality is not preformed. Duration is a flux in which each moment is becoming, but the ceaselessly formed present passing instantaneously into the future is born of the past which streams into it. Therefore, we may not scorn the past.

ECLAMPSIA IN EASTERN PRUSSIA.

THE exact geographical distribution of puerperal eclampsia is a subject which would well repay a study. It is said to prevail in certain relatively small geographical zones in a manner to defy explanation. Often there are no official or even unofficial statistics to bear out such a view, but even in sparsely settled sections cumulation of cases can be readily cited by the natives. Thus 25 years ago in the country surrounding Tampa, Fla., where infectious diseases have a very small incidence, many pregnant women looked forward with great dread to childbed convulsions because, as a local physician stated, recovery from that condition was almost unknown.

In the *Berliner medizinische Wochenschrift* for January 10 is an account of a recent medical meeting in Königsberg, at which Professor Winter gave a sketch of eclampsia in East Prussia which he said was very common and more prevalent in cities and towns than in the rural districts. He believed that convulsions began as soon in labor as syncytial toxins were absorbed into the circulation, and that the earlier in labor convulsions developed the graver was the prognosis. He was speaking strictly of the type of convulsion which develops in the midst of labor. Rapid delivery, he said, was the indication of necessity in all cases seen in the first two hours. Nevertheless the Stroganoff treatment is recommended to the practitioners of East Prussia whenever a conservative plan of treatment seems justifiable. This is the case when, as so often happens, an ordinary practitioner is called to a bedside where the woman has been in labor for some hours or when transportation to a clinic is out of the question. To fix an exact criterion the author calls any labor over four hours too late for operative intervention. Winter has carried out both methods with excellent results, his mortality with the Stroganoff treatment being 11 per cent.

DYSIDROSIS.

IN the course of a long series of articles on itching, of whatever origin, written in the interest of war medicine by the distinguished dermatologist Unna for the *Berliner klinische Wochenschrift* we find in the issue of March 6 a succinct account of dysidrosis under the designation chiropompholyx, an old term which is utilized because the affection does not represent an anomaly of perspiration but a true inflammatory process. Unna believes it to be due to a specific bacillus. Our knowledge of the condition shows no recent modifications, although it has been suggested that it must begin with alterations in the sweat pores, however much this is subsequently masked. The affection has always been classed as refractory to treatment, and as having a natural tendency to subside. The chief indication is therefore to control the pruritus (which is not relieved by furious scratching). For this purpose Unna recommends what he calls "spirit of silver," a 5 per cent, solution of silver nitrate in spirit of nitrous ether. If the roofs of the vesicles are very thick and tenacious these should be first scraped off with a razor. The solution is then pencilled in with excellent results.

SALT FEVER.

MANY years ago Finkelstein discovered that sodium chloride and sugar were pyretogenic when injected into the animal organism. At a later period it was learned that injections of milk exerted the same action. Unlike other substances, Engländer says, salt produces a fever which appears to improve the state of the patient. The salt fever lasts forty-eight hours, and by accelerating the formation of antibodies is able to cut short the duration of a natural febrile process. At the same time it improves the state of the body functions when these have been depressed by an infection. When injected in hypotonic concentration, it is a superior absorbent and diuretic, and will accelerate the absorption of pleuritic effusions. When and how much to inject, and whether the subcutaneous or intravenous route is preferable depends on the nature of the individual case. In the past the pyretogenous action of salt has been employed chiefly in connection with paresis and other non-febrile conditions with a view of obtaining the therapeutic effects of high temperatures. At present it is hoped that it will benefit infectious processes in which some fever is already present.

News of the Week.

City Death Rate.—For the week ending May 20, the death rate in New York City was only 13.65 per 1000, representing a total of 1462 deaths, as compared with a rate of 14.23 for the corresponding week of last year. The decrease was especially marked in the mortality from acute contagious disease, diarrhea, cancer, heart disease, influenza, pneumonia, and diseases of the nervous system. The mortality from Bright's disease on the other hand, was increased by forty deaths, and there was also an increase in the number of deaths due to pulmonary tuberculosis, cerebrospinal meningitis, and violence. During the first twenty-one weeks of 1916 the death rate was 15.25, as compared with 15.49 for the corresponding period of last year.

Salvarsan Imported.—After nearly a year of effort the United States last week received a shipment from Germany of salvarsan valued at \$250,000. The German Government some time ago placed an embargo on the importation of drugs, and in addition to this the British authorities held up everything coming out of Germany, but the appeal of the State Department to both was finally successful.

Epidemic Among Marines.—The hospital ship *Solace*, U. S. N., which had been at Newport, R. I., sailed under hurried orders on May 27 for Fort Liberté, Cape Haitien, where an epidemic was reported to have broken out among the United States marines on duty. Black water fever is mentioned as one of the causes of the trouble.

New State Laboratory.—Governor Whitman of New York on May 22 signed the appropriation bill passed by the Legislature, which included an item of \$65,000 for the purchase of land and the erection of a laboratory building in the city of Albany for the State Department of Health. The site chosen closely adjoins the Albany Hospital and the new Albany Medical School. The laboratory work of the Health Department is at present carried on with great difficulty in an old stable which has several times been condemned as unsanitary, the crowded quarters making it neces-

sary for the employees to work both Sundays and holidays. Although the appropriation was opposed in some quarters, the condition of the present laboratory and the fact that the demands made upon it have increased steadily in the last two years led the Governor to approve the item.

Opportunity for Clinic Work.—The Urological Clinic for men, women, and children at St. Mark's Hospital, New York, is in need of additional clinical assistants to whom a good service and, if desired, opportunities for research work are offered. Application may be made to the superintendent of the hospital, Mr. Ernest S. Lohr, 177 Second Avenue.

Civil Service Examination.—The United States Civil Service Commission will hold a competitive examination, open to men only, on June 27, 1916, for the purpose of filling a vacancy in the position of clinical director in the Government Hospital for the Insane, Washington, at a salary of \$2,000 a year. Competitors will be rated on education, training, and experience; they must be graduates of a medical school of recognized standing, have been in actual charge of a medical service in an institution for the care of the insane for at least five years, and have made contributions to medical literature on the subject of insanity. The director appointed will have general administrative supervision of the medical work of the hospital, together with supervision of the hydrotherapeutic departments, the operating room, and the training school for nurses. Persons desiring to take the examination should apply at once to the United States Civil Service Commission, Washington, D. C. The examination is open only to citizens of the United States who are under thirty-five years of age.

Navy Medical Corps Examinations.—An examination will be held on June 19, next, for appointment in the Medical Corps to vacancies already existing. A candidate for appointment must be between twenty and thirty years of age, a graduate of a reputable school of medicine, and must apply for permission to appear before an examining board. These boards are convened at various places over the country, and assignments to such boards are arranged to suit the convenience of the candidate. Duty in the Medical Corps of the Navy is one that affords plenty of rewards to the ambitious worker, as well as attractions of a varied nature in personal and professional work. Pay begins at the rate of \$2,000 per annum, with ample allowances, and promotion and increase in pay and allowances follow every few years. For detailed information as regards the coming examination on June 19, 1916, applicants should address the Surgeon General, U. S. Navy, Navy Department, Washington, D. C.

Army Medical Corps Examinations.—The Surgeon General of the Army announces that preliminary examinations for the appointment of first lieutenants in the Army Medical Corps will be held on July 17 and August 14, 1916, at points to be hereafter designated. Full information concerning the examinations can be procured upon application to the Surgeon General, United States Army, Washington, D. C. The essential requirements are that the applicant be a citizen of the United States, between twenty-two and thirty years of age, a graduate of a recognized medical school, and of good moral habits, and have had at least one year's hospital training after graduation. After July 1,

when the bill for the reorganization of the Army becomes a law, there will be more than one hundred vacancies to be filled.

Metchnikoff Reported Ill.—A dispatch from Paris states that the condition of Prof. Elie Metchnikoff, who has been ill with heart disease since last January, has become much worse, and that his physicians have given up hope of recovery.

Flower Hospital Graduates.—Sixty-one physicians were graduated from the New York Homeopathic Medical College and Flower Hospital at the fifty-sixth annual commencement of the institution on May 24. The class was addressed by Dr. Royal S. Copeland, dean of the college, and the degrees were conferred by Mr. Melbert B. Cary, president of the board of trustees.

The Flower Hospital Training School for Nurses graduated a class of seven at the annual exercises on May 23, the diplomas being presented also by Mr. Cary.

Gifts to Charities.—The New York Post-Graduate Hospital has received from Mrs. Alfred G. Vanderbilt of New York a gift of \$100,000 to be used for the erection and equipment of a babies' ward. The new structure, which will be placed next to the present hospital building on Second Avenue, will cover a twenty-foot plot and will be at least five stories in height.

Mrs. Elizabeth Milbank Anderson of New York recently made a gift of \$100,000 to the Henry Street Settlement, to promote the work of the visiting nurses of that institution. During 1915, it is stated, the nurses of Henry Street cared for 26,575 patients, making 227,028 visits. Every patient able to do so paid a fee of five or ten cents for each visit, the total amount collected being \$8,000. In the case of those unable to pay attendance, of course, was free.

St. Luke's Hospital of Chicago has received from Mr. Hobart Williams of that city property valued at \$200,000 as an addition to its maintenance fund.

By the will of the late Miss Jessie Gillender the Johns Hopkins University Medical Department, Baltimore, receives a bequest of \$100,000 to be used in establishing "The Epilepsy Medical Research Fund" in memory of a sister of the testator. The income is to be devoted to the investigation of the cause, prevention, and cure of epilepsy. After the deaths of several persons the University will receive a similar interest in an additional \$50,000.

The New York Association for the Blind is made the residuary legatee by the will of the late Mrs. George Stevens of New York, the amount of its interest being estimated at \$100,000.

By the will of the late Miss Sarah E. Clark of Brooklyn, N. Y., the Brooklyn Home for Consumptives, the Faith Home for Incurables, and the Church Home for the Blind receive gifts of \$10,000 each, and the German Hospital, the Long Island College Hospital, and St. John's Hospital receive \$5,000 each.

The Lutheran Hospital, Brooklyn, receives a bequest of \$3,000 by the will of the late Mrs. Anna Hess of that city.

By the will of the late Henry Siedenbach of Philadelphia the sum of \$20,000 is bequeathed to the Jewish Hospital of that city.

By the will of the late Walter E. Mooney of Philadelphia the sum of \$200 is bequeathed to

St. Joseph's, St. Mary's and the Episcopal Hospital, each.

Personals.—Dr. HENRY W. WANDLESS of New York has been appointed clinical professor of ophthalmology in the University and Bellevue Hospital Medical College.

Dr. JOHN R. MCDILL of Milwaukee with a party of surgeons and nurses sailed from New York recently for the purpose of establishing field hospitals in Germany and Austria under the American Surgeons' Expeditionary Committee.

Dr. MICHAEL A. KINSELLA of New Britain, Conn., has been appointed medical examiner for the Civil Service Commission of New Britain.

Increased Registration of Babies.—The New York Diet Kitchen reports that during the week from May 1 to 6 this year 2484 babies were registered at its eight milk stations, this registration being heavier than that through the midsummer season last year, and nearly 50 per cent. greater than during the corresponding week of last May.

Memorial to Dr. Vance.—The Children's Free Hospital of Louisville, Ky., has received a fund to be known as the Vance Memorial Fund, to be used in the continuation of the work of the late Dr. Ap Morgan Vance, who for twenty-three years served the institution, and on May 15 the surgical ward of the hospital was dedicated to his memory and a tablet bearing his name was unveiled in the hospital.

Urges Campaign Against Disease.—The Kansas State Board through its president has started a movement for the improvement of health by writing to all the State universities to urge co-operation in an effort to induce the Government to establish a health experiment and research station or laboratory in connection with each university school of medicine, under the United States Public Health Service.

American Medical Editors' Association.—The annual meeting of this association will be held at the McAlpin Hotel, New York City, on October 25 and 26. The officers of the association for 1915 and 1916 are as follows: *President*, Dr. Edward S. Register; *First Vice-President*, Dr. W. A. Jones; *Second Vice-President*, Dr. G. M. Piersol; *Secretary-Treasurer*, Dr. J. MacDonald, Jr. *Executive Committee*, Drs. C. F. Taylor, John C. MacEvitt, A. S. Burdick, and Joseph MacDonald, Jr. *Committee of Arrangements*, Drs. Thomas L. Stedman, Reginald H. Sayre, Brooks H. Wells, Frank C. Lewis, and Ira S. Wile.

The meeting will be devoted exclusively to problems of a strictly journalistic nature, which will doubtless be of importance and interest to every editor and publisher of a medical journal.

Southern Medical Association.—The tenth annual convention of this society will be held in Atlanta, Ga., on November 13 and 16, inclusive. The association will be entertained by the Fulton County Medical Society.

Medical Society Elections.—NEW HAMPSHIRE MEDICAL SOCIETY.—At the annual meeting held in Concord on May 16, the following officers were elected: *President*, Dr. Emdon Fritz, Manchester; *Vice-President*, Dr. Fred S. Towle, Portsmouth; *Secretary*, Dr. Dennis E. Sullivan, Concord; *Treasurer*, Dr. David M. Currier, Newport.

STATE MEDICAL ASSOCIATION OF TEXAS.—The following officers were elected at the annual meeting held in Galveston on May 10 and 11: *President-Elect*, Dr. Edward H. Cary, Dallas; *Vice-Presi-*

dents, Dr. Robert Y. Lacy, Pittsburg; Dr. Charles R. Johnson, Gainesville, and Dr. William L. Brown, El Paso; *Secretary*, Dr. Holman Taylor, Fort Worth; *Treasurer*, Dr. William L. Allison, Fort Worth. Dr. James M. Inze, Denton, former president-elect, will serve as president during the ensuing year. The convention of 1917 will be held in Dallas.

SOUTHERN OREGON MEDICAL ASSOCIATION.—The annual meeting was held at Roseburg on May 9, when the following officers were elected: *President*, Dr. Fred D. Stricker, Grant's Pass; *Secretary-Treasurer*, Dr. Alvane C. Seely, Roseburg.

AMERICAN PEDIATRIC SOCIETY.—At the annual meeting held in Washington in May the following officers were elected to serve during the ensuing year: *President*, Dr. F. E. Churchill of Chicago; *Vice-President*, Dr. Wilder Tileston of New Haven, Conn.; *Secretary*, Dr. Samuel S. Adams of Washington, D. C.; *Treasurer*, Dr. Charles Hunter Dunn of Boston; *Recorder and Editor*, Dr. L. E. La Fetra of New York; *Assistant Editor*, Dr. O. M. Schloss of New York.

WEST VIRGINIA STATE MEDICAL ASSOCIATION.—At the annual convention held in Wheeling on May 16 to 18, the following officers were elected for the ensuing year: *President*, Dr. Joseph E. Rader, Huntington; *Vice-Presidents*, Dr. W. H. Young, Sistersville; Dr. E. H. Thompson, Bluefield, and Dr. R. M. Baird, Wheeling; *Secretary*, Dr. J. Howard Anderson, Marytown; *Treasurer*, Dr. H. G. Nicholson, Charleston. The next convention will be held at Fairmont.

CONNECTICUT STATE MEDICAL SOCIETY.—The annual convention of this society was held in Bridgeport on May 17 and 18, when the following officers were elected: *President*, Dr. Samuel M. Garlick, Bridgeport; *Vice-Presidents*, Dr. George McM. Burroughs, Danielson, and Dr. John C. Kendall, Norfolk; *Secretary*, Dr. Marvin M. Scarborough, New Haven; *Treasurer*, Dr. P. H. Ingalls, Hartford.

BROCKTON (MASS.) MEDICAL SOCIETY.—The following officers were elected at the annual meeting on May 18: *President*, Dr. Ezra W. Clark; *Vice-President*, Dr. M. F. Barrett; *Secretary*, Dr. Charles D. McCann; *Treasurer*, Dr. G. A. Buckley.

Obituary Notes.—Col. JOHN M. PHILLIPS, Medical Corps, United States Army, formerly in charge of the Walter Reed Army General Hospital, Takoma, Md., died suddenly on May 22, aged 57 years. Colonel Phillips was graduated from the College of Physicians and Surgeons, New York, in 1882, and was a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, and the Montgomery County Medical Society.

Dr. DAVID CHOATE of Salem, Mass., a graduate of the Medical School of Harvard University in 1854, and a member of the Massachusetts Medical Society, and the Essex County Medical Society, died at his home, on April 23, aged 88 years.

Dr. VICTOR A. BLES of Elgin, Ill., a graduate of the University of Colorado, School of Medicine, Boulder, in 1895, and a member of the American Medical Association, the Illinois State Medical Society, the Missouri State Medical Association, and the Kane County Medical Society, died of tuberculosis, in Denver, on May 9, aged 44 years. Dr. Bles was formerly a member of the staff of the Elgin State Hospital.

Dr. CHARLES F. OSGOOD of Ogden, Utah, a gradu-

ate of Rush Medical College, Chicago, in 1896, and a member of the American Medical Association, the Utah State Medical Association, and the Weber County Medical Society, died on May 4, aged 49 years.

Dr. OLIVER H. MCMICHAEL of Minneapolis, Minn., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1871, and a member of the American Medical Association, the Minnesota State Medical Association, and the Hennepin County Medical Society, died on May 11, aged 71 years.

Dr. EDWIN W. HIGBEE of Northampton, Mass., a graduate of the University of Vermont, College of Medicine, Burlington, in 1871, died at his home on May 21, aged 67 years.

Dr. LOUIS YOUNG of Orleans, Vt., a graduate of McGill University, Medical Faculty, Montreal, in 1869, died in a hospital in Butte, Mont., on May 16, aged 68 years.

Dr. FRANK ATWATER ELMES of Derby, Conn., a graduate of Yale University Medical Department, New Haven, in 1905, and a member of the American Medical Association, the Connecticut State Medical Society and the New Haven County Medical Society, died suddenly at his home on May 21, aged 36 years.

Dr. PHILIP H. EDWARDS of Newark, N. J., a graduate of New York University Medical College in 1895, and a member of the Medical Society of New Jersey and the Essex County Medical Society, died at his home on May 26, aged 43 years.

Lieut. LUTHER MITCHELL FERGUSON, Medical Corps, United States Army, a graduate of the Medical School of Harvard University in 1915, and only recently appointed to the surgical staff of the Walter Reed Army General Hospital, Takoma Park, Md., was killed by a fall from his horse on May 22, aged 28 years.

Dr. ALONZO L. LEACH of Cape May, N. J., a graduate of Jefferson Medical College, Philadelphia, in 1868, a member of the Medical Society of New Jersey and the Cape May County Medical Society, and president of the Board of Health of Cape May, died at his home on May 25, aged 71 years.

Dr. FRANK A. JORDAN of Pecatonica, Ill., a graduate of Rush Medical College, Chicago, in 1864, died in Freeport, Ill., on May 19, aged 77 years.

Dr. ELMER M. BROWN of Tacoma, Wash., a graduate of Willamette University Medical Department, Salem, in 1879, and a member of the American Medical Association, the Washington State Medical Association, and the Pierce County Medical Society, died at his home, after a long illness, on May 13, aged 59 years.

Dr. HERBERT L. HULBURD of Morris, Minn., a graduate of the Long Island College Hospital, Brooklyn, in 1875, and a member of the American Medical Association, the Minnesota State Medical Association, and the Stevens County Medical Society, died at his home on May 13, aged 65 years.

Dr. GEORGE MORRIS ECKELS died at Mechanicsburg, Pa., on May 23, at the age of 59 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1885. He was a member of the Pennsylvania Legislature in 1891 and 1893.

Dr. L. G. HAIN, coroner of Bucks County, died at Reading, Pa., on May 23, following an operation for appendicitis, at the age of 45 years. He was graduated from Jefferson Medical College in the class of 1893.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RECRUITING FOR THE MEDICAL SERVICES—COMMITTEE OF REFERENCE—HOSPITAL STAFFS—MILITARY ORTHOPEDICS—TUBERCULOSIS SCHEMES—OBITUARY.

LONDON, May 6, 1916.

RECRUITING for the naval or military service is the absorbing topic in all classes, and in our own profession has several points of special interest. The War Office has issued a statement which amounts to an appeal for enrollment by setting forth the needs of those services and showing that it is in the interests of the civil community no less than of the army that all qualified men should enter their names under the scheme which has been established by the Central Medical War Committee under the authorization of the Ministry of War. This enrollment does not mean that the person will be forthwith called up for service; in fact, he may never be called up, for he will not be so called until his services will be actually required. It is hoped that the scheme will secure that those doctors will be selected for military work who can most easily be spared at a particular date, from a particular locality, with regard to the needs of the civil population, the requirements of the army, and the circumstances of the doctor. The War Office looks to the Central Medical War Committee and the Royal College to assist it in carrying out the equitable distribution of the population by a body competent to make a proper selection—the only alternative being haphazard recruitment. The committees in each of the kingdoms include representatives of the Royal College of Physicians and Surgeons, as well as of the universities and their schools, and they are in constant contact with the several Government departments concerned. A committee of reference has also been formed to consider questions as to hospital staffs, and this has the approval of the War Office. It is estimated that to obtain the medical officers needed for the army, month by month, with the least inconvenience in all directions it is desirable that those eligible for the duty, who have not enrolled, should do so at once. The Central Medical Committee, however, decided at its April meeting not to proceed to this unless and until 75 per cent. of those eligible but not enrolled have received a commission or a letter of provisional acceptance in His Majesty's forces. This committee adopted a resolution in favor of establishing a compassionate fund in connection with medical officers serving in the war.

Military orthopedics is claiming a position as a distinct specialty and can scarcely be refused recognition now that the War Office has appointed an inspector of the subject. The gentleman selected is Lieut.-Col. Robert Jones, F.R.C.S., A.M.S., who has been lecturing on orthopedics in the University of Liverpool and who has had a very extensive experience of injuries to joints inflicted in war and their subsequent consequences, as well as the measures which have been employed to restore, as far as possible, the use of the injured limb. Hospitals or sections of hospitals have been set aside for such cases, and it is probable that derangements and injuries of joints may in them receive early treatment, leading to the prevention in not a few instances of disabling deformities. This is of con-

siderable importance in relation to pensions, in assessing which the capacity to earn is the chief point to determine—not the patient's general condition.

A "Handbook of Tuberculosis Schemes" has been issued by the National Association for the Prevention of Consumption and Other Forms of Tuberculosis. These schemes are so numerous and so varied in their proceedings that the proposal to coordinate them will be welcomed by many workers among scattered reports of most unequal value. The County Councils may be regarded as suitable authorities for organizing the results that are being obtained, but they do not provide for treatment in connection with dispensaries or hospitals—still less with sanatoriums. A beginning, however, has been made in some localities and will probably be followed in others.

Dr. Colcott Fox died April 11. He took the M.B. (London) and M.R.C.P. in 1876. He was dermatologist at the Westminster Hospital and held several other appointments. He was the younger brother of Tilbury Fox and joint author with him of an "Epitome of Skin Diseases."

Dr. Allan Jamieson died on April 21. In early life he spent some time in Queensland and a few months in a Glasgow insurance office. From this he graduated at the university where he devoted great attention to Greek, on which later he became so well known. After practising for a time in Edinburgh he went to Vienna to study under Hebra. On returning he began to practise as a dermatologist, on which he became eventually so well recognized an authority. His presidency of the College of Physicians was most successful.

Progress of Medical Science.

Boston Medical and Surgical Journal.

May 18, 1916.

1. How the State Provides for Its Mentally Ill. L. Vernon Briggs.
2. Hallux Rigidus. Charles F. Painter.
3. Use of Duodenal Tube for Diagnosis and Treatment. Franklin W. White.
4. Chronic Inversion of the Uterus. J. C. Hubbard.
5. Pregnancy and Labor Following Resection of the Ovary. Frederick W. Johnson.

2. **Hallux Rigidus.**—Charles F. Painter, from his clinical observations and the study of a large number of radiograms of dissected feet, shows that the anatomical variations in the lengths of the various metatarsal bones are the cause of rigidus hallux. In looking over this series of radiograms he found that there were by actual measurement variations in the comparative lengths of the bones of the feet, possessed of the same total length, amounting in many cases to as much as $\frac{3}{8}$ or $\frac{1}{4}$ in. These variations were most notable in the lengths of the metatarsals. Furthermore the difference was noted between the two feet of the same individual, thus accounting for the fact that hallux rigidus is very often a unilateral deformity. It is obvious that when such a variation is present the feet will not conform to ready made shoes and that the resultant irritation produces proliferation of the osteoblastic cells, forming a bony overgrowth which mechanically obstructs the dorsal movement of the phalanx upon the metatarsal, and this in turn keeps the joint in a state of chronic irritability and spasm. Several cases are reported as indicating the results of treatment, operative and otherwise, and the pathological changes found. In closing he advises against surgery if an osteoarthritic tendency is present, and says that when operative treatment is employed the after treatment is much the same as in

hallux valgus. He also describes a tongue plate, fashioned somewhat after the manner of the ordinary flat-foot support supplemented by a steel tongue the width of the great toe on its plantar surface and nearly as long as the toe. This line of treatment is applicable to the earlier cases before dorsiflexion is much restricted.

3. **Observations on the Use of the Duodenal Tube for Diagnosis and Treatment.**—Franklin W. White, in summing up a serial article on this subject, says: "The clinical use of the duodenal tube (introduced by Einhorn and by Gross in 1909-10) has proved its value in a limited field. It is a valuable contribution to medicine and deserves far greater use than is being made of it now. The tube was used by the author in 90 cases; in 56 for diagnosis, in 34 for treatment. A fluoroscopic study of the technique of the introduction of the duodenal tube showed that by placing the fasting patient successively in simple postures, the tube may be introduced into the duodenum within one-half hour in a majority of cases, where organic stenosis is not present. Spasm of the pylorus, atonic, and hook-shaped stomachs may delay the tube. A heavy Gross tube enters the duodenum more rapidly than a light Einhorn tube. In diagnosis, examination of the duodenal contents was most useful in diseases of the pancreas and in cases of chronic jaundice. It is the only method of directly obtaining the secretions of the pancreas and liver, and avoids many of the sources of error in other indirect tests, such as the Sahli capsule, Schmidt's nuclear test, the oil test-meal, or testing the feces for ferments. There is considerable normal variation in the pancreatic ferments as determined by our present tests; only absence or marked diminution has much value in diagnosis. Constant marked diminution or absence of trypsin was found (with one exception) only in chronic disease of the pancreas. Examination of the feces on the Schmidt test-diet in some cases was almost equally valuable, and simpler; in others the examination of the duodenal contents was much more valuable. In diseases of the liver, the value of the test in deciding whether the bile passages are completely or partly closed is limited by the lack of a satisfactory test for bile in the duodenal juice. The duodenal tube is a convenient and comfortable means of obtaining stomach contents; and more reliable than the usual stomach tube for aspirating small amounts of clear fasting contents." Almost every case was improved by duodenal feeding, and in a considerable number the symptoms stopped. It is superior to rectal feeding as patients usually keep their weight or gain and keep their balance of nitrogen.

1. **The Tonsilloscope.**—Thomas B. French has devised a method by which the external tonsilloscope, originally intended and used for the examinations of exploratory sections removed from the tonsil at the beginning of operations, and now used for study of the tonsil, as a whole or in part, after operations, may be used for direct tonsilloscopy or for the examination of the tonsil *in situ*. The introduction of the instrument into the throat is accomplished by using the shortest of the Jackson bronchoscopes with a beveled end and a lamp

on a light carrier of the next largest tube, packed securely with gauze so that the lamp is held just within the distal opening and the end of the tube slipped behind the tonsil. In this way the tonsil is lighted up as brilliantly as in the powerful external apparatus. With this instrument the writer has studied the various classes of tonsillar disease, including 333 cases that were operated upon and a large but indefinite number of youths and adults. He concludes that while this may not permit definite and final deductions nevertheless the results seem to indicate that the erstwhile enlarged tonsils of health in childhood may be regarded as permanently diseased if they continue enlarged after the seventh or eighth year, and that the enlarged tonsils of health which undergo a retrograde metamorphosis in late childhood may remain the tonsils of health throughout life. The assumption that the tonsil has no special function because it has not yet been discovered, is an unconscious confession of impotence to which few could agree, but one conclusion reached in this study is that the function of the tonsil is a negligible feature, for it must be conceded that a tonsil which is extensively diseased cannot perform its function, if it has one, and that a tonsil that is partially but permanently diseased, would probably be the potential or actual source of too much mischief to be offset by the value of any function which a part of it might possess. When, however, a tonsil is found to be that of health, it should be left at least in part to perform whatever function it may have, and also incidentally to spare the fauces the now common post-operative deformities and the consequent impairment of the speaking and singing voices.

2. Ineffective Appendectomies.—Robert T. Morris says that so many appendectomies are done upon a basis of incomplete diagnosis that a halt must be called. That matter is getting to be a scandal. He calls attention to a group of cases in which the appendix is really a factor in the patient's discomfort, but not the principal one, in which the chief irritative lesions are fibroid degeneration and syncongestive appendicitis; and, secondly, to a larger group of cases with symptoms in the appendix region, but not including the appendix, appearing to depend upon a large and complicated variety of irritative lesions of the spinal cord, with efferent impulses sent out, not only to the cerebrospinal nerves but also to the sympathetic nervous system, and possibly to the autonomic centers. The most important single diagnostic point upon which the writer depends is that if we press about an inch and a half to the right of the navel and a trifle below, and if we press deeply enough to bring out the response from the right group of lumbar sympathetic ganglia, there is definite evidence that we are to look to the appendix for the source of that particular irritation, provided that the left group of sympathetic lumbar ganglia is not hyperesthetic. This point of tenderness situated several inches away from McBurney's point is one which relates to a chronic irritative lesion of the appendix. Having determined that the appendix is the seat of chronic disturbance we are still left to exercise surgical judgment. This means that we are still to determine if the patient is one of neurasthenic habit and relaxation of peritoneal supports; if the patient is one with chronic enteric toxemia, or if he is one with syncongestive appendicitis along with important organic lesions at a distance.

3. Specific Therapy in Certain Acute Infectious Diseases.—Francis J. Dever reviews literature of specific therapy in acute infectious disease, and concludes that since beneficial effects from the use of vaccines are obtained through the production of an active immunity,

and since active immunity is developed relatively slowly, it is difficult to understand how their employment will be of advantage to the patient suffering from an acute infectious disease, even though sensitized vaccines are employed. Hope for the future seems to lie rather in specific serum, which supplies the antibodies without calling on the cells of the body to do additional work. Experience in the treatment of typhoid fever and pneumonia does not justify their use, even though reports of harmful effects of such treatment are infrequent in the literature. The value of antimeningococcus serum has been demonstrated. The subcutaneous or intramuscular use of tetanus antitoxin is of little value. The combined use of the intraspinal and intravenous injections has reduced the mortality from tetanus and is therefore the method of use at the present time. Reports of investigators lead to the hope that in the near future serums will be available against the various groups of pneumococcus.

7. Gas Gangrene.—E. Kilbourne Tullidge discusses the importance and treatment of gas gangrene in the present war, during which he has had the opportunity of observing and treating 230 cases. He states that the onset in every case was sudden and stormy, the limb became swollen, discolored, and painful, the symptoms in every way resembling those of an acute rapidly progressing venous thrombosis, except for the accumulating gas and the crepitus elicited, and the contused lacerated opening or break in the skin through which the infection has entered. The zone of inflammation is more painful on pressure than the peripheral areas. The infection spreads rapidly and the decision as to the advisability of an operation must be made when the patient is first seen. In five of the foregoing cases prompt amputation of the limb resulted in complete recovery. Amputation of the limb far above the seat of invasion or crepitus must be our teaching and practice. Care should be exercised to examine all the tendinous sheaths bordering on or near the infection, and when as much as possible of the gangrenous tissue has been removed, sprays or jets of hydrogen peroxide should be thoroughly played upon all the remaining structures, taking pains that every corner and crevice receives its share. Following this a wet dressing of sublimate solution 1 in 1,000 should be applied, and the treatment repeated each day for four days, after which the time is lengthened to every other day. As a result of this treatment 177 cases recovered and amputation for gas gangrene became a practice of the past. The remaining patients in this series were either too feeble to withstand the operation or were received in a dying condition.

2. **The Determination of Alveolar Carbon Dioxide Tension by Simple Method.**—W. McKim Marriott describes his method of collecting the alveolar air and analyzing the sample which may be carried out in a few minutes and with no special discomfort to the patient. The method is essentially that of Plesch. A rubber bag of 1500 c.c. capacity is connected by means of a short rubber tube to a glass mouth piece. About 600 c.c. of air are blown into the bag and the rubber tube clamped off. At the end of a normal respiration the subject takes the tube in his mouth and breathes back and forth into the bag four times. At the end of twenty seconds the tube is clamped off and the air analyzed. The analysis should be carried out within three minutes as carbon dioxide rapidly passes through rubber. A special mask for collecting the air has been devised for infants. For analysis of the air samples, the apparatus comprises eight test tubes, containing standard phosphate solutions; a standard bicarbonate solution, a small test tube drawn out to a capillary point, and a box for color comparison. The method depends on the fact that if a current of air containing carbon dioxide is passing through a solution of sodium carbonate or bicarbonate until the solution is saturated the final solution will contain sodium bicarbonate and dissolved carbon dioxide. The reaction of such a solution will depend on the relative amounts of alkaline bicarbonate and the acid carbon dioxide present. This in turn will depend on the tension of carbon dioxide in the air with which the mixture has been saturated and will be independent of the volume of air blown through, provided saturation has once been attained. High tensions of carbon dioxide change the reaction toward the acid side; low tensions have the reverse effect; hence the reaction of such a solution is a measure of the tension of carbon dioxide in the air with which it has been saturated. This method is useful in making a diagnosis of acidosis, though conditions other than acidosis may affect the carbon dioxide tension, such as stimulation of the respiratory center or changes in the pulmonary epithelium, such as would prevent the air in the lungs from coming into equilibrium with the blood in the capillaries. In normal adults at rest, the carbon dioxide tension in the alveolar air, determined as described above, varies from 40 to 45 mm. Tensions between 30 and 35 mm. are indicative of a mild degree of acidosis. When the tension is as low as 20 mm., the individual may be considered in imminent danger. In coma, associated with acidosis, the tension may be as low as 8 or 10 mm. In infants, the tension of carbon dioxide is from 3 to 5 mm. lower than in adults.

3. **Some Modern Views of Syphilis of the Nervous System.**—Archibald Church discusses first the prevalence of syphilis and cites statistics from which he thinks one can estimate within conservative lines that one man in every five is syphilitic. Different authorities estimate that from 3.7 to 6.27 per cent. of syphilitic men develop tabes or paresis. Women are less susceptible to tabes and paresis than are men. He then discusses somewhat at length the variations in the spirochete *in vivo* and *in vitro* and points out that to-day, in the Laboratory of the Army Medical School, investigators can produce several varieties of spirochetes. They can breed a variety that can produce a hard chancre, or one which will produce a chancre lacking the old Hunterian characteristics of a cancer-like in-

durated base. They can produce a spirochete which will give a rich mucocutaneous efflorescence, or one which will be poor in cutaneous manifestations, with a tendency to confine its influence to the nervous system. Perhaps we may reach a time when, if we can determine the source of infection of the syphilitic patient, the stage of the disease and its characteristics in the carrier, we may be able to draw some conclusion as to the course that lies before the patient, and the nature of the clinical history which he may be expected to run. In the treatment of locomotor ataxia and general paresis it is essential that we be guided, not by the Wassermann in the blood, but by the condition of the cerebrospinal fluid. No man is giving his patient the best treatment, or even the proper treatment, who withholds the administration of these remedies before he has obtained, for a period of years, negative results by the Wassermann, the other accepted tests, and the cell count in the spinal fluid. The granting of marriage certificates to those who have had syphilis should not turn on the examination of the blood by the Wassermann method, but on careful examination of the spinal fluid.

4. **Recurrent Generalized Herpes of Infectious Origin.**—Frank Cohen relates the history of a patient having generalized herpes simplex that was recurrent over a period of two years. A course of treatment with autogenous vaccines and later by a course of sensitized autogenous vaccines effected a cure. The isolation of the organism from the skin in this case, the institution of a negative phase by its injection, with skin manifestations, and the cure, unattainable by any other means than the increase of the immunity for the streptococcus by the injection of the streptococcus vaccines, are all, in the opinion of the writer, indirect evidence of the infectious nature of this type of herpes. He believes that this case has gone a step towards proving the infectious origin of herpes and another step in the direction of showing the common origin of all herpes.

7. **The Charcot-Marie-Tooth Type of Progressive Neuromuscular Atrophy.**—Dr. Charles Rosenheck reviews the literature on this subject and describes the clinical course of this affection, the distinguished feature of which is the symmetry of the atrophy and its distal character. The proximal portions of the limbs are well preserved and show their normal contour, in striking contrast to the wasted distal portions. As a result of the atrophy, the extensors give way, thus giving rise to various degrees of claw hand, foot drop, and equinovarus deformities. The atrophy and paralysis are absolutely parallel. Bony atrophy is absent and constitutes a singular feature of the case. Face, chest, and trunk muscles are normal and remain unaffected throughout the course of the disease. Fibrillary contraction constitutes a persistent feature of the affection. It exists only in atrophying muscles and ceases when they are completely wasted. The reflexes in most cases reported were abolished. The sensibility was not much disturbed subjectively. Forms of cramps and parasthesias have been described but violent and continuous pain is not a feature of the disease. Sphincter troubles are absent, the organs of sense intact, the psychic state good, and the general health remarkably well preserved. The writer reports two cases and hopes this study will stimulate workers in the field of neurology to recognize and isolate these neural disturbances as belonging to a distinct clinical entity and not to class them with the dystrophies with which they are often confounded.

9. **The Bacillus Epilepticus.**—Charles A. L. Reed presents a third report on this subject in which he re-

affirms the correctness of his view that constipation is a very essential factor in the causation of epilepsy, and that this forms the connecting link in some form of infection. In this study he outlines his more recent experiments which lead him to the following conclusions: (1) Epilepsy is an infection depending on a specific spore-bearing organism which it would seem that one is justified in calling *Bacillus epilepticus*. (2) The *Bacillus epilepticus* invades the system through the alimentary canal, its chief focus being the cecum, from which it reaches the circulation by forced absorption induced by mechanical retardation of the fecal current. (3) The *Bacillus epilepticus*, by virtue of its sporebearing characteristic, under ordinary circumstances and without appropriate treatment, has the ability in most cases to perpetuate itself indefinitely in both the cecum and the blood. (4) In a certain very limited number of instances, the *Bacillus epilepticus* seems to be overcome by the natural immunity, but only where there is no focus in the intestines for the continued infection of the system—a circumstance which would seem to account for the spontaneous recovery. (5) Treatment, surgical and bactericidal, to be rational and effective, must be addressed to the organism, with reference, first, to arresting its intake from the intestines, and, secondly, to its neutralization and eradication from the blood.

14. The Pseudoreaction in the Schick Test and Its Control.—Abraham Zingher calls attention to the fact that the pseudoreaction in the Schick test is caused, not by the soluble diphtheria toxin, but by the protein substance of the diphtheria bacillus which is present in the solution used for the test. It is important to control these pseudoreactions and to this end he has devised an outfit similar to the Schick test outfit, but the toxin in the capillary tube has been heated to 75 deg. C. for five minutes. This destroys the soluble diphtheria toxin, but does not appreciably affect the protein of the diphtheria bacillus. These outfits are now distributed by the New York City Board of Health together with the Schick test outfits and accompanied by directions for their use. In an individual who gives a positive reaction only, the control test with the heated toxin will be negative. In one who gives a *pseudoreaction*, the control reaction will be of about the same size and appearance, and pass through the same clinical course as the original reaction; *e.g.*, the two reactions showing a similar central area of redness of varying size, surrounded by a secondary areola which shades off into the surrounding skin. Both reactions begin to appear in about six to eighteen hours, reach their height in twenty-four to thirty-six hours and disappear in three to four days, leaving a poorly defined area of pigmentation and generally no scaling. In an individual who gives a *combined* reaction in the original test, both the positive and the pseudoreaction may be detected. The positive reaction becomes manifest in the original test at the end of three to four days, when the pseudo-element of the reaction has disappeared, as a definite circumscribed area of redness, which measures from 1 to 2.5 cm. in diameter and shows superficial scaling with beginning brownish pigmentation. The pseudoreaction is detected in the control test with the heated toxin; the reaction will not be as marked as in the original Schick test, but passes through the typical clinical course of a false reaction.

6. The Significance of Presystolic Cardiac Murmurs. Thomas Lumsden.

1. Infant Mortality and the Relative Practical Value of Measures Directed to Its Prevention.—S. G. Moore presents a study of the infant mortality rates of England and Wales and ventures the opinion that in these reports too much importance is given to general sanitation in accounting for the reduction in infant mortality in recent years and too little importance is given to work especially directed to meet the particular circumstances of infant life. He believes that hygienic procedures directed to counteract the disability resulting from a premature entrance into the world would meet a not inconsiderable measure of success, since statistics show that premature birth holds first rank among the causes of infant mortality. The mortality rates of 30 of the large towns of England and Wales are presented which show that the infant mortality had been lessened by one-half since 1877. He finds that the fall in the infant mortality rate has been sudden while the improvement in sanitation has been gradual, and sees in this one of the reasons which has led him to the conclusion that it is by direct rather than general measures that one must hope still further to improve the baby's chance to survive. He reviews the activities of the various organizations having as their object the care and protection of infants, but makes the objection that all this work partakes of the nature of charity, while the infant has a right to protection.

3. Some Perforations at or Near the Pylorus.—W. H. Battle emphasizes the importance in perforations at or near the pylorus of accurate suturing so that the weakened part will be able to withstand the strain of vomiting, coughing, or pressure from distention of the stomach. If one or more sutures fail and leakage occurs after an abdominal incision has been closed and the patient put back to bed, death will ensue from peritonitis within a few hours. If, by some rare chance, the gastric juice is prevented from a general diffusion, there is a possibility of recovery, but the fistula which results leads to a rapid dehydration of the patient with remarkable emaciation, quite as startling as that from partial strangulation of the stomach in a diaphragmatic hernia. Recovery from such a fistula is so rare that he reports such a case. He also cites, among other cases, one of the type seen after the perforation of a gastric ulcer which has not come under early care. In such a case there was sometimes a period of repose after the first severity of the symptoms have passed, but operation must not be postponed under an impression that the patient will recover. Free fluid in the flanks as indicated by shifting dullness should warn against such a fatal error. In nearly every instance of perforation of a duodenal ulcer or one situated at the pyloric end of the stomach gastroenterostomy must be considered. In the large number it is contraindicated by the state of the patient. In most, the operation would have to be an anterior operation, for to open up new areas to the risk of infection would appreciably increase the danger of complications. Usually it is better for the patient to undergo a gastroenterostomy by the posterior method at a later date if symptoms of pyloric obstruction arise. In addition there is danger of the formation after an uncertain period of time of a jejunal ulcer when the anterior method has been employed. One of the cases cited illustrates this sequence of events. The sutures in duodenal perforations should be passed by Lembert's method in the direction of the long axis of the duo-

denum, so that further diminution of the passage may not be induced. If, however, the sutures do not hold securely in the tissue immediately around the perforation it may be possible to bring a fold of the adjacent stomach wall across and fix it in position. This method of cleaning the perforation, Battle says, has proved useful in a number of instances coming under his observation.

4. Pneumococcal Bronchitis.—James Goodhart states that during the past year or two there have occasionally come under his notice youths of somewhat degenerate development, who at some prior period have suffered from pneumonia, or maybe an empyema, below the root of the left lung. This has left behind it a patch of solid or condensed lung with a cavity within it from which there occasionally comes a slight hemorrhage, the youth being otherwise healthy. In such patients it is possible to distinguish between this condition and tuberculosis with tolerable accuracy even before a bacteriological examination has been made. The writer records of some 60 cases coming to his notice during a period of some years in which such a pneumococcus infection might have aroused suspicions of tuberculosis. A number of these cases are reported. He thinks there is generally a something in the quality of the crepitation that is heard that raises a question as to the presence of tuberculosis; the râles are often dry and rustling rather than consonating. There is no accompanying bronchial breathing or other evidence of consolidation of softening of the lung. This condition is found in people mostly, but not exclusively, of middle age or older, with a frequent or long history of colds or cough, sometimes with a little hemoptysis, none of them revealing any bacteriological evidence of the presence of tubercle bacilli, but all of them some one or more variety of micrococcus or bacilli, a diplococcus resembling the pneumococcus invariably, but also the *Micrococcus catarrhalis*, staphylococci, the influenza bacillus, and once the *Micrococcus paratetragenus*. A further point was that the diplococcus above referred to appeared to be very persistent, and to be associated with more or less bronchial disturbance for quite a long time. Some of these cases, the author says, had been treated with vaccines, but none with conspicuous success.

5. Blood Findings in Epilepsy.—Ralph H. Spangler has made a study of the blood of 369 epileptic patients from which he draws the following general conclusions: (1) The percentage of hemoglobin in epilepsy is comparatively high (84 per cent. in the present series of 100 cases). (2) The red cells show no marked diminution and, with few exceptions, no evidence of degeneration in cases of uncomplicated epilepsy. (3) The white cells in cases of epilepsy fall within the normal limits during the interparoxysmal periods; uniformly, however, there is a tendency to leucocytosis, and occasionally a hyperleucocytosis at the time of, and frequently for 24 hours following, an epileptic seizure. (4) The average percentage of the small lymphocytes and the polymorphonuclear cells in the 100 cases fell within normal limits; the large lymphocytes averaged 9 per cent. above the normal range; there was no evidence of eosinophilia. (5) The clotting time of the blood is shortened before an epileptic seizure. The range of the clotting time of the blood in 98 of the cases of epilepsy in this series which were studied to determine this point, was definitely shorter during interparoxysmal periods (1.5 to 4.75 minutes) than it is in normal individuals (3 to 8 minutes as given by most investigators). (6) Finally, the alkalinity of the blood is lower in cases of epilepsy than in control individuals on the same diet.

1. Notes on Military Orthopedics.—Robert Jones describes the positions of election for ankylosis following gunshot injuries of the joints and gives illustrative figures. In answer to the question, "What should be done with flail joints?" he says, "Secure by operation an ankylosis in the most useful position." The only exception is in the case of the hip joint where by the use of a simple mechanism a very useful limb may be obtained in spite of the joint being flail.

2. Method for the Preparation of a Non-toxic Dysentery Vaccine.—H. R. Dean and R. S. Adamson present this preliminary report. They state that up to this time their experiments show that the toxicity of an emulsion of *B. dysenteriae* (Shiga) can be enormously reduced, or even entirely destroyed, by the action of a dilute solution of eusol or of hydrogen peroxide. The injection of such an emulsion in which the toxin has been destroyed is followed by the production of a satisfactory degree of immunity. With regard to the production of a suitable Shiga vaccine they suggest the following procedure: Prepare an emulsion containing 200 million bacilli per c.c. Heat this for an hour at 58 or 60 deg. C. Mix with an equal quantity of a 1 in 500 solution of freshly prepared eusol in normal saline. Allow the mixture to stand at room temperature for 24 hours. Inject subcutaneously 1 c.c. of this mixture; which will contain 100 million bacilli in 1 to 1000 solution of eusol. The second dose may be given ten days later and at this time an emulsion containing 800 million bacilli to 1 c.c. should be prepared. This is heated to 58 or 60 deg. C. and mixed with an equal quantity of one in 500 eusol. A third dose of 200 million bacilli may be necessary in order to complete the immunity.

3. Therapeutic and Reaction Effects of Kharsivan.—H. C. Lucey makes an appeal to the medical profession to furnish it with accurate records of the results of the use of kharsivan, the British preparation of the same chemical constitution as salvarsan, and presents a definite scheme for recording such results. He has a record of 600 injections and believes this agent every bit as potent as the original German preparation. He calls attention particularly to a peculiar reaction which he attributes to an abnormal arsenical toxicity in a particular batch which occurred in 0.5 per cent. of the cases in which this particular batch of kharsivan was used. This reaction came on toward the end or a few minutes after an intravenous injection and consisted in slight edema of the lips and eyelids, a sense of fullness in the throat and epigastric pain. In addition to this there might be a rise in temperature, headache and diarrhea. He has had no such reactions with later batches, they all having proved satisfactory.

5. The Prevention, Symptoms, and Treatment of Tetryl Dermatitis.—Enid Smith who has acted as medical officer to munition works employing about 250 women, where tetryl (tetra-nitro-methyl-aniline) is used, points out means of avoiding the dermatitis and a method of treatment which he has found effective. He says women with obvious eye or skin diseases should not do this work, and all workers should be taken on

probation. Before going into the work rooms each worker hardens her hands in a spirit lotion (filtered methyl spirit 20 per cent., water 80 per cent.) and dusts her face freely with powder (zinc oxide 1, starch 3). The workers are warned against touching their faces with their hands. On leaving the works they wash their hands using olive oil soap or bran. The face is wiped free of powder and a simple greasy preparation may be used at the end of the day. The symptoms of this dermatitis consist in a yellow staining of the skin, irritation and roughening. In the severest cases there is an edema of the whole face. There may be an accompanying conjunctivitis, nasal irritation, pharyngeal irritation and sometimes slight constitutional symptoms, though the latter are almost always absent. For the dermatitis, in the severest cases, steaming the face with subsequent application of wet cloths reduces the swelling and allays the irritation. Later on, and in less severe cases from the first, calamine lotion acts well, though some prefer an ointment composed of zinc ointment, lanoline, and castor oil, equal parts. He avoids lead lotion, as lead has a dangerous affinity for tetryl. For conjunctival irritation colloidal silver acts well, though it smarts on application. For nasal irritation he uses liquid paraffin.

Deutsche medizinische Wochenschrift.

April 6, 1916.

Practical Significance of Protective Inoculation in Typhoid Fever and Cholera.—Fejes writes of his personal experience in the Hungarian army. These immunizations have now been carried out systematically for a year, and first of all we note a falling off in morbidity, but it is too soon to quote figures. Not only is incidence much less but the type is much milder—so much so that diagnosis by the coarser methods became at times impossible. When the inoculated subject develops typhoid it appears in one of two forms. In the first the disease begins with violence, as in the typical case, but in a few days remarkable improvement is noted, while by the eighth or tenth day fever is absent and there is no period of convalescence. When fever ceases we do not speak of convalescence but of recovery. The second form in the inoculated is highly atypical and diagnosis can be made only by blood tests. The patient has a peculiar fever. While afebrile in the morning, there is a medium rise of temperature later in the day which ends during the night in profuse, spontaneous perspiration. The sensorium is clear, patient cheerful, heart and pulse only in proportion to degree of temperature. A roseolous rash and slight enlargement of the spleen are always present. The patient does not lose his appetite or power of assimilation and hence loses but little weight. Ulceration of Peyer's patches and perforation are never seen. This mild, atypical form is very common. Retention of consciousness is all important for the prevention of certain accidents and complications. The mouth does not become foul and a source of secondary infection. Cholera immunization is much less efficacious. Aside from prevention outright—and its power here cannot yet be determined—it does not mitigate the course of the disease. This difference is not difficult to comprehend if we bear in mind that cholera is a local process and not a bacteriemia. The cholera vibrio cannot be reached through the blood and the chance of attacking it in the intestinal mucosa is slight. The blood in cholera is in a state of endotoxemia and can only be influenced by a substance having antientotoxic powers.

Pediatrics in Russian Occupation Territory.—Flusser, a surgeon in the Austrian army, but originally a pediatrician of Prague, gives his experience in treating the

native Russian children for typhus, diphtheria, and dysentery. A nine-year-old boy seen on the eighth day of typhus showed the most unabated restlessness accompanied with facial grimaces. Every few minutes he emitted a peculiar scream as if suddenly frightened. There was as good as complete insomnia. The striking pallor of the skin made the exanthem the more conspicuous. Conjunctivitis and rhinitis were marked, as in measles. Bronchitis was also present. The mouth resembled that of typhoid. Death occurred on the eleventh day. This case must have been a notable exception to the rules stated by some clinicians that typhus runs a mild course in childhood, not unlike that of measles. The cases of diphtheria seen were of the severest type, with special tendency to laryngeal stenosis. The lymph-node packets in the neck sometimes reached the size of the fist. The power of the serum was wonderful. In forty-two cases the author lost but one and that from cardiac failure. The initial injection of antitoxin was from 1500-3000 units, partly in the veins and partly subcutaneous. The improvement was rapid. The author saw an epidemic of dysentery confined to children which he has already reported. After the subsidence of this epidemic he saw one isolated case in a child with sclerema. As a complication, noma was present, a condition which has almost died out. The entire right cheek was destroyed. The child, aged 2½ years, was almost moribund when first seen, and died the same day. Finally the author saw a case of mongolism in an infant aged six months which was unusual by reason of peculiar eye complications—nystagmus, rigid pupils, etc.

Excretion of Salvarsan after Intravenous Injection of Concentrated Solutions.—Stern made 420 examinations of urine from 200 persons who had received salvarsan in definite concentration in a vein. He found that under these conditions elimination goes ahead more slowly than when salvarsan is infused in dilute solutions. In theory as well as from the experience of clinicians, the longer the drug stays in the blood the better the therapeutic effects. The slow escape of residues of arsenic in the tissues is not concerned here, i.e. there is no strict parallelism between the two. Weak reactions in urine tests should not necessarily be accepted as positive. One of the tests for salvarsan in the urine in addition of an alkaline solution of resorcin. When the drug is escaping in the desired quantity the resorcin in solution is colored a pronounced red and a red ring is formed. This can be interpreted as indicating the escape of the injected salvarsan from the blood. If this color reaction is feeble it has no significance in this connection. This superiority on the part of the intravenous injection of concentrated solutions synergizes well with the relative simplicity of technique.

Acute Syphilitic Nephritis.—John H. Stokes calls attention to the fact that this complication of syphilis may develop in the course of efficient mercurial treatment. The best recognized points in diagnosis are: (1) the establishment of the existence of early syphilis; (2) high albumin content; (3) double refractive lipoids in the urine; (4) therapeutic tests. Of course 3 and 4 are probably the most reliable. The writer emphasizes the following points: The administration of salvarsan is a valuable aid in the diagnosis and treatment of acute syphilitic nephritis. The risk in administering salvarsan to a nephritic suspected of being syphilitic, to establish a diagnosis, is no greater and perhaps less than that incurred by using a sufficient dosage of mercury. The general therapeutic response is probably better with salvarsan than with mercury. Renal injury from salvarsan seems to be the result of overdosage. From 0.15 to 0.2 gm. of salvarsan, given at weekly intervals, is adequate and must not be exceeded at the outset, but may be cautiously increased to 0.4 gm. later.—*Journal of the American Medical Association.*

Insurance Medicine.

Syphilis and Life Insurance.—In an article in the *Journal of the American Medical Association* of May 6, 1916, John A. Kolmer discusses syphilis and life insurance with special reference to the Wassermann and luetin reactions. He says that the question of frequency of syphilis is of minor importance in relation to insurance, as it has no direct bearing on any one applicant for insurance, and figures on the subject require revision in view of the results of the application of the Wassermann reaction in the diagnosis of the disease. Statistics, however, long since taught insurance companies the necessity for exercising some care in accepting syphilitics for insurance. The disease is from three to eight times more prevalent among the higher than the lower classes, although this may be apparent only because the former are more likely to seek medical attention; and it is also more prevalent among those living in cities than in the country districts. It has been variously estimated that from 10 to 20 per cent. of applicants for insurance have been infected with syphilis, the lower figure being probably nearer correct, and that the majority of men are infected before the twenty-third, and women before the twentieth year of age.

The relation of syphilis to duration of life bears a more or less direct relation to the question of treatment. Virulent infection, especially of the immature and debilitated may destroy life in a comparatively short time; in any event, the expectation of life among syphilitics must be shortened. Bramwell has estimated that the duration of life in cases of tertiary syphilis is shortened by ten years, and the general experience among insurance companies is to the effect that the disease has a heavy extra mortality at comparatively early ages, and that they have suffered considerable loss by them.

Cases of untreated syphilis are almost certain to develop late or tertiary lesions; on the other hand, syphilis is a curable disease in the majority of cases, especially when vigorous and proper treatment is instituted early in the disease. Treatment, therefore, has a very important bearing on the relation of syphilis to insurance; some companies refuse to accept the syphilitic applicant until three years have elapsed since infection, two of which must be spent under vigorous and intelligent treatment with mercury or salvarsan and the third year under observation, during which time the person is free from symptoms of the disease. Patients receiving treatment by iodides only are regarded as bad risks; likewise alcoholics and free livers. With regard to the Wassermann reaction the highly specific nature of the syphilis reaction has been proved by extensive investigations with the serums of normal persons and of persons afflicted with diseases other than syphilis. Unfortunately, the reaction is beset by so many possibilities of technical error that a review of the literature, especially of the early literature, shows results that are quite confusing and contradictory.

The luetin reaction of Noguchi is specific for syphilis, and constitutes an allergic reaction similar to the tuberculin reaction in tuberculosis. The luetin reaction is of most value in tertiary, congenital, and latent syphilis and especially in those under treatment which are the group of

cases of most interest in connection with the question of life insurance. The test is of little value in primary and secondary syphilis. Kolmer concludes as follows:

1. A syphilitic applicant is not as good a risk for life insurance as a nonsyphilitic person, and never constitutes a first-class risk.
2. Persons acquiring syphilis after forty-five years of age, and syphilis among alcoholics and free livers and those showing early involvement of the nervous system are especially bad risks.
3. No syphilitic applicant should be accepted who has not undergone proper and thorough treatment nor any who show active signs and symptoms of the disease in any of its stages.
4. It is clear that the statements of an applicant cannot always be accepted in either a positive or more particularly a negative way, in answering the question concerning infection with syphilis. He may believe that he has contracted syphilis at an earlier date and be mistaken; more likely, however, he is ignorant of having contracted syphilis, or wilfully denies knowledge of infection or believes he is cured. It is frequently impossible on the basis of questions and answers and physical examination alone for the medical examiner to state positively that an applicant is or is not syphilitic or if so, that he is cured. In applicants presenting frank primary lesion or its scar, or secondary lesions or well marked tertiary lesions, the diagnosis may readily enough be made; but an applicant in the late and occult stages appearing in good bodily health and denying infection may readily enough pass as a first-class risk. In the detection of these cases, the Wassermann and luetin reactions will prove of great value likewise in deciding the question of acceptance and risk in the case of a syphilitic applicant who has undergone treatment.

Each company must decide for itself the value of such knowledge in risks and ratings; in the opinion of Kolmer an unquestionably positive Wassermann reaction in competent hands may be accepted as a sign of syphilis; a positive luetin reaction may be accepted as an indication that the applicant is or has been syphilitic. With the question of the presence, absence or cure of syphilis settled in this manner, in conjunction with a thorough physical examination, the company should be guided in accepting risks and rates by at least the same rules as govern such cases when the diagnosis is made on the basis of an applicant's statements on the results of the physician's physical examination.

The Relation Between the Life Insurance Agent and the Local Medical Examiner.—Dr. P. H. Scardino read a paper before the Section on Life Insurance, State Medical Association of Texas, at Fort Worth, on May 5, 1915, dealing with the relation between the life insurance agent and the local medical examiner, and in summarizing he emphasizes the following points: Primarily, the examiner is the employee of the company; therefore, the benefit of any doubt should always be given to the company. He should give courtesy to the company, applicant, and agent; he should be fair to all three, and prompt in all his appointments. He should assist the agent diplomatically to secure a good, though often reluctant risk. He should never disclose an applicant's name to another agent. He should never have applications lying about where a rival agent may have easy access to them. He should turn all applications in promptly on completion of examination.—*Texas State Journal of Medicine*.

Book Reviews.

PELLAGRA—An American Problem. By GEORGE M. NILES, M.D., Gastroenterologist to the Georgia Baptist Hospital, Wesley Memorial Hospital, and Atlanta Hospital; Consulting Gastroenterologist to the Atlanta Antituberculosis Association and to the Moore Memorial Clinic, Atlanta, Georgia. Second Edition. Illustrated. Price, Cloth, \$3.00 net. Philadelphia and London: W. B. Saunders Company, 1916.

THE title of this book is well chosen, for pellagra is truly now an American problem and one of which the solution does not appear to be in sight as yet. Dr. Niles in the second edition of his very excellent work on the subject has set forth in a clear and concise manner our existing knowledge of this disease, together with his own views concerning it. In the discussion of poor food as a cause of pellagra the author does not refer directly to the investigations of certain members of the United States Public Service, which appear to suggest that pellagra may be due to the absence of vitamin content in the food, probably because these investigations were not completed at the time this edition was prepared. Dr. Niles' book may be recommended as a most valuable reference book for those who desire to acquire reliable information concerning a disease which has made so great headway in the South during recent years.

WOUND INFECTIONS and Some New Methods for the Study of the Various Factors Which Come Into Consideration in Their Treatment. By Sir ALMROTH E. WRIGHT, M.D., F.R.S., Consulting Physician to the Expeditionary Force. Being an address delivered before the Royal Society of Medicine and taken from the Research Laboratory attached to No. 13 General Hospital, Boulogne-sur-Mer. Price, \$1.00. New York: William Wood & Co., 1915.

SIR Almroth Wright, in his address delivered before the Royal Society of Medicine recently, discusses the treatment of wound infections, criticises the methods now in vogue, and advocates the employment of the lymphagogic application which he has recommended for some years past. He believes that the use of a 5 per cent. solution of common salt, mixed with $\frac{1}{2}$ per cent. of sodium citrate brings into play osmotic forces and "draws" the lymph out of the walls of the wound by a vis a fronte. Perhaps the British professor is somewhat too severe on existing methods for treating wound infections, as, after all, his mode of treatment has yet to be thoroughly tested.

MAN—AN ADAPTIVE MECHANISM. By GEORGE W. CRILE, F.A.C.S., Professor of Surgery, School of Medicine, Western Reserve University; Visiting Surgeon to the Lakeside Hospital, Cleveland. Edited by ANNETTE AUSTIN, A.B. New York: The Macmillan Company, 1916.

IN this volume the distinguished author has collected and elaborated all the data which he had previously obtained relative to the matter here considered. The former publications which he has contributed on this subject are freely drawn upon and the whole theory is presented in a clearer and more complete form than has hitherto been the case. Readers are probably fairly familiar with the theory by this time, and with many of the observations and conclusions presented we can have but little quarrel. It is well known that we are the sons of our fathers and that instincts (here called "action patterns") are the result of generations of experience. Some of his deductions seem too fantastic for our acceptance at present, perhaps only because they are so strange, but the subject is presented attractively and is one that lends itself easily to philosophical discussion. It is not our intention to discuss the theory here, but rather to recommend that each one read and study for himself. Many of the objections are obvious and others will come to mind on careful reading and we can assure a prospective reader that the effort will be stimulating.

THE CLINICS OF JOHN B. MURPHY, M.D., at Mercy Hospital, Chicago. Volume IV, Number 6, December, 1915. Octavo of 238 pages with 72 illustrations. Published bimonthly. Price per year, cloth, \$12.00; paper, \$8.00. Philadelphia and London: W. B. Saunders Company, 1915.

IN this number of the Clinics we have a long and varied list of clinical cases ranging from leucoplacic papillomata of the buccal mucous membrane, angiomas, sarcomata, and other affections of the soft parts to

various bone lesions, among the most interesting of which are three cases of congenital luxation of the hip. About two-thirds of the cases discussed present some form of bone lesion. After reading the description of the technique employed in the cases of undescended testicle one wonders how large a percentage of these testicles stay "put." Often there is a tendency for the cord to retract; and as the testicle is stitched to the bottom of the scrotum, this latter becomes more or less invaginated if retraction takes place and follows the retracting testicle up to or within the inguinal canal. It was to nullify this tendency that the Torek operation was devised.

A GUIDE TO GYNECOLOGY IN GENERAL PRACTICE. By COMYNS BERKELEY, M.A., M.D., M.C., F.R.C.P., Obstetric and Gynecological Surgeon to the Middlesex Hospital, and VICTOR BONNEY, M.S., M.D., B.Sc., F.R.C.S., M.R.C.P., Assistant Obstetric and Gynecological Surgeon to the Middlesex Hospital. Price, \$6.50. New York: Oxford University Press, American Branch, 1915.

THIS book is written especially for the practitioner to assist him in supplementing his academic knowledge of the subject with a practical understanding of its clinical difficulties. The subject is arranged in a rather unusual but none the less natural manner. The first part discusses the history and the methods of examination, all of which are given in detail. The second part takes up the significance of symptoms, that is, subjective symptoms, and part three has to do with the interpretation of physical signs. In these two parts the symptom is described and then the conditions in which it may appear with a brief differential diagnosis. While this method of attack necessitates a good deal of repetition it nevertheless furnishes the physician with an easy and quick means of locating the information he is after. Part four contains the treatment from which all details of operative technique have been omitted. It is condensed but sufficient and quite consistently clear and conservative. Part five consists of an admirable discussion of the medicolegal aspects of gynecology which, although founded upon English law, can nevertheless be used very largely in this country. This is the most complete and best discussion of the kind which we have seen and should be of great service to the profession. The index is large, with numerous cross-references, so that anything can be quickly found. The illustrations addition to being a complete and authoritative work are numerous and well drawn. The work possesses all the advantages of the ready reference handbooks, in on the subject.

DISEASES OF THE STOMACH AND UPPER ALIMENTARY TRACT. By ANTHONY BASSLER, M.D., Professor of Clinical Medicine, New York Polyclinic Medical School and Hospital. Third Edition. Philadelphia: F. A. Davis Company.

THE demands for this work have enabled the author to get out a new edition which is quite extensively revised and brought up to date. The book is profusely illustrated especially in respect of half tones of Roentgen ray plates and microphotographs and the new edition retains all the best characteristics which have made the former editions as popular as they have been.

MEDICAL AND VETERINARY ENTOMOLOGY, a Textbook for Use in Schools and Colleges as well as a Handbook for the Use of Physicians, Veterinarians and Public Health Officials. By WILLIAM B. HERMS, Associate Professor of Parasitology in the University of California, Consulting Parasitologist for the California State Board of Health. Price, \$4.00. New York: The Macmillan Company, 1915.

THIS volume is not intended to be a comprehensive treatise but rather an attempt to systematize the subject. It contains a discussion "of all the more important diseases and irritations of man and of the domesticated animals in which insects and arachnids are concerned, either as carriers or as causative organisms." The plan of the work is a broad one and it is carried out in detail. Naturally the greatest attention is devoted to the fly and the mosquito, but the other insect pests receive ample attention. The author has an extensive acquaintance with his subject and has had the book in preparation for a long time so that he writes smoothly and authoritatively. His discussion of the medical side of the subject is marked with restraint and sanity. There are very many illustrations, for the most part photographs that really illustrate. The book makes interesting reading and is a veritable mine of information. It can be highly recommended.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16-18, 1916.

(Special Report to the Medical Record.)

(Continued from page 982.)

SECTION ON MEDICINE.

Wednesday, May 17—Second Day.

THE CHAIRMAN, DR. JOHN L. HEFFRON, IN THE CHAIR.

The Value and Limitations of Physiological Therapeutics.—Dr. JOHN M. SWAN of Rochester read this paper and also presented some lantern slides. He said that the various forms of modern hydrotherapy, gymnastics, massage, passive motion, etc., were the direct descendants from an ancient cult which flourished so long ago in the hills of the Argolic Peninsula. It must not be supposed, however, that it would do to-day to tell a patient to go to a health resort and "take a few baths." The details of the various forms of treatment employed must be studied and understood and careful prescriptions must be written for the kind and duration of the treatment desired. In this day of scientific research into the causes of the various effects following different forms of treatment, it would no longer suffice to say, as it was said many thousand years ago, that the value of the waters at Apidaurus depended upon some drops of Gorgon's blood which had been given Aesculapius by Athena, nor would it do to ascribe the benefits to changes in metabolism when no metabolic studies had been made, to influences on the skin, heart and blood pressure not backed up by figures as to the influences of salts, gas, etc., in the water, not confirmed by control experiments with plain water. Dr. Swan quoted a few paragraphs taken from Honan's paper which was published in 1910, and entitled "Bad Nauheim: Its Treatment and Therapeutic Value." "There is so much of real therapeutic value in the baths of Nauheim that I know all progressive practitioners of to-day will appreciate a truthful and unprejudiced opinion of the most recent studies of these waters." "It is a well-known fact that carbonic acid baths have a special action on two organs of the human body—the heart and the skin. The heart is strengthened by the increased flow of blood in the coronary arteries due to the action of the carbonic acid on the vasomotor nerves and the increase in the coronary circulation." "To the presence of certain salts is due the activity and great therapeutic activity of these Nauheim baths. The carbonic acid, as we know, greatly accelerates the action of the calcium and sodium salts." Dr. Swan then reported several cases that he had treated with the brine baths, carbonic acid baths and with fresh water only. In one case of a male, aged 51, who was suffering from a moderate amount of cardiac hypertrophy with beginning arteriosclerosis, the water in the fourth bath instead of the usual 1-6 dilution of brine was fresh. The patient observed no difference. This was an example of several other cases in which the patients noticed no difference in their condition from these baths and in which the pulse rate was not affected. Dr. Swan said that his object in presenting this subject in this manner was not to discredit physiological therapeutics but to endeavor to stimulate those who were engaged in the administration of health resorts to study the effects of the methods employed by every method obtainable so as to provide some accurate basis for the statements made. They should try to get away from mysterious statements whether it was Gorgon's blood or radium, to get away from commercialism which tried to make patients believe that "X"-spring was the only place in the world where the individual could get well.

The Nauheim Method of Bath.—Dr. SIMON BARUCH of New York read this paper by invitation. (To be published later.)

A Study of the Cerebrospinal Fluid in Fifty Cases of Cerebrospinal Syphilis.—Dr. CHARLES CLYDE SUTTER of Rochester, N. Y., said he had analyzed the findings in 50 cases of cerebrospinal syphilis. This series included 10 cases of cerebrospinal syphilis, 11 cases of tabes dorsalis, 20 cases of general paresis and 9 cases of tabo-paresis. He found the greatest value of the examination in paresis and taboparesis, next in cerebrospinal fluid and lastly tabes. The Noguchi butyric

acid seemed the most reliable of the globulin tests. It was present in almost all the cases examined, 41 out of the 50 cases and weak in 4 others. The cell count was a very important element in the study of the cerebrospinal fluid. When studied differentially it gave some insight into the severity of the meningeal reaction. The Hange colloidal gold chloride reaction was a useful adjuvant to the Wassermann and other tests. In paresis he found the typical "paresis curve." In tabes dorsalis the reaction was not quite so characteristic and was present in a less percentage of cases. The chief advantages in this reaction were the small amount of fluid used, its technical simplicity, the sharpness of the reaction, and its delicacy. The reaction was particularly useful in differentiating incipient general paresis and neurasthenic disturbances in a syphilitic. The positive Wassermann reaction was now a more constant finding in the cerebrospinal fluid since larger (five times) quantities of fluid was used in performing the reaction. He stated that a negative response should not be accepted as decisive until the technic with the larger amount had been used. In conclusion Dr. Sutter emphasized the value of the examination of the cerebrospinal fluid in both the study and in the treatment of syphilis. He also said that the serum Wassermann should be used routinely in the physical examination of all patients with or without a history of venereal disease. A positive reaction should be followed by a lumbar puncture with a study of the fluid in order to determine whether the nervous system was implicated. The treatment should not be suspended until after a systematic course of treatment and only after a negative Wassermann reaction in the cerebrospinal fluid.

Cancer as a Non-Surgical Disease.—Dr. L. DUNCAN BULKLEY of New York City read this paper. Cancer, he said, was not a surgical disease, although it was true that the local results of the cancerous process might be removed by surgical measures, that the wound might heal primarily, and in some proportion of instances the tissues might remain sound. But the experience of all had shown that the mere removal of the cancerous tumor and adjoining tissues surgically did not insure that the disease would not return in or near the scar, or elsewhere. It was well recognized and acknowledged that somewhere about 90 per cent. of those affected with cancer died from that malady. Surgery as a cure for cancer had been tried in the balance and found wanting since under the supervision and treatment the death rate had increased to a lamentable degree of late years. According to the United States Mortality Reports, the deaths from cancer under surgical control had increased steadily and alarmingly since 1900, when they were 63 per 100,000 of the population, to 79.4 per 100,000 in 1914, or over 25 per cent. During the same period the mortality from tuberculosis, under intelligent medical supervision, had diminished from 201.9 to 146.8 per 100,000, or over 27 per cent., making an actual difference of over 50 per cent. in their relative mortality since 1900. At this rate the deaths from cancer would outstrip those of tuberculosis in 14 years more. Was it not time for them to consider whether the present attitude toward cancer was correct or not? The points thus far acknowledged by those who had most deeply studied cancer were both negative and positive. First he considered the negative as follows: (1) Clinically and experimentally cancer was shown to be *not* contagious or infectious; although under just the right conditions certain malignant new growths could be inoculated in some animals, but human cancer could not be transplanted. (2) Although micro-organisms of many kinds often had been found and claimed as the cause of cancer, there had been no concurrence of opinion in regard to them, and it was now pretty conclusively agreed that cancer was *not* caused by a micro-organism or parasite. (3) Cancer was *not* wholly a result of traumatism, although local injury might have much to do with its development in some particular locality, even as in connection with late lesions of syphilis. (4) Cancer was *not* hereditary in any appreciable degree; although some tendency in that direction had been demonstrated in certain strains of mice. (5) Occupation had *not* any very great influence on the occurrence of cancer, although it was more frequent in some pursuits than in others. (6) Cancer was *not* altogether a disease of older years, although its occurrence was decidedly influenced by advancing age. (7) It did *not* especially belong to or affect any particular sex, race, or class of persons. (8) Cancer was *not* confined to any location or section of the earth, but had been observed in all countries and climates.

He then considered the positive results of the laboratory investigation which were more encouraging and were as follows: (1) We know now that the local mass, which they called cancer, represented but a deviation from the normal life and action of the ordinary cells of the body. These once normal cells for some as yet unexplained reason, took on an abnormal or morbid action, with a continued tendency to malignancy which invaded and destroyed contiguous tissue, and was associated with a progressive anemia which destroyed life. (2) Microscopic study had shown that there was a certain change in the polarity of cells about to be cancer-genetic, with an altered relation of the centrosome to the nucleus. These changes were again attributed to an alteration in the enzyme contained in the cell, which further depended on the nutrition of the cell as influenced by a faulty metabolism of food elements. (3) The exclusion of all other possible causes led them naturally to look to a disordered metabolism as a cause of the disturbed action of the hitherto normal cells; and they found much to confirm this view both in laboratory studies on the biochemistry of cancer, and also in clinical and statistical observations. (4) The blood in advancing cancer had repeatedly been shown to exhibit many manifest changes, which indicated vital alteration in the action of the organs which formed blood, and so controlled the nutrition of the body and its cells. (5) Laboratory and clinical evidence demonstrated that the secretions and excretions of the body, both in early and late stages of cancer, exhibited departures from normal which deserved consideration. Although none of these had as yet been established as pathognomonic of cancer, they indicated metabolic disturbances which influenced the nutrition of the cellular elements, and so these secretory and excretory disturbances were of importance in connection with its causation. (6) As all healthy cells of the body, by their catabolism and anabolism contributed a hormone or something to the general circulation, so experimental evidence showed that the cells of a cancer mass itself, when fully developed, secreted a hormone or something which was poisonous to animals, and which probably hastened the lethal progress of the disease. (7) Repeated laboratory experiences had demonstrated, in a most remarkable manner, the absolute controlling effect of diet on the development of inoculated cancer in mice and rats, so that the process was inhibited almost entirely with certain vegetable feedings. (8) They thus saw that as the laboratory had eliminated the local nature of cancer, it had also, in a measure, established the fact that there were medical aspects of the disease which further studies would show to be of the utmost importance. These all tended to demonstrate its constitutional origin, that was, its relation to deranged metabolism, which was recognized as the basis of so many diseases.

But clinical and statistical studies came in with overwhelming force to confirm the correctness of this position. (1) We had already seen that with utter medical neglect cancer mortality had steadily and greatly increased in the United States, of late years, in spite of the prodigious advances in surgery during the same time. They had seen also that tuberculosis, as a result of careful medical attention, had decreased in mortality, by an even greater percentage. The same was reported by reliable observers all over the civilized world. (2) Any member of observers, in many lands, had recorded the almost entire absence of cancer among aborigines, living simple lives, largely vegetarian; they had also shown the definite increase in the disease, and in its mortality, in proportion to their adoption of the customs and diet of so-called modern civilization. (3) This increase of cancer seemed to depend largely upon the altered conditions of life, particularly along the lines of self-indulgence in eating and drinking, and in indolence. (4) Statistics from any countries showed that increase in the consumption of meat, coffee, and alcoholic beverages, appeared to be coincident with a very great and proportionately greater augmentation of the mortality from cancer. (5) Clinical observation had time and again shown the effect of specific nerve strain and shock in the development of cancer; and there seemed to be little question but that the enormous nerve strain of modern life was an element of importance in this direction, both through metabolic disturbance, and by direct action on living cells. (6) At present no clear demonstration was possible of the direct method by which errors of metabolism effected the changes in cells to which they gave the name malignant any more than they knew how other alterations on the body were

produced, such as arterial degeneration, bone changes, obesity, etc., which were recognized as due to metabolic derangement. (7) The results which had been observed in connection with the starvation of cancer, by ligature of vessels, illustrated the relation of the blood supply to growing cancer. (8) Finally, the repeated observation and report of the spontaneous disappearance of cancer, by careful and competent medical men, showed that conditions of the system might arise which were antagonistic to malignant growth, even when it had begun to take place; just as there were other conditions of the system which favored aberrant action of previously normal cells, resulting in cancer. The medical aspects of cancer thus appeared in quite a different light from that in which they had been commonly viewed. We now began to see some of the reasons why cancer was not primarily a surgical disease, and some of the lines along which observation and investigation should proceed, namely, biochemistry, secretory and excretory derangements, metabolic disturbances, diet, etc., etc.

Election of Officers.—*Chairman*, Dr. John M. Swan of Rochester; *Secretary*, Dr. Arthur F. Chase of New York City.

The Determination of Uric Acid in the Blood and Remarks Concerning Its Value.—*Dr. MORRIS S. FINE* of New York presented this paper. He said that the publication of the Folin-Denis method for determining the uric acid of the blood might justly be regarded as an epoch in the development of the physiology and pathology of uric acid metabolism. The method commonly employed had involved the use of 300 c.c. of blood, from which by a tedious process in the course of several days the uric acid was isolated. At best only approximate results could be obtained. Folin's method called for but 25 c.c. of blood and the determination could be completed in a day. In the hands of Folin and his co-workers this procedure appeared to yield practically quantitative results, although many users of the method were unable to report such favorable experiences. Many of the difficulties inherent in the method of Folin and Denis were analyzed by Benedict, who introduced modifications which made the procedure, so far as simplicity and accuracy were concerned, little short of perfect. To one who had worked with these methods, Benedict's modification appeared hardly less a contribution to the subject than the original Folin-Denis method itself. The procedure for determining the uric acid of the blood as now carried out in their laboratory required but 10 c.c. of the blood and might be completed within an hour and a half. The method was then described. Until about one year ago, it was generally considered that normal human blood contained 1 to 2 mgm. per 100 c.c. and gouty blood 4 to 6 mgm. Since the introduction of Benedict's modification of the original Folin method, they had rarely noted figures below 3 mgm. for apparently normal individuals, nor below 6 mgm. for gouty patients. Emphasis should be placed on the observation that despite the common association of uric acid and retention with gouty symptoms, a high blood uric acid did not necessarily indicate gout. Similar accumulations of uric acid might be noted in the early stages of nephritis, where gouty symptoms were absent, and therefore great care should be taken to exclude nephritis before regarding such retention as evidence of gout. The determination of uric acid concentration of the blood might be an aid in the differential diagnosis between gout and the non-gouty arthritides if their newer standards of comparison were kept in mind. It should be emphasized, however, that arthritis complicated with early interstitial nephritis might have exactly the same blood picture as was found in gouty conditions. The method as carried out at present had made it possible to eliminate the large and unaccountable variations frequently noted on successive examinations by the original Folin-Denis method.

Metabolism in Gout.—*Dr. NELLIS B. FOSTER* of New York said that two questions were stated for discussion: (1) The cause of the increase of uric acid in the blood and (2) the explanation for deposits of uric acid in cartilages. In gout as in health the sources of uric acid were known and did not differ, there was no new source of supply. All the evidence indicated that man was unable to destroy uric acid once formed. Man resembled birds in respect to his purin metabolism. It seemed likely then that the uric acid increase in the blood in gout was due to defect in excretion. The same increase in the blood was noted in renal disease. For the deposition of uric acid as tophi, no explanation

was at hand. It was not due to the blood being saturated, since this was not the case; serum dissolved more uric acid than water because of the phosphate content. The explanation was probably to be found in the chemical state of uric acid, which existed in two forms in many animals, free and combined. This was not demonstrated for man as yet, but evidence pointing to this conclusion was accumulating. One might then summarize the facts which bore upon the metabolism in gout in this way: The uricemia was not due to abnormal production of uric acid, neither was it due to a defective destruction; it was due to a defective excretion. From this it was evident that the disease was due primarily to a defective renal function. The retention of uric acid was not peculiar to gout, but was more pronounced with this disease. Due to unknown conditions a deposition of urates from the blood into the cartilages occurred. Why this phenomenon did not occur commonly in nephritis but did occur with gout was unknown.

Treatment of Gout.—Dr. ARTHUR F. CHACE of New York said that the determination of the amount of uric acid in the blood was an aid to the diagnosis of gout and served as a guide in its treatment. A list of cases showed an accumulation of uric acid in the blood, above 3 mg. per 100 c.c. in patients with clinical gout and below this figure in cases of infective arthritis and neuritis. Differential diagnosis between the uric acid retention of incipient nephritis and gout was made by clinical symptoms. The treatment was directed toward lessening the formation of uric acid and to facilitating its elimination. A table was shown illustrating the amount of uric acid reduction due to dietary restrictions and to the administration of salicylates and atophan. This table also showed that the elimination of uric acid was not increased by giving quinine, colchicum or diuretin. Alcohol, tea, and coffee caused a retention of uric acid in the blood. A purin free diet was given containing all foods except meat, meat extracts, peas, beans, spinach, tea, coffee and alcohol and an accessory diet consisting of meats and fish of which the uric acid-forming possibilities were known, being based upon the fact that 100 grams of roast beef produced 14 mg. of uric acid of which approximately one-half was excreted in the urine. By determining according to suggestion of von Noorden, the eliminative capacity of the body for exogenous uric acid, it was possible to keep the intake of purins well within this limit. Or, according to Umber, the number of days required to eliminate the uric acid arising from a definite amount of purin substances could be ascertained, and articles on the accessory diet be given at such intervals that retention of uric acid was avoided. For practical purposes these methods had proved cumbersome, particularly, as they necessitated the accurate collection of twenty-four hour specimens of urine and the careful weighing of prepared diets and are being superseded by the simpler procedure of examining the blood for uric acid. Continuous use of alkaline drinking waters induced a deposition of sodium biurate in the joints and cartilages and was capable of precipitating an acute attack of gout. The value of the periodic administration of atophan or, in non-nephritic cases of salicylates, in depleting the blood temporarily of uric acid was emphasized as a means of giving symptomatic relief and preventing the deposition of uric acid in the joints, thereby aborting acute gouty attacks. Exercise, massage and hydrotherapy assisted in the elimination of uric acid while the treatment of acute attacks was limited to the giving of colchicum, large doses of hydrochloric acid, salicylates, water and the application of soothing lotions.

Functional and Organic Differentia in Nervous Diseases as Shown by Cases.—Dr. TOM. A. WILLIAMS of Washington, D. C., (by invitation) presented this communication. He said that a new nervous symptom occurring in a neurotic patient should never be attributed to his neuroticism. It should first be thoroughly observed and analyzed, for it might be an index of organic disease. For instance, a nervous man who had been drinking was sent to him an account of a tremor which had been treated for three months by hydrotherapy without benefit. Proper examination showed it was not a neurotic tremor at all and that there was dysgeria, impairment of speech, exaggerated reflexes, impaired pupils and diminished deep pain sense. Syphilis was diagnosed and was confirmed by the examination of the spinal fluid. In another case, in spite of negative laboratory findings, a diagnosis of insular sclerosis was rejected because of the absence in a

grave case of all three important differentia, nystagmus, Babinski's sign and white pallida. Again, a diagnosis of psychasthenia by a family physician because of the fear of going out was rejected because there was absent such necessary differentia as obsessions, monomania, anxiety, compulsive movement, serupolosity, and sense of incompleteness; the examination then showed the condition to be a vasomotor one. It was by psychological criteria that corticollis, facial grimace or other tic was differentiated from spasm due to irritation of a reflex arc, as well as by the fact that the muscles involved were not innervated by a single nerve arc. No neurotic condition should be diagnosed by exclusion; it was only by finding positive stigmata that one had a right to diagnose it.

Tobacco Smoking and Blood Pressure.—Dr. W. GILMAN THOMPSON and Dr. WILLIAM H. SHELDON of the Cornell University Medical College in New York City, embodied the results of 109 experiments conducted upon 58 patients selected for their advanced arteriosclerosis and high blood pressure. The patients, several at a time, were seated in a small closed room and required to smoke cigars energetically while observations were made upon their systolic and pulse pressures at intervals up to an hour. It was interesting to note that considerable variation in results was obtained not only in different patients having the same initial pressures, but in the same patient when tested again after intervals of from one to three years. Thus, there was a rise of systolic pressure in 35 per cent. of the cases and a fall in 45 per cent., the remaining 20 per cent. showing no change. The maximum elevation produced in any one case was 35 mm. systolic pressure. The results were not uniformly proportional to the initial blood pressure in the individual patient. The pulse pressure sometimes rose and sometimes fell, the average change on either side of the patient's normal being 11 mm., and it did not invariably rise with the systolic pressure. The effects of cigarette smoking were also tested and found similar to those of cigar smoking. The average increase in pulse rate was 13 beats per minute. These considerable variations emphasize the importance of studying each case of arteriosclerosis with high blood pressure individually before imposing restrictions upon smoking, but, in general, it was shown to be undesirable for anyone to smoke whose constant systolic pressure had reached 200 mm. or more; and secondly, it was undesirable for anyone to smoke whose initial pressure was above 160 when the use of tobacco was found uniformly to produce a considerable rise in systolic pressure.

Studies in Acidosis.—Drs. CHARLES G. STOCKTON and JOHN L. BUTSCH of Buffalo presented this paper which was read by Dr. Butsch. They stated that much attention had been given to acidosis in the past few years. With acidosis, as with many other things, the clinician must wait until the chemist, physicist, or mechanic gave him processes with which conditions might be studied. They reviewed the true cause of acidity in any solution; all acidity was due to free hydrogen ions, and all alkalinity was due to free hydroxyl ions. When these two ions were balanced they had neutrality. If, however, one was in excess of the other, they had an acid or an alkaline reaction. The degree of acidity or alkalinity was measured by comparison with some known standard and this standard was, as in many other instances, water. They could measure the number of the hydrogen ions very accurately. Such measurement showed that in pure quadruple distilled water they had one hydrogen ion for each 10,000,000 parts of water. They did not, however, use this form of expressing hydrogen ion concentration or acidity. They used the logarithm of the number. To show how delicately balanced the solutions of the body must be, it was only necessary to keep in mind that if the body fluids were to become as acid as ordinary distilled water, the organism would die. The same was true if its fluids were to become as alkali as tap water. The tendency in metabolic reaction seemed to be toward producing acid. It behooved the body, therefore, to keep in store plenty of alkalies to keep the acidity reduced, or to use other means that it had to neutralize acid. After discussing three questions on the subject of acidosis: (1) What were the acids that were produced, and what was their source? (2) What protection had the body against this acid production? and (3) What processes might they use to detect an early acidosis, they said that what they offered was an untechnical description of the meaning of acidosis, but

the importance of the subject to the clinician was manifest. Clinically they were faced by a toxic state, often accompanied by dyspnea, edema, and coma, and upon investigation, acidosis was found to be present. When the acidosis was relieved by a suitable diet and by the administration of alkalis, the condition was relieved. They often encountered acidosis in nephritis, in diabetes, in the puerperal state, in hepatic and cardiovascular disease, in persistent vomiting, in the gastrointestinal diseases of childhood, etc. While it was true that some cases appeared to suffer from certain types of intoxication in addition to the acidosis, most of them were promptly relieved by increasing the alkalinity of the blood. The benefit that followed the introduction of alkaline hypertonic solution of sodium chloride, Fischer's solution, intravenously or per rectum, in some cases of nephritis was very remarkable. Similar results might be observed in the approaching coma of diabetes and in other states. The persistent use of alkaline waters or of alkaline mixtures was of great importance in the more chronic conditions. In conclusion it might be stated that the search for acidosis was demanded in most cases of coma, edema and persistent vomiting; also, that when found present, acidosis should be combated and overcome by thorough alkaline treatment.

SECTION ON SURGERY.

Tuesday, May 16.—First Day.

Dr. HARRY R. TRICK OF BUFFALO IN THE CHAIR.

Postoperative Ventral Hernia.—Dr. EDWIN MACD. STANTON of Schenectady read this paper. For the past thirty years he had found but one exhaustive study of data concerning postoperative hernia, that of Dr. A. Bell. His technique included the use of iodized gut, silkworm and horse-hair. He seldom used the McBurney incision. In 456 operations by the midline or rectus route, he had hernia in but 21. The McBurney, on the other hand favored the development of hernia. The stability of any wound depended upon the healing between the sutures. The fascial layers, too, afforded support of the abdominal contents. Above the semi-lunar fold the fascial barrier comprised the transversalis fascia and the posterior layer of the aponeurosis of the internal oblique muscle. Below, the fibers of the transversalis fascia protected the peritoneum behind the rectus muscle. These fibers with the peritoneum must be sutured in closing the abdominal wound. He reported one "clean" case in which healing was delayed for ten months. Although drainage was necessary in many operations, it did not necessarily contribute toward the production of postoperative hernia. He had five hernias develop in 52 midventral wounds after drainage and 2 in 135 without drainage. In 64 "clean" rectus incisions, he had hernia in 1; in 67 acute cases after rectus incisions, hernia in 3, and after drainage of suppurative appendicitis in 63, hernia in 8. Unless the drain was large, it was not a potent factor—that is a drain of 3 cm. diameter or less did not increase the probability of hernia formation. In 12 drained cases he traced the production of hernia to suppuration in the fascial planes. In these cases, the faulty character of the union in the sutured parts of the fascial layers made hernia possible. Coughing might be a contributing cause. Nerve injuries had not favored hernia in his experience. The prognosis of all abdominal wounds depended upon the character of the fascial union. In the upper abdomen, whether a drain was used or not, hernia was exceedingly rare. He had none after 61 gall-bladder operations, none after 10 high rectus without drains, none after 39 lumbar incisions. He concluded by remarking that statistics of hernia following McBurney incisions were highly desirable.

Dr. SAMUEL LLOYD of New York added that he did not know that postoperative hernia was more common in the McBurney incision. He said that such herniae were often small protrusions of gut at the lower or upper extremities of wounds due to imperfect fascial closure. Had noticed failures to close the posterior layer of fascia with the peritoneum and omissions of the extremities in suturing.

Dr. HOWARD LILIENTHAL of New York continued the discussion. He did not think the McBurney incision was more prone to produce hernia. He advised the transverse incision in the upper abdomen, having been led to use it after seeing a case of Dr. Moschcowitz thrice opened transversely through the same incision, with

pus after the third opening, heal without being followed by hernia. Neither he nor Dr. Moschcowitz had had a hernia following a transverse wound in the upper abdomen.

Dr. STANTON concluded by saying most of the hernia cases he had seen had come from McBurney incisions. Had written for reports from surgeons without obtaining definite data from them. Johnson held hernia more common after the gridiron incision.

The Surgery of Splenic Anemia.—Dr. GEORGE W. COTTIS of Jamestown cited a case of Banti's disease in a patient, 43 years of age. Had lost weight, strength; skin was pigmented; spleen was large and palpable to level of the iliac crests, the blood showed 5,120,000 red cells and 45 per cent. hemoglobin. He removed the spleen. He found the liver slightly enlarged, the gall-bladder full of stones, and no enlarged mesenteric nodes. The convalescence was uneventful. The red-cell count remained over 5,000,000. He felt, as Mayo had intimated, that there was a causative relation between the gall-stones and the splenomegaly. The spleen was found to contain tuberculous tubercles. Of fifty-one cases of tuberculosis of the spleen reported but one was primary. He discussed the physiology of the spleen and its relation, as he understood it, to the liver and bone marrow. It withdrew bacteria, white cells with bacteria, and injured red cells from the blood stream. Liver extracts were said to leave a hemolytic action upon red cells. This was not true of splenic extracts; but splenic extracts given with liver extracts enhanced the hemolyzing property of the latter. The spleen, too, probably contained a hormone that regulated the production of red cells by the bone marrow. The spleen was not essential in that its function was vicariously assumed by the lymph and hemolymph nodes. The color index in pernicious anemia was recognized as high, the spleen small, and the toxic element of intestinal origin. For splenic anemia, splenectomy was associated with good immediate and probably not ultimate results.

Dr. PACKARD of New York said in Banti's disease the finding is always hypersplenism, not hyposplenism; but in pernicious anemia the spleen might be large or small. Polycythemia followed increased CO₂ or a need for increased oxygen. Hemolysis was the important indication for the removal of the spleen.

Dr. G. W. COTTIS of Jamestown added that in the case reported by him, the skin was "muddy," not jaundiced, and that hemolysis is the important characteristic in such cases. He said it was difficult to differentiate Banti's from Gaucher's in many instances. Of nineteen spleens removed by the Mayos for pernicious anemia, one alone was found enlarged.

Dr. PACKARD added that he had never seen a case of Banti's disease with more than 4,000,000 red cells.

Radium Treatment of Various Surgical Conditions.—Dr. JOSEPH B. BISSELL of New York reported his experience with radium in 100 non-malignant cases. He thought that the stimulating rays might be of service in bone necrosis. Miss B. had radium applied for 20 minutes and 6 times to a bleeding corn. The callosity dried and dropped off. Ten milligrams cured another corn, previously cauterized and incised without relief. Mrs. C. had 25 milligrams applied to uterus for fibroid, causing tumor to decrease in size and to make operation unnecessary. Mrs. S. of 47 years, had a fibromyoma, the size of an orange, for which radium was applied in 50 milligram doses three times. She experienced rises in temperature, pulse, and backache; later she developed cystitis; but eventually the fibroid had decreased to a small nodule. A keloid on the neck disappeared after 15 milligrams for 30 minutes and (after one week) 25 milligrams for 10 minutes. Radium softened a scar from a razor wound of cheek after a 20-30 minute application. Two applications removed the discharge and granulations from an amputation stump following the removal of a toe osteomyelitis. He reported two infected knees similarly relieved by the use of radium. He believed that the present results in bone cases justified more extended trial.

Recent Progress in the Operative Treatment of Empyema of the Thorax.—Dr. HOWARD LILIENTHAL of New York said the death rate at Mount Sinai Hospital for empyema during the past ten years was 28 per cent. Of those that survived 16 per cent. had to have a secondary thoracoplasty. Cases of empyema without adhesions got well with suction. After adhesions, more extensive operative procedures became necessary. If the confining membrane could be removed the lung would approach the chest and he was not obliged to

bring the chest wall against the lung. All the cases treated were first x-rayed to determine a unilocular or multilocular empyema and to differentiate pneumonia. Diagnostic puncture was not recommended until the patient was prepared for operation. He preferred local or nitrous oxide anesthesia. He performed a "minor" thoracotomy for the case when first seen (unless a more radical operation was specially indicated), and if the case did not get well in one week, it was x-rayed again. The "major" operation was carried out often after the minor had failed. This called for a 4-6 inch incision between the ribs for the relief of the fluid and a vertical incision to expose and free the adhesions and tough membrane. His mortality for this latter operation was 20 per cent. During postoperative care it was possible to explore the wound digitally if desired. Of the 63 empyemas during the past 2 years, not one case required a thoracoplastic operation.

Dr. SAMUEL LLOYD of New York said he did not resect ribs but incised between them. Was gratified that Dr. Dowd and now Dr. Lilienthal were following his methods. The important step was the expansion of the lung within the chest. It was necessary to free the adhesions. He used ether anesthesia. It was difficult to free adhesions from the diaphragm and from the pericardium, his mortality was 20 per cent. It depended upon the type of the infection, being greater with the virulent and mixed than in the pneumococcal infections; interlobar abscesses should be guarded against.

Dr. LILIENTHAL concluded by saying resection was necessary in abscess of the lung.

Melanotic Sarcoma of the Small Intestine, with Report of a Case.—Dr. EDGAR A. VANDER VEER of Albany held that sarcoma was more common in the small and carcinoma in the large intestine. Mrs. A. S., 50, U. S. A., housewife, was constipated, suffered abdominal pain for 4 weeks before coming under observation; pain was localized in left side and radiated to right, vomited 2 days before admission to hospital, and had tenderness marked over the descending colon. The operation disclosed an intussusception and a mass in the middle third of the ileum. Six inches of ileum were resected. The tumor was melanosisarcoma. Generally symptoms were concealed until kinking or intussusception was produced. Anemia and cachexia were early symptoms; abdominal distention, a late one. The prognosis depended upon early diagnosis and complete removal of the growth.

Dr. ELLIS KELERT of Albany said the patient coughed up material resembling mostly granulation tissue, and that the tumor was definitely sarcomatous.

Wednesday, May 17—Second Day.

Types of Cerebral Defects in Children That May Be Benefited by Operation.—Dr. HERMAN G. MATZINGER of Buffalo read this paper. He said that he was not concerned with orthopedic defects of childhood but only with those cases in which head operations were indicated. The nature of the underlying cause involved progressive and irreparable injury to brain tissue. All cerebrally defective were essentially feeble-minded and many of the worst cases, fortunately, died early in life. Nevertheless, one should not discourage any attempt to relieve them. In the inherited types, including infantile paralysis and Mongolian idiocy, prevention offered the soundest method of cure while operation remained purely experimental. This cause was so obscure that autopsies failed to reveal it. Proof was wanting that meningeal hemorrhage gave rise to diplegia. At necropsies, cysts, area of softening, wrinkling, or adhesions, indicative of more deeply situated pathological changes, were found but characteristic local pathology, gross or microscopical, of a causative nature, were entirely absent. As infantile cerebral paralysis attacked the brain early in life operative relief must be sought early if any good was to be expected from it. He considered hemorrhage a definite indication for operation. Similarly might Little's cases be operated upon. Operations were of no avail where there were early changes in the pyramidal tracts. Increased intracranial pressure added new symptoms to the old symptom complexes but was accountable for deaths in only 7 per cent. of cases. Operation might be attempted for the relief of increased intracranial pressure but it must be remembered that simple incision of the dura was often not sufficient, for fluid might be enclosed in regions away from the site of incision. Dividing the falx or tentorium might, therefore, be necessary. Epilepsies developed in one half of the cerebral palsies. Eye-

ground examinations gave operative indications in infantile cerebral paralysis.

Results of Cranial Decompression in Selected Types of Cerebral Spastic Paralysis Due to Hemorrhage.—Dr. WILLIAM SHARPE of New York read this paper. He said he wished to report the results of operations undertaken by Dr. B. P. Farrel and himself for the relief of spastic paralysis during the past three years. He had examined 211 cases of cerebral spastic paralysis and had determined the ophthalmoscopic findings and intraspinal pressure for each individual. He had operated upon most of these. The time elapsed since the operations was not great but the results to date were gratifying. He did not operate upon the constitutionally inferior, the microcephalic, or cases of spastic paralysis due to lack of development, the so-called Little's syndrome. Dr. Sharpe was operating on children that had gone through difficult labor and that revealed changes in the optic discs and in the spinal fluid indicative of increased intracranial pressure. Of these, the most satisfactory were those with no impairment of mentality. The condition of spastic paralysis following birth trauma, appeared before, during, or after birth. The spasticity produced deformities that were usually flexor in type. Later Jacksonian epilepsy might intervene. As these children grew older their mentality was noticeably impaired. They became imbeciles or idiots. It was important to recognize in them the possibilities of "hemorrhage of the new-born." Such bleeding resulted from rupture of a tributary vein of the longitudinal sinus from the application of forceps to the child's head or from other rough handling. The hemorrhage became cortical or subcortical. In cortical hemorrhage the damage to brain tissue was due to pressure; in subcortical bleeding there was direct injury to brain substance. Motor symptoms followed and depended upon the area of brain impaired. The author held intracranial hemorrhage accounted for 70 per cent. of the spastic paralyses. The remaining 30 per cent. included meningoencephalitis, cases of agenesis, etc. Defects in the pyramidal tracts did not affect mentality excepting through impairments in the associations. Pertussis might give rise to meningoencephalitis and to spastic paralysis. Treatment accomplished little in the extreme cases because of the defects in brain tissue. On the basis of the old theory that the brain remained small because the skull was small, treatment was formerly directed toward enlarging the skull. Trephine openings were made and dura was divided. The author said the dura must be left open. He performed subtemporal decompression on one or both sides. Twenty-six per cent. of these cases showed increased intracranial pressure. He had had 16 deaths. Of these 9 were extreme diplegias. Had operated upon three on the second day and two on the third day after birth. Improvement was less in the older children.

Dr. C. G. KERLEY of New York said that Dr. Sharpe's operations were likely to spread rapidly among the people. A vast number should not be included under this operative type. Among them were the mongols, cretins, macrocephalics, microcephalics, and the feeble-minded or inherited defects. The traumatic cases should be operated upon. Many of these suffered from hemorrhage or transudation following the pressure of forceps or unskilled handling. There were comparatively few who developed spastic paralysis from other causes. Therefore it was necessary to improve the obstetrics to apply prevention to birth palsies. He believed it would be well for every prospective mother to be confined in a hospital by expert attendants. Cesarean section would have prevented many of these traumatic cases. If it was not practicable for mothers to receive special attention, it was a calamity. It made little difference whether feeble-minded children were 50 or 75 per cent. feeble-minded so long as they belonged in that class.

Dr. B. H. WHITBECK of New York said that the orthopedic surgeon had to deal with the deformities of such children. These cases returned after operation and had to be reoperated upon or abandoned. The examination of the eye-grounds confirmed by lumbar puncture determined the selection of the case for Dr. Sharpe's operation. The cases with beginning changes, as congested discs, were suitable ones. He reported a case of marked improvement following decompression. This child now went about without appliances. He believed obstetrical trauma was on the increase. Nerve-suture, tenotomies, and the prevention of deformities were in their hands, but the cases should not occur.

Dr. P. I. NASH of Brooklyn asked if there was any case in which an ophthalmoscopic examination had not been made.

Dr. CLARKE believed the sooner the case with cerebral hemorrhage was turned over to the surgeon, the better. He reported a child 3-4 days old delivered by the morphia-scopolamine method and one in whom there were no paralyses but athetoid movements and nystagmus, a case of probable fracture of the skull. Inasmuch as the parents refused operation, he treated the child palliatively. At 16 months, one could place a finger in any of the sutures. At 2 years, he had lost his nystagmus, could raise his head, and played with the buttons on his mother's dress. He fed the infant concentrated milk, that was all that he had done. He believed in early operation but wanted to know where to draw the line.

Dr. ROBY of Ohio wanted to know how the spinal fluid pressure was measured.

Dr. MATZINGER declared himself fascinated with the work of Dr. Sharpe. Good sense was shown in the selection of cases. He asked for proof of the estimate of 70 per cent. spastics with intracranial hemorrhage. Did not think the history of distocia was sufficient evidence for electing it as the cause of brain injury in the majority of cases. The fetal head was pressed out of shape in most cases. If hemorrhage was so easily produced why did so many escape? Why not some vulnerable condition? The results in Dr. Sharpe's cases would remain good. As long as the cases operated upon did well, why should not more be included?

Dr. SHARPE, in conclusion, said more cases were not included in the operable list because brain losses could not be made good. He could remove an extradural clot and mitigate the effects of hemorrhage. The work of Oppenheim and of Hoch was authority for 70 per cent. of spastics being due to hemorrhage of the cortex or of the base. Preventive measures should be urged. Cases with increased intracranial pressure offered hope of improvement. In answer to Dr. Nash,—some individuals with intracranial hemorrhage gave clear fluid on spinal puncture. The early evidence was (1) history of a first child, (2) convulsions after birth, (3) blurring of the nasal half of the optic disc, (4) and increased intraspinal pressure. He used the Strauss needle, had the child on side, spine on level with head, and the child quiet. The needle was graduated, showing the rush of the fluid from the spinal canal, in centimeters. Eight to 12 cm. were normal measures of pressure. Above that was pathological. One instance of 37 cm. was mentioned. He obtained a wet, edematous brain in one case of suspected hemorrhage. Dr. Roby's case belonged to the type difficult to restore after birth and one that might break out into a spastic state 7-8 months later. He believed that early operation in selected cases produced normal children.

Toxemia of Intestinal Origin in Children.—Dr. DE W. H. SHEARMAN of Buffalo read this paper for Dr. I. M. Snow of Buffalo. He said that the cause of death was shown by experiment to be not bacterial but altered mucous membrane, that the injection of fluid from a closed intestinal loop caused death with symptoms similar to obstruction, and that much had been learned through the investigations of Whipple, Hartwell, Draper, and others. These were tissue-dehydration and cerebral anemia from failure of absorption and from vomiting. A second theory of death was the absorption of bacteria through the damaged mucosa. A third theory ascribed the cause of death to an active toxin. Hartwell held the toxin might originate from the food, bacteria, or from a substance secreted from the intestine. High intestinal obstruction was considered more poisonous than low. The stagnation of detritus and of bacteria was not considered sufficient to account for the toxin. Hartwell occluded a loop of intestine 10-14 cm. from the pylorus. They were made to fast 55 hrs. All the animals so treated recovered from the operations and lived 5-7 days. They vomited when given water. There was no peritonitis, and no apparent cause of death. The dogs given sterile water or saline lived longer than those that were not. Hartwell was said to be the only experimenter who worked without damaging the intestinal wall. He, also, eliminated the bile, pancreatic, and duodenal secretions from the site of obstruction. A retained secretion, as the gastric, was dangerous to the economy; an injured mucosa failed to alter its poisonous nature but allowed it to be absorbed in its toxic state into the blood stream. Hartwell believed, according to the author, that high intestinal obstruction might not produce death when the

mucosa was not damaged, that changes in obstruction were found in the liver and in the kidneys, that hemogenous bacteriemia did not necessarily occur, and that bile, pancreatic, and duodenal secretions were not necessary for the production of death in intestinal obstruction because double occlusion of the ileum was lethal. The lethal toxin was the product of secretion of the injured mucosa or of bacteria. He did not consider that Whipple had excluded bacterial activity in his study of intestinal death. The contents of a closed loop injected into an animal of the same species produced death. If this secretion was duodenal, death occurred in 4 hrs. and in such cases the duodenum was found to be congested.

Intestinal Obstruction in Children with Special Reference to Intussusception.—Dr. EDWARD W. PETERSON of New York read this paper. Intestinal obstruction occurred in imperforate anus, congenital bands, acquired intussusception, obturation, volvulus, intestinal paralysis, and in infarction of the mesenteric vessels. Congenital occlusion high up in the intestinal tract was difficult to recognize. Intussusception occurred at any age but more frequently early. In the first year the picture was clean-cut, and the mortality was insignificant in those cases that were recognized early and operated upon. If the diagnosis was delayed the death rate was high. No other form of obstruction was more mismanaged and in no other form was the mortality due as much to criminal procrastination. There was obstruction of the blood supply as well as of the fecal current. The obstruction might be intestinal, colic, or ilioecolic. It might be simple or compound. Seventy-five per cent. of the intestinal obstructions were in the ilioecolic region. As a rule, a well, strong child was seized with abdominal pain, tumor, and bloody stools. The child would become calm after this initial attack. Mucous-hemorrhagic stools developed two hours after obstruction. Vomiting was prominent, especially late in the disease, but seldom fecal in character. In every case there was an abdominal tumor which was admittedly often difficult to palpate because of the rigidity and distension. From the beginning, the pain and stools varied with the degree of the strangulation and the toxemia arose from the injury to the lining epithelium of the gut. Occasionally the symptoms might be less acute; there might be no strangulation of the vessels. One should differentiate purpuric disease. The x-ray helped diagnose difficult cases. The safe method of treatment was open operation and manual reduction. The incision served best at the midline below the umbilicus or at outer edge of the rectus. It was important to push and not to pull out the intussuscepted loop. It was well to remove the appendix in all cases, for the appendix might be an exciting cause of the obstruction in many instances. After operation water was given and morphine was avoided. He had seen twenty-five cases, of which twelve, the successful ones, appeared within an average twelve hours following the obstruction and four within twenty-four hours. Of the twenty-five nineteen were ileocecal, one was colic, one ileo-ileocecal, and the other colic. In conclusion he said that intussusception presented a uniform clinical picture, aerohydrostatic measures succeeded in a few cases, and early operation with manual reduction offered the best chances of cure.

The Surgical Treatment of Intestinal Toxemia.—Dr. JEROME M. LYNCH of New York read this paper. He quoted from the *Scottish Medical Journal* of 1855 showing the early significance of intestinal obstruction. Stick had injected the feces of one animal into the same or other animals to show the symptoms following intestinal absorption. Sir Arbuthnot Lane attempted to cure these cases of fecal absorption by improving the intestinal drainage. Other surgeons, lacking the diagnostic acumen and operative skill of Lane, have imitated him with varying measures of success. Wright introduced vaccine therapy. Satterlee of New York tried out colonic vaccine on cases of intestinal stasis. The mixing of the colonic with the intestinal contents, such as occurs in iliocecal insufficiency, might be harmful to the individual but operations calculated to correct incompetent valves did not seem justified. The physiologists had shown the parts played by the cerebrospinal nerves in the control of intestinal movements, but the work on the internal secretions and the sympathetic system of Cannon, supported by Bayliss and by Starling, was probably to bring the greater help to the surgeon. The ileocecal valve was occasionally missing in man. He showed how the valve was developed in the third month while the iliocecal junction occupies the upper

right quadrant of the abdomen. The terminal ileum was intussuscepted into the colon, the invaginated portion lost its longitudinal and retained its circular fibers. The mechanisms of the intestinal valves were important: the ileocecal sphincter functionated after division of the cord at the tenth dorsal vertebra; the internal sphincter of the anus was under voluntary as well as involuntary control. In general, the sympathetic system and adrenalin were probably the more important. Dr. Lynch enumerated the operations that were undertaken to relieve intestinal toxemia and condemned many of them for being unphysiological. The authors had performed twenty-five "reconstruction" operations with encouraging results.

Dr. S. LLOYD of New York said the question of intestinal obstruction was an interesting one. Wished Dr. Peterson had reported the statistics of the other services besides his own. He recalled one case of absence of the colon. The use of hydrostatic pressure in the colon was unheard of to-day. Diagnosis and early operation required care. The necessity of resection demanded judgment. The possible presence of a rupture of the bowel should be ascertained before an operation upon the bowel.

Dr. G. R. PISEK of New York said an intestinal paper should be read in every meeting of the Pediatric Society. The pediatrician was prone to give castor oil and wait. When he asked about the stools and was told they contained mucus and blood, he instituted mechanical treatment. The surgeons thought of an appendix or of an obstruction, and were more apt to make a diagnosis. Prompt diagnosis and prompt surgical intervention were needed.

Dr. F. D. TURCK of New York said that obstruction was well discussed by those present. Senn's work was most important. He had found 70 per cent. of intestinal obstruction caused no symptoms until venous stasis was produced. The intracellular proteins from the intestinal mucosa were liberated by the injury to the mucosa. Had produced ulcers in animals similar to those occurring in burns by feeding bacteria to animals. In venous stasis there was atrophy of the walls and bacteria entered them. Within the walls they underwent bacteriolysis. As a result of this breaking down of bacteria antibodies had been formed. These antibodies produced death suddenly when injected into like animals, and the author believed their sudden liberation, after the relief of intestinal obstruction, caused the sudden anaphylactic death. He suggested hot intracolonic irrigations, for he observed these antibodies less increased after flushings of the bowel. Spasms were relieved by the same means. He suggested the use of a rubber apron or a piece of rubber dam through an opening in which an intestinal operation might be performed without soiling the abdominal cavity with toxic products from the intestinal walls. Heat might be sustained during the operation by placing hot water bags in the abdominal cavity.

Dr. C. G. KERLEY of New York disagreed with Lloyd's contention that the evidence of intussusception was clean-cut. In his experience one case, three days old, presented vomiting, abdominal distension without tumor, and obstinate constipation. Was it intussusception, or what? Surgeons, called, decided it was obstruction, and at operation found a constricting band at the middle of the transverse colon. He saw another case without an abdominal tumor, believed it was intestinal obstruction, recommended operation, and found tuberculosis of the sigmoid with adhesive closure of the gut. Another case at the Babies' Hospital offered intermittent, acute distension and at operation two diverticula were found in the descending colon, one in the ileum and two in the colon at the orifice of the ileocecal valve. Any obstruction that was not relieved should be operated upon at once. A child of eighteen months or two years that passed mucus and blood, and without an abdominal tumor, was thought to be purpuric, but at operation, later, revealed high intestinal obstruction. Diagnosis of intestinal obstruction, in his experience, was not easy.

Dr. L. T. LEWALD of New York said that, as Dr. Kerley had said, there were cases of intestinal obstruction without tumor, even with the patient under anesthesia, so that absence of tumor did not exclude intussusception. The obstruction of the pylorus from any cause produced constipation, therefore it was necessary to make roentgenographic study very complete.

Dr. J. M. LYNCH said that he was interested in Dr. Peterson's paper. He had had five cases of intussusception with Dr. Draper. One case in the second year with fecal vomiting was not recognized, but intus-

susception was found at operation. One, one and one-half years in shock was watched until out of shock, and then operated upon. Another case in Richmond, Va., was found to have a tumor of the transverse colon before operation and carcinoma of the ileocecal valve with intussusception at operation. Washing out of the bowel was very important in these cases.

Dr. JOHN W. DRAPER of New York said the discussion was particularly interesting to all who had done work on intestinal obstruction. He had commenced experimental study with Dr. Weir in 1901. He had concluded that the animals, dying with intestinal obstruction, died from autogenous toxins absorbed through the duodenum, or resulting from the activity of the duodenum. In 1907 a proteose was mentioned as the toxic factor. Whipple has since corroborated and enlarged this work. Hartwell's association of the toxin with desiccation of the tissues was not in accordance with his findings. By feeding a dog pilocarpine his tissues were robbed of 10 per cent. of their water, although he showed no symptoms of obstruction, and intestinally obstructed animals lost the same or less, and presented the classical symptoms. From a study with Dr. Schultze at Rochester no constant organic changes were found in the liver or kidneys, but when the glyconic paring capacity of the liver was measured after obstruction, it was found to have been reduced 30 per cent. Intense congestion in terminal colon was a constant finding. Underhill of Yale recently showed death was in part due to the products of bacterial digestion of amino acids.

Dr. G. REESE SATERLEE of New York said that the colon bacillus was prominent in chronic appendicitis. There were forty-seven or more varieties of this organism identified. About three years ago he began injecting autogenous colon vaccines for intestinal toxemias. One case, undoubtedly toxic, grew worse after operation; urine was full of indican and contained albumin, casts, and blood; patient was delirious. In three weeks all these symptoms improved after administration of the vaccine. Another individual with the symptoms of intestinal obstruction was unrelieved by calomel and catharsis, but got up and about after three weeks of vaccine therapy.

Dr. SHEARMAN said that diagnosis was not easy in his experience of twenty cases. He had got one case early to the surgeons and that one lived—all the others died. Dr. Turck explained the cause of death well. It seems to be "up to the surgeon" to save the late case.

Dr. PETERSON said he had reported all his own cases. He had had twenty cases and eight deaths. The picture was "clean-cut" in babies. The pain, constipation, and mucohemorrhagic stools were characteristic of intussusception which should be diagnosed in 98 per cent. of cases. Children died not as the result of the operation, but because of the toxin. Dr. Draper pointed out the impairment in liver function. By operation he had saved those that would have otherwise died.

Dr. DRAPER said that intestinal obstruction was many-sided. There were bacterial, biochemical, neuromuscular, and mechanical theories of the condition. His early work had been corroborated by Whipple. The lethal agent was probably a proteose, the toxicity of which varied with the digestive activity of the gut. Animals withstood obstruction in the colon and terminal ileum for days, but in the duodenum for hours only. Developmental reconstruction had, in his hands, produced the best results for properly selected cases.

Wednesday Afternoon.

Officers.—Chairman, Dr. Paul M. Pilcher of Brooklyn; Secretary, Dr. T. F. Laurie of Auburn.

The Causation and Treatment of Idiopathic, Operative, and Postoperative Anorectal Hemorrhage.—Dr. SAMUEL G. GRANT of New York enumerated the many conditions that gave rise to hemorrhage from the anus and rectum. It was the frequent manifestation of anorectal disease. Bleeding was called external when apparent, and internal when concealed. Hemorrhage was primary when it occurred immediately after operation, recurrent when it came four or five days after operation from a cause such as the slipping of a ligature, and late, when weeks or months post operative it occurred as the result of the passage of hardened feces or foreign bodies. Among the causes of internal hemorrhage were proctitis, constipation, impaction, varicosities, and villous tumors. Other causes of hemorrhage were the use of edged needles, divulging a strictured rectum, omitting to pack the upper rectum in high rectal operations, pulling down rectal wall for examination, carelessly introducing specula, failing to cauterize rectal stumps in

hemorrhoidal operations, administering strong cathartics that produce straining at stool, and the careless withdrawal of packing. External hemorrhage was quickly recognized; internal, often not until patient was in a dangerous condition. Incessant desire to go to stool was a symptom of hemorrhage. Abdominal distension, pallor, syncope, and shock were later manifestations. Occult blood was of no diagnostic importance. Blood from the sigmoid was coffee-ground in appearance. The treatment included rest in bed and hot flushings of rectum. Accessible vessels should be ligated, but packing was most reliable.

Dr. D. C. MCKENNEY of Buffalo remarked that when hemorrhage from the bowel was due to pathology of anorectal canal, it was usually recognizable by inspection. X-ray assisted him in diagnosing causes of bleeding in certain cases. Cleaning out of the rectum after hemorrhage removed blood and sources of irritation. He recommended colostomy for bleeding in carcinoma, and appendicostomy for dysentery. He favored packing of rectum with gauze strips one inch wide.

Dr. J. M. LYNCH of New York considered the subject unimportant. He never saw any serious results from rectal hemorrhage.

Dr. DEEVER compared the bleeding from the rectum to bleeding from the appendix stump. Said it was well to invert the appendix stump after ligation.

Dr. GANT, in conclusion, said that the use of urea and quinine postponed healing and might cause induration. He preferred gauze to cotton for hemostasis.

The Treatment of Anterior Poliomyelitis.—Dr. CHARLTON WALLACE of New York read this paper. He said that the disease was an inflammation of the anterior bone cells, with resulting degeneration of the motor fibers. The disease was communicable and infectious. The onset might be sudden. There were temperature, constipation, malaise, and pains about the joints or in the muscles. Prevention was important, and to this end the throats of infected patients must be kept clean and their rooms dust-free. He recommended the use of calomel, castor oil, enemata, salts, urotropin (for the spinal canal), salol, heat over spinal cord, atropine, and strychnine (for tonic effect upon the muscles). Plaster-of-paris bandages should be applied to prevent contractures and hot fomentations for pain. During the stage of threatened paralysis, rest in bed was imperative. During the stage of recovery (third month to the second year) massage, stretching, and bracing were recommended. Electrotherapeutics might be employed during the first year. Operative treatment was a prolific field, but should not be resorted to until the third to the fifth year. (Contractures should be immediately overcome.) He said astragalectomy was the best for calcaneus or dangle foot. The transplantation of one of the quadriceps often prevented recurvatum.

Dr. WHITBECK of New York said that such cases came to the orthopedist after they had been to many other physicians. Complete rest (barring electrical treatment) was best for the acute stage of anterior poliomyelitis.

Dr. F. H. ALBEE of New York said every case should be studied separately. Each muscle should be tested for complete or partial paralysis. In transplantations muscle tendons should be buried in grooves beneath periosteum.

Dr. WALLACE closed the discussion by emphasizing the need of complete rest in the acute stage, and illustrated it by a case in point. A young woman, badly paralyzed, was told she might raise her head from her pillow when she could whistle. She was kept on a mattress on the floor. Three years later she walked without braces, could dance, and showed paralysis only in two muscles of one foot and one of the other foot.

Dr. F. H. ALBEE of New York showed moving pictures of his bone-plating and bone-pegging operations. He said that speed was desirable. Many of his spinal transplantations were completed in ten minutes, and one was accomplished in nine. He used bone pegs for ununited fractures of the femora. He was careful to round off the peg to exactly fit the hole in the shaft and head made by the drill.

Thursday, May 18—Third Day.

Diagnosis of Renal Tuberculosis.—Dr. THOMAS F. LAURIE of Auburn said that few cases of renal tuberculosis were referred to the urologist until advanced in the disease. The general practitioner was not thoroughly cognizant of genitourinary practices. He said that continual nocturnal urination and pyuria were suspicious of renal tuberculosis (Braasch). There were

symptoms of cystitis in 80-90 per cent. of cases due either to reflex causes or to mucus changes. Frequency of urination was as great as every one or two hours by day and night. There was hematuria in 25 per cent. of cases and pain or tumor in 10 per cent. The tumor was due to hydronephrosis or to an actual kidney tumor. There might be loss in weight and night sweats. In a case of irritable bladder he secured careful clinical history, including the duration of frequency of urination, he examined the urine for pus and tubercular bacilli, inoculated a guinea pig with urine sediment from the suspected kidney, and catheterized the ureters. Rest and sandle wood oil might quiet the bladder sufficiently for purposes of cystoscopy. Ureters were stricture at time or their mouths might be surrounded by granulations. Tuberculous urine was generally clear and pale, with a low percentage of urea. There might be a nodular vas or epididymis. Radiography assisted by giving the outline of the kidney. The tuberculin test was not to be relied upon. It was important to differentiate nontuberculous cystitis (more acute, no tubercle bacilli), pyelonephritis, and renal calculus (hematuria, absence of bacilli, pus not as common). The cure or the relief of symptoms depended upon an early diagnosis.

Dr. KEYES of New York said that spontaneous cystitis in young people was strongly suggestive of tuberculosis. Indigo-carmin, administered intravenously immediately before cystoscopy, gave dark blue urine which served to more clearly mark out the ureteral orifice. He favored spinal anesthesia for ureteral catheterization as he saw no discomfort from it excepting an occasional headache. He required cystoscopy and ureteral catheterization before operation for renal tuberculosis.

Dr. EDWIN BEER of New York said, in general, the history and clinical examination sufficed to indicate nephrectomy. This applied to 80 per cent. of his 100 cases. The finding of tubercle bacilli implied tuberculosis of the kidney corresponding to the side from which the urine was obtained although contamination with tuberculous urine from the bladder occasionally occurred. It was necessary at times to expose both kidneys in difficult cases. If palpated, the ureter on the affected side was sometimes nodular. Sterile acid pyuria was considered more significant of renal tuberculosis than acid pyuria.

Dr. FURNISS of New York said that acid-fast bacilli in the urine meant tuberculosis of one kidney, at least. Had had two negative pig inoculations and positive tuberculous kidneys in two different cases. He held that delayed indigo-carmin secretion and periureteral changes were sufficient grounds for operative intervention. He favored a continuous small stream of boric acid from the ureteral catheter to prevent contamination from bladder urine. Had seen dilatation of the ureter on the normal side and sterile urine in nephrolithiasis.

Dr. MARTIN TINKER of Ithaca said he felt the general surgeon should cooperate with the urologist. It was important to enforce general hygienic care and sleeping in the open air upon patients with renal tuberculosis. Otherwise recurrences would occur. Careful diagnosis and treatment were essential for improved mortality.

Decapsulation for Chronic Bright's Disease.—Dr. SAMUEL LLOYD of New York read this paper. He said life had been prolonged by decapsulation in cases with chronic parenchymatous nephritis with anasarca. Edebohl reported decapsulation operations in 1901, and 1908, 108 in all, and considered retinitis albuminuria the only contraindication. He (Lloyd) reported a case almost blind relieved by a double decapsulation. Chronic interstitial nephritis was little benefited and two fatal cases were mentioned as illustrations. Of 25 cases operated upon, 15 were parenchymatous (and 2 died) and 7 interstitial nephritis (all died). He had operated upon 146 cases with a mortality of 10 per cent.

Dr. FURNISS of New York spoke of the use of functional kidney tests.

Dr. KEYES of New York added that the functional kidney tests in his experience were inaccurate and untrustworthy.

Dr. BEER of New York reported a case he had decapsulated three times. One case he had intended decapsulating was cured of pyuria by draining the chest for empyema.

Dr. LLOYD in conclusion said a new capsule formed after decapsulation but it did not compress the parenchyma. The benefit from the operation seemed to be the improvement in the circulation.

Ureteral Calculi.—Dr. EDWIN BEER of New York said that extensive exploration and incision for ureteral stones was safe. He had had 98 cases, 34 of which were operated upon. Repeated cystoscopic and radioscopic examinations should be made. Over 90 per cent. of the cases delivered of stones gave radiographic shadows. With argyrol ureterography a higher percentage of positive demonstrations had been made. In 34 operated cases, 24 gave obstruction to the ureteral catheter, 15 per cent. diminished indigo-carmin. The wax-tip bougie was not as reliable in his hands. The (10 per cent.) cases not recognized by x-ray might have contained stones of such a composition as not to throw a shadow, 95 per cent. of cases passed stones or had them withdrawn with forceps. The indications for open operation were (1) calculus of large size, (2) repeated colics that did not pass off, (3) repeated severe pain, and (4) no attempt on part of individual to dislodge stone. In the conservative treatment of the calculus, it was necessary to guard against secondary kidney changes.

Lantern Slide Demonstration of Diagnostic Technique in Kidneys and Urethral Regions.—Dr. HENRY G. BUGBEE of New York said that radiographs of value had been brought by comparison with cystoscopies. He showed a large number of slides. He favored the use of soft ureteral catheters, for such catheters passed readily into the ureters without distorting them and often curved about intraureteral calculi and revealed abnormal angulations or relations of the ureters themselves.

Dr. S. T. SEWALD of New York emphasized the relative importance of the x-ray study of ureteral cases. It was especially serviceable in detecting abnormalities or malformations of the ureters themselves. A pivoted table, assisted in obtaining exposures at different angles. Among other interesting exposures was that of an echinococcus cyst sent into the hospital for splenomegaly.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA BUREAU OF MEDICAL EDUCATION AND LICENSURE.

January, 1916.

PHYSIOLOGY, PATHOLOGY AND BACTERIOLOGY.

1. Name two bacilli that are apt to attack the respiratory tract. Describe the characteristic lesion of each. Outline the laboratory tests used in identifying each.
2. Describe briefly gastric digestion. Diagnose by laboratory methods each of two lesions which seriously impair it.
3. Outline briefly ways in which hypertrophied lymphoid tissue in the pharynx may be detrimental to health, (a) physiologically, (b) pathologically.
4. Given a case of pyuria (pus in the urine) outline the investigations and tests which may locate the source of the trouble.
5. Temperature of the body: Tell briefly how the heat is produced, (b) how regulated, the (c) physiological and the (d) pathological significance of any increase or decrease from normal.
6. Describe the gross lesion in (a) tabes dorsalis, (b) apoplexy. What alteration in function does each produce?
7. Give a general outline of the essential equipment for a clinical laboratory. Outline the type of work which should be performed in such a laboratory.
8. Given a case of irregular fever in an adult which persists, give the laboratory tests which would aid in establishing the diagnosis.
9. State the significance of each of the following: (a) Jacksonian epilepsy, (b) choked disc, (c) Bell's palsy, (d) nystagmus, (e) Argyll-Robertson pupil.
10. Name three localized lymphatic glandular enlargements and give causes for each.

SYMPTOMATOLOGY, DIAGNOSIS, TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. Enumerate the symptoms diagnostic of typhoid fever. Name one disease with which it may be confused and differentiate them.
2. Enumerate the symptoms of cancer of the stomach. Differentiate it from cholecystitis.

3. Enumerate the symptoms of lobar pneumonia and differentiate it from acute pleurisy with effusion.
4. Enumerate the symptoms of scarlet fever. Name two sequelæ which may follow and describe the symptoms of each.
5. Enumerate the symptoms diagnostic of acute alcoholism. Differentiate it from uremia.
6. Differentiate the secondary eruptions of syphilis from other skin lesions.
7. Differentiate acute inflammatory glaucoma from iritis.
8. Enumerate the symptoms of chronic laryngitis. Differentiate it from laryngeal tuberculosis.
9. Enumerate the symptoms of ptomaine poisoning. Differentiate it from other forms of gastroenteritis.
10. Name four conditions of a pregnant female in which a physician would be justified in causing premature birth. What are his duties from a medicolegal standpoint?

OBSTETRICS AND GYNECOLOGY AND PHYSIOLOGICAL CHEMISTRY.

1. Given a patient eight weeks pregnant with a retro-displaced uterus: How would you distinguish the displacement? What are the possible results? How would you manage the case?
2. Given a case of labor with a prolapsed cord: What are the possible results? How would you manage the case? How would you treat the child after delivery?
3. Given a patient six hours in labor who has begun to bleed freely: What are the possibilities in the case and how would you differentiate between them? How would you treat any two of the possible conditions?
4. Given a patient with persistent itching about the vulva: Name four common causes for the condition. Give the local treatment.
5. Name four abdominal enlargements (as large as pregnancy at the seventh month) other than pregnancy. Differentiate them one from the other.
6. Name the more usual bacteria which cause puerperal fever, together with the methods of their introduction into the birth canal. Name the results that may occur from their presence and the prevention of these possible results after the introduction of the bacteria.
7. Should you be called upon to deliver a woman at full term of pregnancy discuss the status of the use of (a) the vaginal douche; the use of (b) an anesthetic; the use of (c) ergot; the use of (d) pituitrin.
8. Discuss the thyroid gland from the chemical and physiological standpoints and state the effect of any change in equilibrium of the essential constituent.
9. Describe a test for each of the following pathological urinary constituents: (a) Bile; (b) blood; (c) acetone.
10. What is cholesterol (cholesterin)? Where is it found normally and in what pathological conditions is it of importance?

ANSWERS.

PHYSIOLOGY, PATHOLOGY AND BACTERIOLOGY.

1. Two bacilli that are apt to attack the respiratory tract: The bacillus diphtheriæ and the bacillus influenzae.

Lesions. In diphtheria, the false membrane may be found on the fauces, larynx, pharynx, trachea, or other mucous membrane. This membrane consists of a network of fibrin which enmeshes round cells, connective tissue cells, streptococci and the specific bacilli; in the fauces and nares the membrane is adherent. The superficial layer of epithelium is necrosed, later on the deeper layers suffer in the same way, the zone of inflammation extends, and the membrane becomes a mass of dead cells undergoing hyaline degeneration and mingled with fibrin. In influenza, there is an inflammatory swelling with hyperemia of the nasal mucous membrane and sometimes of the nasal sinuses and trachea and bronchi; the latter may be covered with muco-pus.

The characteristics of the bacillus of diphtheria: The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aerobic; they are noted for their pleomorphism; they do not stain

uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline methylene blue.

A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of his bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily obtained in pure culture. Loeffler's blood serum, particularly with the addition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C. *Method of staining:* It stains with any aqueous solution of an aniline dye, and quite characteristically with Loeffler's alkaline methylene blue. Neisser's stain is also recognized. The bacilli also stain well by Gram's method.

The bacillus of influenza is a very small bacillus, generally found in pus cells in the nasal or bronchial secretions; it is Gram negative, and stains more deeply at the ends than in the middle; the colonies are small, discrete and transparent.

2. On entering the stomach the food is already crushed, mixed with saliva, and reduced to a pulp; it is rendered slightly alkaline, and a small amount of the starch has been converted into maltose; the proteids and fats are unaltered. In the stomach, where the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved, and fats are set free. Proteids are dissolved and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine. The contents of the stomach at the close of gastric digestion are: Water, inorganic salts, acidified proteids, peptones, liquid fats, starch, cellulose, and the indigestible residues of various foods.

In gastric carcinoma there may be noted absence of free hydrochloric acid, presence of lactic acid, and presence of Boas-Oppler bacillus. In gastric ulcer, there is excess of free hydrochloric acid generally, and blood is often present; lactic acid and the Boas-Oppler bacillus are not present.

3. Hypertrophied lymphoid tissue in the pharynx may result in: Mouth-breathing; snoring; open-mouth; a vacant, dull expression of the face; modification of the voice (nasal twang), with inability to pronounce certain letters. Earache and other ear affections; mental deficiency; frequent attacks of coryza; nose-bleed; stunted growth; convulsions, laryngismus, stridulus, and various other neuroses may also be noticed.

4. In a general way, it may be said that if pus appears in the first part of the urine, it is from the urethra; if it appears in the last part chiefly, or at the end of urination, it is from the bladder; if the pus and urine are mixed, the pus probably comes from the kidney. Further, if the pus is from the bladder, the urine is more or less alkaline; if from the kidney or from some outside source, it is usually acid. By the use of a cystoscope, urethroscope or ureteral catheterization, the lesion may be located; a sound may detect a vesical calculus; x-ray examination may show lesion in kidney, and a bacteriological examination of the pus may also aid.

5. The normal body temperature is regulated and maintained by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost.

Heat is produced in the body by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla and spinal cord.

Heat is given off from the body by: (1) The skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

Increase of body temperature may indicate the presence of infectious diseases, toxemias, inflammation, or some interference with the nerve mechanism of heat regulation.

Decrease of body temperature may indicate wasting diseases, starvation, alcoholism, convalescence from fever, poisoning or collapse.

6. In *tabes dorsalis* the posterior columns of the spinal cord and the posterior nerve roots are involved. The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

In *apoplexy* "the primary effects are tearing and compression of the brain-substance. If the patient does not die immediately, softening occurs. As a result of the staining by the retained hemoglobin the area is known as red softening. Shortly after the blood escapes it undergoes coagulation, forming a cerebral hematoma. This acts as a foreign body, and sets up an inflammatory reaction, with more or less hyperplasia of the surrounding neuroglia. The fluid portion finally becomes absorbed, the corpuscles broken down, and the pigment liberated, which stains the walls of the cavity. Occasionally a cyst filled with a clear fluid may form. If all fluids are absorbed, the walls of the cavity may come in contact and a scar result." (McConnell's Pathology.)

In *tabes dorsalis* the disturbance of function includes loss of sensation in the feet, girdle sensation, loss of coordination of muscles, inability to preserve the erect position with the feet together, impairment of vision, Argyll-Robertson pupil, abolition of patellar reflex, muscular atrophy, loss of sexual power, and paralysis.

In *apoplexy* the disturbances of function depend on the site of the lesion; if this is above the first cervical segment of the pyramidal tract, there will be paralysis of the opposite side of the body; if above the middle of the pons, paralysis of the lower portion of the face on the opposite side is also produced; if below this point, paralysis of the same side. Monoplegias are likely to occur if only a small portion of the fanlike projection-fibers of the pyramidal tract is involved, such as would be produced by a lesion in the cortex or in the centrum ovale. Spasticity arises in the muscles; subsequently their nutrition is impaired, and they contract. Amnesia or aphasia will occur if the lesion is in those portions of the cortex which have to do with speech. Lesions of the optic tract posterior to the chiasm cause hemianopsia. (From Stengel's Pathology.)

7. A clinical laboratory should be provided with a sink, running water, gas, electric light, tables, benches, stools, shelves, reagents, test tubes, beakers, slides, coverslips, microscope, centrifuge, apparatus for estimating hemoglobin and counting blood corpuscles, Petri dishes, flasks, pipettes, litmus paper, distilled water, Bunsen burner, alcohol lamp, burettes, holders for burettes and test tubes, stomach tube, urinometer, ureometer, Esbach's albuminometer, funnels, tripod, wire gauze, sphygmomanometer, incubator, thermometers, steam sterilizer, thermoregulator, platinum wire loops, pure culture of typhoid bacillus. The work which can be done will depend on the size and equipment of the laboratory, the number and experience of the workers, and the time that can be given to such work. It should include urinalysis (at least qualitative and microscopic); examination of gastric contents, and sputum; blood examinations (counting corpuscles, estimating hemoglobin, and searching for parasite of malaria); Widal's test; examination of smears for gonococcus; examination of blood for anemia, chlorosis, leucemia, and the *Treponema pallidum*; estimation of blood pressure; examination of feces for parasites, protozoa, bacteria, and occult blood; cerebrospinal fluid; milk, and various bacteriological methods (such as sputum for tubercle bacillus, nasal secretion or smear from throat for diphtheria bacillus). Wassermann's reaction and Noguchi's reaction may also be included.

8. Irregular fevers are of a negative character, and

indicate the absence of any febrile disease which has a characteristic temperature curve, such as malaria, typhoid, pneumonia. Some other symptom will have to be taken as a guide, and the laboratory tests (sputum, urine, cerebrospinal fluid, and blood) will have to follow such indications as these other symptoms supply.

9. *Jacksonian epilepsy* may indicate: Tumor, softening, abscess, hemorrhage or injury of the brain; general paresis; uremia; it may occur as a sequel to hemiplegia in children.

Choked disc may occur in: Retinitis, tumors of cerebrum or cerebellum, cerebral abscess, tuberculous meningitis.

Bell's palsy may occur in rheumatism and as a result of infection or exposure; it may be found in cases of multiple neuritis or locomotor ataxia, and may follow ear disease and injuries to the petrous portion of the temporal bone.

Nystagmus may indicate: Irritation of the ocular muscle centers, cataract, errors of refraction, optic atrophy, epilepsy, neurasthenia, hysteria, chorea, tumors of brain, Friedreich's ataxia, locomotor ataxia, and chronic hydrocephalus.

Argyll-Robertson pupil may signify: Locomotor ataxia, intracranial syphilis, and general paralysis of the insane.

10. Enlarged lymphatic glands in the neck may be due to: Inflammation, tuberculosis, syphilis, Hodgkin's disease, leucemia; in the groin, the cause may be: Syphilis, gonorrhea, chancroid, Hodgkin's disease, tuberculosis, malignant disease; in the axilla, the cause may be: malignant disease or suppuration in the breast.

SYMPTOMATOLOGY, DIAGNOSIS, TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. **TYPHOID FEVER.** *Symptoms:* Insidious onset, weakness, headache, epistaxis, vague pains. The temperature rises gradually, about 2° in the evening, falling 1° in the morning. Diarrhea, tenderness in the right iliac fossa, enlarged spleen, and a characteristic rash which appears from seventh to twelfth day. During the second week the temperature remains at a uniform level; typhoid state and delirium may be present. The pulse becomes rapid, weak, and dicrotic; the heart sounds are feeble; the tongue is coated, fissured, and tremulous; sordes appear on the teeth; the abdomen is distended; the stools are yellowish and offensive (said to be like pea soup); the Widal reaction may be positive. In the fourth week the temperature becomes normal.

It may be confused with malarial (remittent) fever. The following table is taken from an elaborate one by Thayer:

TYPHOID FEVER.	MALARIAL (REMITTENT) FEVER
Blood shows no leucocytosis; eosinophiles diminished or absent; serum causes agglomeration of typhoid bacilli; malarial parasites and pigment absent.	Blood shows no leucocytosis; eosinophiles not notably diminished; serum does not cause agglomeration of typhoid bacilli; malarial parasites and pigmented leucocytes present.
Fever uninfluenced by quinine.	Fever disappears under quinine.
Usually epidemic; prevailing commonly in cities.	Is an endemic disease occurring particularly in rural districts; rarely epidemic.
Anemia absent, excepting in later stages.	Anemia more or less marked early in the course.
Characteristic roseola.	No characteristic exanthem; urticaria not uncommon.
Has a fairly characteristic course.	No distinct course.
Urine high-colored; bile absent; Ehrlich's diazo-reaction present during the height of the process.	Urine high-colored; may show a trace of bile; Ehrlich's diazo-reaction rarely present.
The temperature does not reach 40° C. (104° F.) before the third or fourth day.	The temperature may arrive at 40° C. (104° F.) within twenty-four hours.
The apathetic expression of the face, the dryness of the tongue, and sordes upon the teeth are well marked and progressive.	These symptoms are not very marked.
Herpes rare.	Herpes common.

2. *Symptoms of cancer of the stomach.* It does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

Cholecystitis is not accompanied by the "coffee ground" vomitus, and the gastric contents do not show lactic acid or absence of free hydrochloric acid. Further, there may be obstinate constipation and jaundice; the pain is at first more diffuse, and bears no relation to the time of eating.

3.

PLEURISY WITH EFFUSION.

Onset marked by chilliness persisting for a few days.

Cough is irritating; no expectoration, or, if present, catarrhal in character.

Sputum negative; tubercle bacilli rare.

Moderate fever of continuous type; declines by lysis.

Prostration moderate.

Unilateral distention of the thorax.

Countenance pale and anxious.

Limited expansion at base of chest on the affected side.

Tactile fremitus diminished or absent.

Interspaces bulging at base of chest.

Percussion shows flatness, with great resistance to the pleximeter finger.

Diminished or absent breath-sounds over effusion the rule. Respiration murmur diffuse, distant, and generally unaccompanied by rales. Bronchial breathing may be present over the entire affected side of the chest.

Friction sound heard in early and late stages.

LOBAR PNEUMONIA.

Onset acute, with rigor, lasting one hour or longer.

Cough more marked, and accompanied by rusty or bloody, tenacious expectoration.

Dense aggregations of pneumococci present.

Fever, 102° to 104° F.; falls by crisis.

Prostration extreme.

Absent.

Mahogany-colored flush of cheeks.

Degree of expansion slightly, if at all, inhibited.

Increased over area of consolidation.

Absent.

Dullness with less resistance, and sometimes a tympanic note.

Harsh bronchial breathing and presence of rales in first and third stages, unless a bronchus is plugged.

No friction murmur; rales present.

(Anders and Boston's *Medical Diagnosis*.)

4. **SCARLET FEVER.** *Symptoms:* Abrupt onset, with rigors, vomiting, sore throat, anorexia, rise of temperature on first or second day to 100° to 104° F. On first or second day a typical scarlet rash appears, on a red background; after a few days desquamation commences, and the epidermis peels off in large flakes.

Two sequelæ: Nephritis and inflammation of the middle ear.

Nephritis is indicated by the presence of urine of a high color and containing albumin, blood, and casts; dropsy of ankles or eyelids or general; and possibly uremia, with convulsions or coma.

Otitis media is indicated by pain in the ear, tinnitus, difficulty in hearing, swelling in the ear; the membrane presents a glistening red and sunken appearance; suppuration may occur, with perforation of the membrane, and possibly facial paralysis or meningitis.

5.

UREMIC COMA.

Deep coma. Slow onset unless convulsions have preceded the coma. Albuminuric retinitis.

Pulse rapid.

ALCOHOLIC COMA.

Can be aroused by supra-orbital pressure unless very profound.

Pupils normal or somewhat dilated.

Pulse more rapid than normal and full.

UREMIC COMA.	ALCOHOLIC COMA.
Respiration, frequent and irregular.	Regular respiration.
Urine shows albumin, casts and low urea percentage.	Normal.

6. The secondary skin eruptions of syphilis are polymorphic in character, do not itch, are roughly symmetrical, are of the color of copper or raw ham, are painless.

	GLAUCOMA.	IRITIS.
Age	Over forty.	Any.
Tension	Plus.	Normal.
Congestion	General, especially scleral.	General, especially circumcorneal.
Cornea	Cloudy and steamy surface.	Cloudy.
Anterior chamber	Shallow.	Unchanged.
Pupil	Dilated, oval.	Contracted, synechia.
Pain	Severe, continuous.	Especially at night.
Vision	Much reduced.	Somewhat reduced.

(From Alling and Griffin's *Diseases of the Eye and Ear*.)

8. The symptoms of chronic laryngitis are: Hoarseness and discomfort in the use of the voice, a tendency to cough, and possibly aphonia.

Laryngeal tuberculosis has, in addition, dysphagia with severe pain as an additional symptom. Further, the laryngoscope will show tuberculous ulcers.

9. The symptoms of ptomaine poisoning are: Onset more or less sudden, abdominal pain, persistent nausea and vomiting, chill, diarrhea, headache, weakness, vertigo, faintness, neuromuscular pains, sometimes fever.

In other forms of gastroenteritis, the vomiting ceases when the stomach is emptied, but in ptomaine poisoning the nausea, retching, and vomiting are persistent; in gastroenteritis the onset is less sudden, and the symptoms not so severe.

10. Four conditions which may justify the induction of premature labor: Certain pelvic deformities; toxemia of pregnancy; habitual death of a fetus toward the end of pregnancy, and when the mother's life is in imminent danger owing to the presence of disease of the heart or kidney.

The physician must obtain the consent of the woman or of her husband or guardian, and he should be sustained in his view by a recognized consultant.

OBSTETRICS AND GYNECOLOGY AND PHYSIOLOGICAL CHEMISTRY.

1. At eight weeks, the retrodisplaced uterus will cause pain and difficulty in micturition, owing to the pressure of the cervix on the bladder; similarly, pressure of the fundus may cause pain in the sacrum and constipation; vomiting, and other reflex phenomena may occur; the cervix is found higher up than usual, and the body of the uterus is in Douglas' pouch. The condition may right itself (spontaneous reposition), or the uterus may become incarcerated, or spontaneous abortion may occur. The patient should be placed in the knee-chest position, and the bladder being empty, the uterus should be replaced by the physician's fingers or a repositor; it should be kept in place by adequate tampons or pessary. Incarceration is not likely to occur till the third month.

2. The possible results of a prolapsed cord are compression of the cord causing death of the fetus, and for the mother, hemorrhage due to premature detachment of the placenta and breast complications due to the death of the fetus.

Treatment of prolapsed funis consists in: (1) Not rupturing the membranes prematurely unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually or with some form of repositor; (4) speedy delivery, by forceps or podalic version. If the child shows signs of asphyx-

iation, the various methods of artificial respiration should be tried and persisted in.

3. The possibilities are: Placenta prævia, premature detachment of a normally placed placenta, rupture of the uterus, and lacerations of the lower part of the birth canal.

In placenta prævia, the hemorrhage is abrupt, painless, and there are generally repeated hemorrhages of increasing severity; the placenta may be felt through the cervix.

In premature detachment, the hemorrhage is sudden, and is generally attended with sharp pain; the hemorrhage persists until the uterus is emptied or the patient dies; vaginal examination shows nothing abnormal.

Ruptured uterus is announced by a sudden, acute, and persistent pain. Sometimes the sound of the rupture is heard by the patient; the symptoms of internal hemorrhage and shock are present—collapse, air-hunger, cyanosis, rapid, feeble pulse; the uterine contractions cease. Vaginal examination shows that the presenting part of the child has receded from its former situation owing to escape of the fetus (partially or completely) through the rent into the abdominal cavity, where it may be felt by abdominal palpation.

Treatment of placenta prævia, at term: (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation turn the child and make the breech engage in the os; or, if the head presents forceps may be used if speedy delivery is necessary. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child. (Landis' *Obstetrics*.)

Treatment of rupture of the uterus: "After rupture has occurred, especially if it be 'complete' and extensive, and the child should have escaped, wholly or in great part, through the rent into the abdominal cavity, laparotomy should be done at once, child, placenta, blood clots, etc., being removed through the abdominal incision; the peritoneal cavity cleansed with hot saline solution; the rent in the uterus repaired by suture; or in case of an infected uterus, or one that will not contract, or in which the rupture cannot be well secured, the entire uterus should be removed." (King's *Obstetrics*.)

4. Pruritus vulvæ may be caused by: Parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion, irritating discharges, lack of cleanliness, diabetic urine; it may also be of nervous origin or idiopathic. Local treatment consists in applications of solution of bichloride of mercury, 1:2000; or carbolic acid, 1:100; or lead and opium; dusting powders of bismuth subnitrate, calomel, or zinc oxide are also useful.

5. Pregnancy: The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

Ascites: Absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides, the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies with the position of the patient.

Fat: Absence of signs of pregnancy, also of fibroid, or ascites.

Pseudocyesis: The uterus is not enlarged, and the administration of a general anesthetic causes the collapse of the "tumor."

6. The bacteria which cause puerperal fever are: Streptococcus pyogenes, staphylococcus pyogenes aureus, gonococcus, bacillus coli communis, bacillus diphtheriæ, bacillus typhosus. They are generally introduced by the fingers of the physician or nurse, or by instruments,

or general lack of cleanliness. The results are shown by chill; rapid rise in temperature, to about 103° or 104°, higher in the evening than in the morning; sweats; rapid pulse; depression; dry tongue; anorexia; carphologia; scanty, high-colored, albuminous urine; restlessness; sometimes delirium or coma. The uterus is large, and tender; the lochia are diminished or suppressed; the milk secretion is often suppressed; pain in the abdomen; peritonitis may develop. *Treatment:* Prophylaxis is of the greatest importance. Purgatives; vaginal douches; some recommend curettage, others decry it; the introduction of antiseptics into the uterus; supportive and general treatment are indicated; specific sera and vaccines have been recommended by some.

7. *Vaginal douches* should not be given unless distinctly indicated, such as in cases that are probably septic or prior to version or forceps or other operative procedure.

Anesthetics are used in labor to lessen suffering produced by labor pains; to lessen the pain attending obstetric operations; to relax the uterus when its rigid contraction interferes with version; to promote dilatation of the os uteri; to reduce excessive nervous excitement which may interfere with progress of early stage of labor; to relieve eclamptic convulsions and mania; in cases of uterine inversion to relax the constricting cervix and so facilitate replacement; in bipolar version to lessen pain of introducing the hand into vagina; in precipitate labor to suspend action of voluntary muscles and retard delivery; in all cutting operations upon the abdomen; and sometimes in sewing up a lacerated perineum when many sutures are required. (From King's *Obstetrics*.)

Dangers: They lessen the efficiency of the uterine contractions; predispose to postpartum hemorrhage; and, if given too freely, may be followed by headache, nausea, and vomiting.

Ergot should be used after the placenta is expelled, so as to secure uterine contractions. Before this period, the use of ergot is dangerous, the objections being: (1) That it may produce tetanic contractions of the uterus and so cause rupture of the uterus, death of the mother, or asphyxiation of the child; (2) that it increases the chances of lacerations of the cervix and perineum; (3) that it tends to cause retention of clots and membranes, etc.; and (4) that it retards the secretion of milk.

Pituitrin may be used in cases of uterine inertia, provided the os is dilated and there is no obstruction to delivery.

8. The *function of the thyroid* is not definitely settled; (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances; and (3) it produces an internal secretion.

Removal of the thyroid gland causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out, and the patient becomes unwieldy and clumsy in both body and mind. The complete removal causes death in most animals, and it is not considered justifiable in man.

Removal of all the parathyroids causes death from acute tetany. Their exact function is unknown, but it is supposed that some of the evil effects attributed to removal of the thyroids is really due to the removal of all the parathyroids as well, and that if the parathyroids are left (with their blood supply intact) these results will not ensue. Thyroid substance is composed of water, 82 per cent., and solids 18 per cent. The solids consist of nucleoprotein and iodothylin. This latter is found in the colloidal substance, and contains carbon, hydrogen, oxygen, nitrogen, phosphorus, and iodine. The thyroid is the only tissue in the body which normally contains iodine, and it is believed that the changes which occur in disorders of the gland are due to the excess or lack of the iodothylin.

9. *Test for bile pigments in urine:* Put 33 cc. of nitric acid in a test tube and heat until the acid is yellow; cool; then float some of the urine on the surface of the acid. If bile pigments are present a green band is formed at the junction of the two liquids, which gradually rises and is succeeded from below by blue, reddish violet, and yellow.

Test for blood in urine: Place a few drops of the urine in a test tube, and add a drop of freshly prepared tincture of guaiacum and a little ozonic ether; then agitate. In the presence of blood the ether, which rises to the surface, is blue.

Test for acetone in urine: Add a few drops of a freshly prepared solution of sodium nitroprusside, and then solution of KHO, when, in the presence of acetone, the liquid is colored ruby-red, and on supersaturation with acetic acid, changes to purple.

10. *Cholesterol* is a monoatomic alcohol, with the empirical formula $C_{27}H_{46}OH$, but of unknown constitution. It is found chiefly in bile, but also in blood, nerve tissue, brain, and nearly every animal tissue and fluid. Pathologically, it occurs in biliary calculi, pus, hydrocele fluid, cancer, brain tumors, atheromatous patches, dermoid cysts.

(To be concluded.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE TONSIL AND ITS USES. By RICHARD B. FAULKNER, M.D. Published by The Blanchard Company, Pittsburgh, Pa. Price, \$1.

"JAMES NORRIS." By ALBERT PYRMONT. Published by C. Regenhardt, New York. Copyright Edition. 560 pages.

THE INFLUENCE OF JOY. (Mind and Health Series.) By GEO. VAN NESS DEARBORN, PH.D., M.D. Published by Little, Brown & Company, Boston. 223 pages. Price, \$1 net.

A MANUAL OF PRACTICAL NURSING. Prepared for the Washington University Training School for Nurses in the Barnes and St. Louis Children's Hospitals. Edited by Helen Lillian Bridge, B.S., B.N. Published by C. V. Mosby Company, St. Louis, Mo. 84 pages. Price \$1.

MANUAL OF OPERATIVE SURGERY. By JOHN FAIRBAIRN BINNIE, A.M., C.M. Published by P. Blakiston's Son & Co., 1012 Walnut Street, Philadelphia, Pa. Seventh Edition, revised and enlarged. With 1597 illustrations, a number of which are printed in colors. 1363 pages. Price \$7.50 net.

ROENTGENOGRAPHIC CONTROL OF THE PNEUMOTHORAX TREATMENT OF PULMONARY TUBERCULOSIS.

By I. SETH HIRSCH, M.D.,

NEW YORK.

PROFESSOR OF ROENTGENOLOGY, NEW YORK POST GRADUATE HOSPITAL AND MEDICAL SCHOOL, DIRECTOR OF X-RAY LABORATORY, BELLEVUE HOSPITAL, NEW YORK CITY.

THE necessity of carefully, persistently, and continually controlling the pneumothorax treatment of tuberculosis of the lung by the Roentgen ray need hardly be emphasized, since it is generally agreed that the more constant the study and the checking of the cases by radiographic and fluoroscopic examinations, the more certain and effectual is the treatment.

The application of the Roentgen method is manifold. It assists in the selection of cases fitted for this treatment, it permits the estimation of the degree of collapse of the lung and of the effect on the opposite lung, it allows the study of the progress of the disease, it indicates graphically the displacement of the heart and mediastinum, and makes possible the early discovery of complications. These conditions cannot always be determined by the ordinary methods of examination, for the air in the pleural cavity makes a sounding box of the chest, which results in exaggeration and transformation of every sound and in the obliteration of the finer differences of tone. It accordingly appears to be almost impossible by the usual physical examination to map out the extent of pneumothorax, to determine what is the actual position of the collapsed lung, or to estimate the displacement of the mediastinal structures.

These difficulties demand that all the diagnostic means at our disposal be employed in the effort to obtain a true idea of the conditions existing in this disease.

The examination may be made either with the aid of the fluorescent screen (roentgenoscopy), which permits the study of the movements of the thoracic viscera, or a record of the pathological conditions may be obtained upon the photographic plate (roentgenography). Both methods are to be employed and the examination cannot be considered complete without either. For no description, however accurate, of the fleeting image seen upon the fluorescent screen can compare as a graphic record with the permanent impression on a photographic plate, which also gives the finer structural detail not to be seen with the screen. The picture of pneumothorax is so striking and characteristic that once seen the condition is thereafter readily recognized.

For its clear understanding a rapid analysis of the normal sagittal view of the thorax will be made.

On either side of the triangular median shadow, due to heart and mediastinal contents, are seen two brightly illuminated areas shaped like Gothic windows—the pulmonic fields. These are bounded above by a convergence of the spinal column and ribs, and below by the curve of the diaphragmatic domes. Radiating outward from two winged shadows (hilum shadows) which lie close to the median shadow, are linear shadows which fade out as they extend to the periphery, into fine reticulations. These are known as the pulmonic markings and are due in greatest part to the blood-vessels, but the bronchi and lymphatics also contribute to their make-up. At the periphery the shadows of the thin-walled bronchioles are lost in the brilliancy of the illumination due to their air content, but at the hilum the larger bronchi may be seen in longitudinal section, as white rings (bronchial wall) with illu-

FIG. 1.—Partial pneumothorax of the right pleural cavity. The exposure made during forced expiration. The middle and lower lobes are about equally retracted. Complete retraction of the upper lobe, which is most diseased, is prevented by adhesions.

minated centers (air content). With respiration the lung markings move. The brightness of the illumination of the pulmonic fields is an index of the air content of the lungs, in other words, of its state of aeration. This degree of illumination is estimated by a comparison with the illumination of that portion of the plate or screen which is uncovered by any structure. The normal pulmonic illumination is less than this. Any encroachment on the air-containing capacity of the alveoli will show itself as a clouding either local or general of the field. This clouding may vary in degree from a slight haziness through which the pulmonary markings are visible to a complete shadowing which obscures completely all the pulmonic markings. So, also, any increase in the air content above the normal will show itself as an increase in the brilliancy of the illumination of the pulmonic fields. Thus in

pneumothorax, because of the replacement of the normal lung tissue by air, the illumination attains its highest brilliancy. For the ray now affects the screen or plate almost as if nothing had been interposed. The contrast between the brilliantly illumi-

FIG. 2.—Same case as shown in Fig. 1. Partial pneumothorax. Exposure made during forced inspiration. Shows the inflation of the lung, both the middle and lower lobes moving to the same extent. The upper lobe, however, shows diminished motion because of the existence in it of the focus of disease and adhesions.

nated pulmonic field and the central dense structures is now very marked. The pulmonic field is divided into two parts—an outer, very brilliantly illuminated, corresponding to the air-containing pleural space, and an inner, less brightly illuminated, which corresponds to the more or less collapsed lung. Examination of this brilliantly illuminated area will show that the normal lung markings are absent, while in the irregularly rectangular or oval shadow with its well defined outline in the inner part of the field these markings may be visible. This shadow of the retracted lung may enlarge and grow lighter during one or the other phases of respiration. The lattice-work effect of the ribs over the bright area is very clear, the structural detail very distinct and of a lighter shade than the ribs on the normal side. The intercostal spaces are widened. The costo-diaphragmatic space is widened, sharply defined, and clear. The diaphragmatic shadow is depressed, irregular, and relatively immobile.

The Roentgen ray study is made at three periods: (A) The preliminary examination for the estimation of the amount of disease and the selection of the site of the puncture. (B) The study during and immediately after the injection of gas. (C) The subsequent study with the determination of the amount of collapse, restitution, etc.

A. *The Examination Preliminary to Injection.*—There is no necessity of entering into a detailed description of the findings which indicate tuberculous involvement. This may be studied in four stages: (1) The stage of congestion: shown as hypervascularization, diminished illumination, and adenopathy. (2) The stage of infiltration: shown as more or less localized, large areas of absent illumination (consolidation), more or less generally distributed smaller areas of absent illumination about the bronchi (peribronchial consolidation), localized or general miliary infiltration—pin-point shadows. (3) The stage of necrosis: shown as cavitation. (4) The stage of repair: shown as calcification or fibrosis.

It is beyond the purpose of this paper to discuss

the indications for the production of pneumothorax. It is generally understood that the condition of the lung as seen in the radiographic examination is not the sole criterion for the determination as to whether or not gas is to be injected. The subjective phenomena are after all the important standard. Extensive disease on both sides is, however, not a contraindication against the induction of even double pneumothorax.

In the determination of the site of injection, it is of course important to avoid an area over which extensive adhesions are present. This may be done by shunning areas where consolidation exists or where the linear shadows extending from hilum to periphery indicate interlobar pleurisy. Marked general clouding of a portion of the pulmonic field in one view with normal illumination in examination in the opposite direction indicates adhesions.

But, though extensive fibrosis gives the characteristic picture of obliteration of the pulmonic field, narrowing of the intercostal spaces, retraction of the heart shadow, etc., unfortunately mere localized pleural thickening is not always visible radiographically, especially over the lateral portions of the lungs. At the root and base of the lung adhesions show as a distortion and downward extension of the hilum shadow and as irregularities and distortions of the diaphragmatic outlines, the smooth convex surface of which is thrown into wavelets. These are best demonstrated during deep inspiration, which also show the limitations in diaphragmatic movement.

B. *The Examination During and After the Injection.*—For the proper comprehension of the phenomena which follow the injection of gas into the pleura a consideration of the mechanics may be of value.

When air is admitted between the pleural layers, the negative intrapleural pressure is diminished; that is to say, it approximates the atmosphere. The lung may now satisfy its inherent tendency to shrink. There appears to exist a belief that even the smallest opening of the pleura or the admission

FIG. 3.—Complete collapse of right lung, visible as an airless mass lying at the central and basal portions of the thorax.

of the smallest amount of air invariably results in the immediate and complete collapse of the lung and that under these circumstances the lung takes no part in respiration. But animal experiments long ago demonstrated that

the lungs do not collapse perfectly, and continue to functionate even when there is a pleural opening the diameter of the trachea, and that considerable quantities of gas are necessary to obtain extensive collapse. In fact, the opening in the chest

FIG. 4. Massive collapse of left lung. Displacement of upper pleural septum into right thorax. Marked displacement of heart to right.

wall may be very large and yet the lungs will continue to functionate if the animal be so placed that the perforation is lowest and this in spite of the fact that in dogs there is often a communication between the two pleural cavities just above the tendinous center of the diaphragm, so that nearly every pneumothorax is really bilateral and that the unusual mobility of the mediastinum considerably impairs the activity of both the sound and the affected lung.

So, also, in human beings it has long been known that in pneumothorax under certain circumstances not only is there no shrinkage, but there may be an actual protrusion of the lung through the wound in the chest wall constituting a hernia and that complete collapse of the lung can usually be produced only by the administration of large amounts of gas into the pleural cavity. But whether the open or closed form of pneumothorax exists, the lung in the affected thorax usually continues to functionate to a greater or less extent so that even double, though incomplete pneumothorax is compatible with life.

What are the conservative forces which counteract the tendency of the lung to retract? The forces concerned in the maintenance of the lung in its normal position may be divided into two classes: Those acting from without, which may be styled extrinsic, and those due to properties inherent in the lung tissue itself, which may be called intrinsic. The extrinsic forces consist of, first, the pressure of the atmosphere on the exterior of the chest; second, the pressure of the air within the lungs (intrapulmonary), which, with some variations, is that of the atmosphere; and third, the tension which exists between the pleural layers (intrapleural negative pressure). The intrinsic forces consist of, first, the elasticity of the lung, which constantly tends to diminish the tension under which its structure has been placed; and second, the tonus of the lung, due to its bronchi, muscular and vascular tissue, which maintains definite structure and shape of the organ.

Besides this there is the power of vicarious distension of the alveoli which the lung tissue may exhibit in response to an afferent impulse.

The integrity of the lung and its intrinsic forces,

however, is of the utmost importance as affecting the degree of collapse.

When the lung is but slightly diseased, with its intrinsic forces not markedly impaired, the tendency to collapse is counteracted by the compensatory dilatation of parenchyma, in the immediate vicinity of that portion subjected to the stress of the atmospheric pressure.

This increase of the pulmonary volume, associated as it is with increased intrapulmonary tension due to exaggerated respiratory activity, is sufficient not only to maintain the approximation of the pleural layers, but when there is added the expiratory pressure from the sound lung, collapse is prevented, necessitating the exhibition of considerable positive pressure.

When the lung is partially involved, and its tonus is depressed by the disease, the degree of collapse will depend considerably on the amount of involvement and the quantity of gas injected. The lobe more affected will shrink more and remain more immobile. The redistension takes place through the agency of the same forces as mentioned above, except that the expiratory pressure from the sound lung plays a more important part. The lung continues to take part in respiration when the collapse is not complete, but its movement at times differs from that of the sound lung; that is, it expands with expiration and collapses with inspiration. As more and more gas is absorbed, the type of respiration changes to the normal.

If, however, because of extensive disease, its tonus is completely lost, the collapse is complete and its mobility impaired. Restitution to the normal is delayed and may never take place. The most extensively diseased lobe casts a larger shadow than the less involved lobe. This is, however, not due to a lesser degree of collapse but to the infiltration which gives a greater mass than the uninvolved lung.

C. *The Subsequent Study with the Determination of the Amount of Collapse, Restitution, etc.*—The x-ray examination after the injection gives the following data:

FIG. 5. Partial collapse of the lower and middle lobes. The upper lobe containing two large cavities is collapsed to a greater degree, the rigid walls of the cavity preventing complete retraction.

1. The degree of pneumothorax. Is the air present in all parts of the pleural cavity or confined to a particular part?

2. The condition of the lung. Is the lung com-

pletely or only partially collapsed? What is the position and mobility of the retracted lung? Does it functionate?

The collapse of the lung is not proportional to the amount of gas injected. If free from adhesions, the

FIG. 6.—Left pneumothorax. The upper lobe is only partially collapsed and contains a very large cavity. The lower lobe is partially consolidated in its upper portion and is only partially collapsed.

collapsed lung is usually found lying about its root, but the stereoscopic examination shows that it is never concentrically displaced. With a small amount of gas the partially compressed lung casts a distinct shadow of considerable extent, with a sharply defined border, but as the lung continues to shrink, with continued injections, its shadow grows denser and smaller until in long standing cases it is finally barely visible, airless and motionless, a ribbon-like mass along the spinal column. The collapse may be toward the anterior or posterior chest walls, toward the apex or base of the pulmonic field. This depends considerably upon the amount of adhesions and infiltrations. A large area of consolidation may not permit the lung to collapse to any marked extent or extensive adhesions may present free retraction, though now adhesions become clearly visible. By the examination in the oblique position the extension of the adhesions in all directions may be demonstrable. The lobes of the collapsed lung may now also be differentiated, for they do not collapse similarly. The cavities are the last to collapse. The firm, rigid walls of these cavities maintain their form even when the surrounding lung is collapsed.

The opposite lung should be studied and the compensatory emphysema noted. There appears a clear outlining of the markings due to the pulmonic blood vessels, but whether this is due to an increased blood supply in the opposite side (congestion) or just to a clearer delineation of the vessels because of the increased air content, one is not able to state; perhaps both factors are concerned. Aside from the compensatory emphysema the treatment has no appreciable effect on the opposite side, it surely does not intensify the disease if the proper technique is employed in the administration of the treatment.

An apparent improvement in the lesions on the other side has been noted, but this is not always a correct observation. Because of the greater dilatation of the air vesicles these lesions become more widely separated and an area which gives a shadow of apparently almost consolidation due to a confluence of areas of infiltration has now the appear-

ance as if this infiltrated area has cleared up by the absorption of the tuberculous process.

3. The Condition of the Pleura—does it contain effusion? The difficulty of detecting by the usual diagnostic means, either the presence or the amount of effusion within a pleural cavity containing air, is well known to every clinician. With the aid of the Roentgen ray the smallest effusion may be detected. The effusion is first observed in the costophrenic space. The lower angle of this space is cut off by a shadow with an upper horizontal border, and as the level of this shadow rises the pulmonic field becomes divided into three zones. There is a bright upper zone, a brilliant middle zone and a dark lower zone. The bright upper zone corresponds to a part of the collapsed lung retracted and pressed against the upper and posterior part of the chest. The middle brilliant zone represents the parts of the chest containing air. The contrast between this zone and the dark zone beneath it is very marked. The lower zone represents the fluid. It is a dense, homogeneous shadow which may obscure the shadow of the ribs. Below it merges without any defined boundary into the shadow of the subdiaphragmatic organs, while its upper level is sharply defined and perfectly horizontal.

This upper level is sharply defined, no matter how small the quantity of air. In simple effusion the upper border of the fluid is concave, rising higher at the periphery, while a change in the position of the thorax has no immediate appreciable effect on the level. This level of the fluid in hydro-pneumothorax remains horizontal in every position and changes freely with every position of the thorax or movement of the body. Thus the rise and fall of the level corresponding to the respiratory movements, the undulations synchronous with the systole and diastole of the heart, the agitation of its surface when the chest is percussed or during coughing, and the waves produced by the more forcible succussion are all phenomena to be observed with the fluoroscopic screen. When considerable in amount the level of the effusion rises with inspiration and falls with expiration—a reversal of what should normally occur. This paradoxical condition

FIG. 7.—Complete collapse of lung prevented by numerous fibrous bands.

is due to the loss of tone of the diaphragm whose movements become altogether passive and follow the abdominal pressure changes. When the effusion occurs late, that is, after the collapsed lung has become airless, or if the condition is an old one, then

but two zones will be seen, an upper brilliant zone corresponding to the air and a lower dark zone corresponding to the fluid. The lung in these cases lies against the spinal column and its shadow merges with that of the mediastinum. This is the picture when the patient is examined in the upright position. In some cases it is neither feasible nor advisable to examine in the erect posture. It should

FIG. 8.—Collapse of right upper lobe only. The superior surface of the middle lobe is visible, bounded by the two linear shadows extending from the hilum to the lateral chest just below the pneumothorax.

be borne in mind, however, that when lying down, the fluid flows over the posterior wall of the chest, while the air rises above it. The picture now obtained is a little more difficult of interpretation. Instead of two sharply contrasted zones indicating the air and fluid, the entire chest is obscured by a light shadow, and it is only at the sides that the brilliant illumination due to the air is visible. The lung, however, still holds its position at the root.

4. Displacement of the heart and mediastinal contents—how are the mediastinal contents displaced and to what extent? Is an excessive strain brought to bear on the vessels? The displacement of the heart is not proportional to the amount of gas injected and varies with the same amount of gas. Though the displacement is marked immediately after injection, restitution quickly takes place. It is in pneumothorax due to pathological causes that most marked displacement is seen. The displacement is more marked when the left pleural cavity is injected and when effusion is added to the air. Under these circumstances there is also a rotation of the organ, so that the left ventricle lies more anteriorly. A dilatation of the pulmonary artery and left auricle may be noted. The circulation in the large vessels may be interfered with as a result of distortion, due to displacement.

Besides the displacement of the mediastinal structures, heart, vessels, trachea, etc., certain parts of the pleural septum are frequently displaced to a considerable degree. These are, so to speak, weak areas in the dividing pleural wall.* One is anterior, in the pleural fold between the sternum and large vessels above the arch of the aorta, and the other in that portion of the septum lying posteriorly between the heart and the spine. The displacement varies considerably in different individuals. The

*Nitsch: Die schwachen Stellen des Mediastinums. *Beitr. z. Kl. d. Tbk.*, Bd. 18.

importance of bearing this possibility in mind lies in the necessity of explaining the radiographic appearance of the upper and lower portions of the median shadow and of the pulmonic field in pneumothorax. A thin convex linear shadow enclosing an area of bright illumination may be seen encroaching on the upper or lower portion of the normal pulmonic field and representing this herniated pleural fold. Thus is also explained the encroachment of medium sized exudates, apparently across the median line into the normal pulmonic field. These simple pleural displacements have been erroneously diagnosed, particularly so in many published articles, as pneumopericardium, associated with artificial pneumothorax because of the localized area of bright illumination over the cardiac shadow.

5. The position and movement of the diaphragm—how and in what degree is the motion affected and limited, once retraction of the lung occurs? The movements of the diaphragm are inhibited and the dome becomes flattened and irregular when the lung is collapsed to a marked degree. In some cases the muscle appears to lose its tone and rises and falls paradoxically.

6. Subcutaneous emphysema. The extent of the subcutaneous emphysema may be studied radiographically. The air may be demonstrated not only underneath the skin but throughout the various fascial layers on both sides of the chest. It is as a rule rapidly absorbed.

7. Restitution—re-inflation. The absorption of a moderate amount of gas, 600 c.c., will take place in about two weeks. The outer brilliantly illuminated field gradually becomes fainter, smaller, and is last visible in the peripheral part of the pulmonic field as a narrow triangular strip.

8. Effect on disease. This should be studied from time to time and comparisons made. The healing by fibrosis takes place in cases wherever destructive lesions are present. Where simple infiltrated lesions existed the foci appear smaller, show areas of calcification. The entire pulmonic field shows an illumination far less bright than the uncollapsed side and this appears to be maintained

FIG. 9.—Hydropneumothorax. Note the shadow of the compressed lung at apex of field. Below it the brilliantly illuminated area corresponding to the air in the pleural cavity and below this the horizontal upper border of the dense shadow of the fluid.

over a long period. The pulmonic markings are also apparently more numerous and clearer. This is perhaps due to an increase both in vascular content and fibrous tissue.

GASTROHYDRORRHEA IN CIRRHOSIS OF THE LIVER ACCOMPANIED BY PYLORIC STENOSIS.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

(From the German Hospital, New York.)

By the term "Gastrohydrorrhea" is meant the flow of a watery fluid from the stomach, containing neither hydrochloric acid nor the characteristic ferments.

I may be permitted to describe the case in which gastrohydrorrhea was most marked and first noticed.

Antonio C., about forty-two years old, consulted me August 31, 1915, for the first time. He then complained of vomiting small quantities of fluid, principally in the morning, anorexia, slight constipation, and great loss in weight, during the last six months about fifty pounds. He used to consume great quantities of alcoholic beverages, and had syphilis twenty years ago. The examination showed no abnormalities in the chest. The abdomen, likewise, failed to reveal any gross pathological changes. The stomach extended to the navel. The liver was not palpable. The urine contained no albumen nor sugar, but a considerable quantity of urobilinogen.

Based upon the symptoms and etiology, a tentative diagnosis of gastric catarrh (due to the abuse of alcohol) and beginning cirrhosis of the liver was made.

Patient was instructed not to partake of any alcoholic beverages, and to eat plain foods, avoiding much meat and highly seasoned substances. He was also given—

Extr. fluid Condurango,

Extr. fluid Quassia,

Extr. fluid Cascar. sagr. ãã 10,0.

M. Sig.: 20 drops t.i.d.

Patient (who lived in a distant country) then improved for quite a while (during the whole month of October, eating with impunity, without vomiting), when all of a sudden the old symptoms returned with greater severity. At the beginning of November he was seized with incessant vomiting. The attending physician instituted rectal feeding for about two weeks, but even then the vomiting persisted. Patient was then brought to the German Hospital and placed under my care.

November 15, 1915.—Patient is extremely emaciated and weak; he can hardly talk. His tongue is dry and reddish. Heart sounds are very weak, but no murmur is present.

The stomach is somewhat dilated, extending to one finger's width below the navel, and somewhat painful to pressure. No resistant mass can be discovered. Liver dullness is slightly diminished, extending merely to one inch above the right costal margin. The vomited matter contains no hydrochloric acid and is of a neutral reaction; blood is present, but no Oppler-Boas bacilli. Rennet is absent. The urine, spec. gravity 1,010, contains no albumin nor sugar but a great quantity of acetone.

On November 16, the stomach is emptied in the fasting condition, 75 c.c. being obtained; fluid looks dark-brown, containing a large quantity of mucus: Hcl = 0; Acidity = 18; lactic acid + trace; blood +; large amount of bacteria, mostly cocci; no sarcinae.

The duodenal bucket, given with atropin, did not pass the pylorus. Stool not formed, dark brown, contains a considerable quantity of mucus; occult blood, present.

Blood—hemoglobin, 80 per cent.

Red blood corpuscles, 5,000,000.

White blood corpuscles, 12,600.

Polynucl., 77 per cent.

Lymphocyt., 21 per cent.

Transitional, 1 per cent.

Eosinoph., 1 per cent.

Patient complains of great weakness and vomits almost constantly. The diagnosis at present appeared to be severe gastritis with multiple erosions, stricture of the pylorus (with the possibility of malignancy), and cirrhosis of the liver. The patient was given—

R Menthol 1,0.

Spirit. Vin. 50,0.

Aq. dest. 120,0.

Syr. Zingib. 30,0.

M. Sig.: One tablespoonful, t.i.d.

and placed on the following régime: one ounce of either barley water or egg albumin water, alternating every hour by mouth; 1,000 c.c. glucose solution 6 per cent. by the Murphy drip per rectum twice daily; gastric lavage every morning in the fasting condition. Under this régime the urine increased and the tongue became moist. Patient felt somewhat easier; but the vomiting persisted. The quantity vomited always exceeded by far the ingested amount of fluid. Thus on the 19th of November the intake per os amounted to 540 c.c., while the quantity vomited was 1,310 c.c. In this vomited material there was no trace of gastric juice (reaction neutral or rather slightly alkaline), nor was there bile nor pancreatic juice. It always contained some blood and mucus, the blood at times macroscopically visible, at times found merely by chemical tests. Although a Wassermann test was negative, we decided to apply antisyphilitic treatment. Mercury salicylate was given subcutaneously, and potassium iodide per rectum.

Nutritive enemas were added to the glucose solution and for a time nothing was given by mouth for twenty-four hours, but the vomiting persisted, 1,500 c.c. being collected during that period. Patient gradually grew weaker, and notwithstanding gastric lavage and total abstinence of fluids by mouth kept on vomiting 1½ to 2 quarts daily of a watery mucous fluid, at times tinged with blood. November 24, the patient became irrational and also developed a slight rise in temperature. On November 25 he lost consciousness and died on November 27, without any additional new symptoms.

The autopsy was performed in my presence about five hours after the exitus by Dr. Humphreys, the pathologist of the German Hospital whose report I herewith submit.

"Anatomical Diagnosis: Carcinoma of the Pylorus and Stomach; Dilatation of the Stomach; Chronic Passive Congestion; Atrophic Cirrhosis of the Liver; Lobar Pneumonia. Body is that of an elderly man of large frame but much emaciated. The skin is pale and of a subicteroid tint. Rigor mortis is present. Post mortem lividity slight. Marked emaciation of face, trunk and limbs. One lymph node is palpable in the neck about the size of a hazlenut.

"Diaphragm: Fourth rib right side, fourth interspace left side.

"Peritoneal Cavity: The intestines are moderately ballooned with gas. The stomach is very markedly ballooned, crowding over beyond the line of the gall bladder. The serous surfaces are smooth and glistening throughout. The lesser omentum is shortened and thickened, and adherent to the pylorus. The bladder is distended with dark urine. The mesentery fat is slight in amount but not absent. On the surface of the mesentery are found numerous small reddened areas resembling petechia. The free border of the lumen is entirely invisible behind the border of the ribs.

"Pleura: Left pleura normal. Right pleura shows old adhesions posteriorly.

"Pericardium: Normal.

"Heart: Normal in general size and appearance. The valves and orifices are normal. Myocardium slightly pale, shows no areas of degeneration or fibrosis.

"Lungs: Both lungs show marked hypostatic congestion of the lower lobe. On the left side are found numerous small areas of consolidation of very recent origin, poorly marked off from the surrounding tissues as dark red spots. The lower lobes of both sides are edematous but show no pneumonia.

"The bronchi are moderately congested.

"Spleen: Somewhat enlarged measuring 12 by 7 by 4 cm. It is rather firm but friable in consistence. The capsule shows one or two areas of local thickening. The pulp is of a deep purplish red color, appears swollen. The stroma is still visible. Malpighian bodies are invisible.

"Liver: Much diminished in size, weighs 1,600 grams. The surface is coarsely granular and of a pale yellowish brown color. It cuts with resistance. The cut surface appears of a yellowish brown color, subdivided by fibrous tissue trabeculae into islands 3 or 4 mm. in diameter. The normal markings are completely obliterated. The gall-bladder appears normal excepting for adhesions on its outer surface; contains a small quantity of thick bile.

"Kidneys: About normal in size and consistence;

*Read at the annual meeting of the Association of American Physicians, Washington, May 12, 1916.

their capsules strip readily leaving a smooth rather deep red surface. On the left kidney near the hilus is a small cyst about 1.5 cm. in diameter filled with clear yellow fluid. On section the cortex appears moderately congested, slightly thickened but otherwise normal. The pelvis and ureters appear normal. The bladder

infiltration is exclusively through the connective tissue. The subserous fat tissue is also the seat of small groups of hyperchromatic cells of indefinite type. The mucosa is missing and there is little submucous tissue present. On careful inspection the infiltrating cells prove to be typical of gastric fibrocarcinoma. They are small poly-

FIG. 1.—Section through the gastric mucosa. The glands are destroyed to a great extent. Numerous infiltrating cells are noticeable, also, at places, surface defects of the mucosa. (Small magnification.)

shows one or two petechia on its surface but otherwise is normal.

"Pancreas: Somewhat small and firm but on section appears normal.

"Gastrointestinal Canal: Esophagus normal. Stomach immensely ballooned with gas, contains a small quantity of brownish fluid. At the pylorus is felt a hard tumor which apparently encircles the lumen. It measures about 3 cm. in all dimensions. The blade of a scissors can be run throughout it from the duodenum into the cavity of the stomach. On opening the organ the mucous membrane throughout the whole stomach is of a deep purplish red color. At the pylorus the wall is thickened, measuring about 1.5 cm. through. The mucosa at this point is ulcerated and eroded, but the floor of the ulceration appears clean. No metastases were found in the lymph nodes in the lesser or greater omentum. The duodenum is intensely congested similarly to the stomach. The small intestine less so. The large intestine is very markedly congested in the lower portion. Nowhere is there any ulceration. The aorta is rather narrow, shows a few deep atheromatous patches in its first portion. The abdominal portion appears normal."

A section of the pyloric tumor was submitted to Dr.

FIG. 2.—The Same as Fig. 1 under higher magnification.

James Ewing, who was kind enough to examine it. He reports as follows:

January 14, 1916.—"Report on Fibrocarcinoma of Pylorus. The pyloric muscle is infiltrated with somewhat indefinite cells which form an anastomosing net work dividing up the muscle bundles into large groups. The

FIG. 3.—Section through the pyloric tumor. The connective tissue of the pyloric muscle is infiltrated with small polyhedral cells forming an anastomosing network and dividing the muscle bundles into large groups. (Small magnification.)

hedral with compact hyper-chromatic nuclei and opaque acidophile cytoplasm. Many of them show large mucous globules which may occupy the whole cell, pushing the nucleus to one side in crescent form. In several foci, especially in the fat tissue, there is definite formation of small alveoli lined by cuboidal epithelium. These appearances are characteristic of this type of gastric carcinoma. In wider extent they appear in the lesions known as linitis plastica."

I am indebted to both Dr. Humphreys and Dr. Ewing for their kind reports.

To illustrate the state of the gastric mucosa, which was extremely congested and inflamed throughout and eroded all over, and the thickened pylorus, we give the following four drawings:

Epicrisis.—In considering the clinical picture of the disease, which consisted of a severe gastritis with pyloric obstruction and the last stages of cirrhosis of the liver, the following features are

FIG. 4.—Same as Fig. 1. In the center, a group of four cells are noticeable in which large mucous globules occupy the whole cell, pushing the nucleus to one side in crescent form. (Large magnification.)

somewhat out of the ordinary and demand our attention:

1. The vomiting greatly exceeded the quantity ingested and persisted even when nothing was taken by the stomach. It contained neither HCl nor bile.

2. In this extremely emaciated man, who had lost over 70 or 80 pounds, the blood picture a few days before death shows 80 per cent hemoglobin and over 5,000,000 blood corpuscles.

3. Notwithstanding the high degree of liver cirrhosis, there was no trace of ascites found in the abdominal cavity.

Vomiting in excess of fluids ingested is encountered off and on. It is either due to hypersecretion of gastric juice or to a regurgitation of bile and intestinal juices into the stomach. In the case before us, however, neither of the two factors played a part. There was no ordinary gastric secretion present, as evidenced by the absence of HCl and the ferments, nor bile nor intestinal juice, as shown by the lack of biliary pigment or pancreatic ferment. Besides, the pylorus was stenosed to such a degree that nothing could enter or leave the stomach through this outlet. The vomitus was a watery fluid mixed with mucus, frequently tinged with blood, of slightly alkaline reaction. The characters of ordinary gastric secretion being absent in this fluid, it

The regulatory arrangement of the organism can bring temporary relief by emitting some of the congested fluid in the circulatory apparatus of the stomach through the walls of the latter into its cavity. Or there will be an exudation of fluid into the stomach, very much on the same order as the ascitic fluid in the peritoneal cavity in ordinary cases of cirrhosis of the liver without pyloric obstruction.

The process described appears to have happened in the case before us. The fluid exuded in the stomach, was no gastric secretion, but rather a transudate. Accumulating in this organ and not being able to pass the pylorus, the liquid was then vomited.

The origin of the fluid explains in a satisfactory manner the two other anomalies here, namely, the absence of ascites and the good condition of the blood. The ascites was missing, as the act of liberating congestion took place in the stomach. The blood showed an almost normal amount of red blood cells, as the superfluous fluid was constantly drained off through the gastric walls.

In the case before us, in which gastric secretion was entirely missing, the gastrohydrorrhea was easily recognized. There is no doubt, however, that in other cases of cirrhosis of the liver accompanied by pyloric obstruction a similar transudation into the stomach or a gastrohydrorrhea takes place. The fluid, however, being mixed with gastric juice will not be easily recognized in its true light.

The following case I have recently observed will illustrate this point, also the relationship of pyloric stenosis and cirrhosis of the liver to the place of transudation (stomach, or peritoneal cavity). The case is briefly as follows:

FIG. 5.—The celiac artery and its branches.

appears to me that we may explain the latter (gastrohydrorrhea) as an exudate due to the extreme congestion and accumulation of blood in the circulatory apparatus of the stomach.

For the development of hyperemia and extreme venous congestion in the latter organ, the conditions here were particularly favorable. If we take into consideration the intimate relationship between stomach and liver with regard to their blood supply, abnormalities in the liver will easily affect the stomach. This the more so as they both derive their inflow of blood from one and the same trunk artery, the "celiac."

In cirrhosis of the liver the connective tissue constricts the acini and also the arterioles with the result that the blood does not find an easy access here. It is dammed back and in consequence the blood from the celiac artery, instead of flowing into the hepatic artery which is already overfilled, enters in more abundant quantity the vessels supplying the stomach. In a similar manner, in complete pyloric stenosis, when the small intestine is empty and cut short from its work, the blood supply there will naturally be at a low ebb, and in consequence there will be a more active circulation in the blood vessels situated higher up, namely, in the celiac artery and more particularly the gastric arteries. The venous supply of the stomach, on account of the difficulty of reaching the liver through the clogged up portal vein, will likewise be overfilled—in the case before us—almost to bursting.

November 30, 1915.—Thomas M., about fifty-three years old, was always well until about a year ago, when he commenced to complain of fulness in the abdomen and slight nausea. Patient used to partake liberally of alcoholic beverages and smoked considerably. For the last five months there was vomiting, at first occasionally, and during the last two months almost constantly. The vomited matter in twenty-four hours frequently exceeded in quantity the total amount of ingested substances in the same period of time.

The examination showed an extremely dilated stomach (extending to the *symphysis*) with active peristalsis visible. There was constant isochymia: HCl +, acidity = 40, much mucus. The liver dulness ceased three fourths of an inch above the right costal margin. Patient complained of great weakness, thirst, and vomiting. The duodenal bucket failed to pass the pylorus. The diagnosis of cirrhosis of the liver and obstruction of the pylorus—probably of a benign type—was made.

Patient was put on rectoclysis and no fluids given by mouth. Although the stomach was washed out daily, vomiting of a watery fluid, containing HCl and showing an acidity of about 30, was a constant feature. The whole quantity of ejected fluid would amount to one and one-half to two quarts daily. Apparently nothing could pass the pylorus. Patient had meanwhile lost over 80 pounds in weight. A surgical operation, although considered of great risk, had to be undertaken and was performed in my presence by Dr. Willy Meyer on December 8, 1915.

The pylorus was found completely stenosed, presenting an even swelling of thumb-size for one to one and a half inches; no swollen glands were found. A gastroenterostomy was then established. After the operation patient did badly for about four days, continuing to vomit. Lavage was again instituted with great benefit. Nourishment was then given in small quantities and retained. December 16, diarrhea set in; patient, however, felt better and picked up in strength and general well being. On December 24 ascites was observed in the abdominal cavity. Patient continued to gain in strength and weight, although the fluid in the abdomen likewise slowly progressed. Calomel and diuretin were

given in order to hold the ascites in check. It never entirely disappeared, although there was considerable improvement in the condition of the patient.

The noticeable features in this case are: before the operation when vomiting was incessant there was no ascites. After the operation, as soon as the gastroenterostomy opening put the intestinal tract into activity, ascites appeared, and there was no more vomiting.

The explanation here again is satisfactory if we assume that during the period of pyloric obstruction the vomited fluid relieved the congestion and was to a great extent in the nature of a transudate. As soon as the gastroenterostomy established the activity in the intestines, the venous congestion was overcome by exudation of the dammed back fluid through the intestine and omentum into the peritoneal cavity.

The frequent occurrence of vomiting in chronic alcoholic gastritis with cirrhosis of the liver (vomitus matutinus) may be due in part to a similar regulatory mechanism. The vomited matter would then represent to a certain extent transuded fluid and indicate a beginning faulty portal circulation.

20 EAST SIXTY-THIRD STREET.

OSTEOCHONDROFIBROMA, OR OSTEITIS FIBROSA.

WITH THE REPORT OF A CASE.

By V. P. GIBNEY, M.D.,
NEW YORK.

At a meeting of the Society in December, 1913, I presented a specimen from an operation on a case of what was regarded at that time as Osteitis Fibrosa, involving the upper end of the femur (MEDICAL RECORD, Feb. 7, 1914). This report was based upon the findings of the pathologist to the Hospital for the Ruptured and Crippled, Dr. Jeffries. The section referred to him was taken from a wedged-shaped piece of bone from the neck of the femur, the gross specimen as shown by the x-ray (Fig. 1). The operation was done through the middle of this mass, and our pathologist reported as follows: "Bone and cartilage both exhibit inflammatory changes the etiology of which does not appear. No neoplasm was observed on section cut. One bit is a portion of perichondrium."

Dr. George Barrie of the hospital staff was present and secured a section from the upper portion of the wedge and submitted it to Dr. O. S. Hillman, who reported as follows: "Microscopic examination shows the tumor to be made up of a frame work of cellular fibroblastic with rather delicate bone trabeculae embedded in it and circumscribed areas of cartilage. The growth is covered by a fairly dense connective-tissue capsule; only a moderate number of blood vessels are seen throughout the fibrous portion of the mass. No definite evidence of malignancy can be detected. The growth is essentially an osteochondrofibroma."

Since my report of the case before the Practitioners' Society in 1913 there has arisen more or less discussion in the hospital as to the nature of this growth. At the time of the first operation it was a question whether it was a sarcoma or a benign tumor, but this question was soon settled by both of the pathologists. From my own study of the case with a reference to similar ones reported by Hirschberg in 1889, von Recklinghausen in 1891, Bloodgood in 1910, Silver in 1911, and Freiberg in 1912, I was persistent in my original diagnosis of osteitis fibrosa. I find, however, that some of my

*Presented at a meeting of Practitioners' Society, Feb. 4, 1916.

colleagues, including Dr. Barrie, adhere to the one which heads the title of this paper. Neither one is regarded as malignant, and both occur as a rule in early life.

The latter is regarded as congenital, yet the his-

FIG. 1.—The radiograph of the case in 1913 just prior to the first operation.

tory of the case I am about to present does not furnish conclusive evidence.

CASE.—A boy was admitted to the Hospital for Ruptured and Crippled November 13, 1913. He was born and brought up in the country and, but for lameness involving the left hip, was always regarded as healthy and well nourished. The mother gave the history for our record that the boy was not lame until he was two years of age. Barrie learned from a neighbor that there was some defect about the hip at the time of birth, but this has not been confirmed. During the nine or ten years prior to his admission to the hospital he was treated for hip disease of the quiet type, and until we secured the x-ray the case was regarded as one of hip disease or sarcoma. Examination in the ward revealed a deformity just over the left hip simulating a

FIG. 2.—The case as shown March 30, 1914, after second operation.

tumor, range of motion over very nearly the normal in flexion and extension, but adduction and abduction were limited to about one-half the normal range; there was about 1 inch shortening and only a moderate amount of atrophy. The details of the routine examination are not given and the presumption is that there was no involvement of the leg, for the reason that I personally examine and dictate notes of all the orthopedic cases, when on duty, coming into the hospital with

rarely an exception, and this case I remember very well. I did not discover any lesion below the knee or I should have made a record of same. Shortly after admission an incision was made over this mass and a large cauliflower growth involving the femoral neck and part of the head came into view (see Fig. 1).

FIG. 3.—Cross-section of lesion shown in Fig. 1. (From the *Annals of Surgery*, Feb., 1915.)

A wedge-shaped portion was removed and the limb brought into abduction, closing the space from which the wedge was removed. The wound healed promptly, and on March 30, 1914, an x-ray was taken showing the growth much smaller (see Fig. 2) and apparently undergoing resolution rather than further involvement of the shaft. The second operation was on April 7, 1914, and more of the tissue was removed, while an osteotomy was done below the trochanter minor to correct the deformity. It is to be regretted that x-rays of the entire skeleton were not taken either in November or during the succeeding six months. The order was given on one or two occasions, but for some reason, such as the machine being out of order, the plates were not taken. No note was made during his residence in hospital for the first six months of any growth on his leg, and the presumption is there was no growth, for the reason that our routine examinations are made every month and are very thorough so far as the size of the limbs and the function of the joints go. It was not until a readmission to the hospital on March 12, 1915, that any involvement of the fibula of the same side was noted. An x-ray taken August 12, 1914, showed an involvement of the upper extremity of the

FIG. 4. The femur after the second operation, which included the osteotomy, taken a year later.

femur for at least 3 inches, and at this time only the femur was x-rayed. On March 16, 1915, a long incision was made over the mass of the left fibula and a large portion of it removed with a curette and chisel; this was cartilaginous in substance and the pathologist reported chondroma, with extensively calcified

areas and some cellular connective-tissue, but no signs of highly malignant process. The wound healed without incident and the boy continued to wear his brace, permitting motion at the knee joint. He was discharged July 19 and readmitted for the second time on January 28, 1916, merely for observation and for repair of his brace, x-rays have been taken of all the bony structures, including the spinal column and ribs, the bones of upper extremity, the lower extremities, and also of the feet; all of the plates are quite free of any lesion except those showing the hip and upper portion of the femur (see Fig. 4) and those showing the fibula on the left side (Fig. 5). In one x-ray it would seem that the astragalus and os calcis are involved, and the clinical signs rather confirm this suspicion. An x-ray of the entire foot does not show any involvement of these bones. If the fibula was not involved prior to 1915, then the metaplasia has extended; if, however, it was present at the date of the boy's first admission to the hospital, then there has been no progress of the case. The boy is quite active, his general health is excellent, and I have resisted the appeals of some of my colleagues to resect the fibula.

The argument presented for this procedure is a good one, namely, that a benign tumor may at any

FIG. 5. A. The fibula, same side, as shown prior to operation in 1913. B. The fibula as shown January 31, 1916, nearly a year after the operation.

time develop into a malignant one, but Dr. William B. Coley, one of my colleagues whose opinion where malignancy is involved is most valuable, advises against resection. R. C. Elmslee, in the *British Medical Journal* for November, 1912, reports a case occurring in the practice of Mr. Lawford Knaggs that lasted from adolescence up to the fifty-third year, and then a sarcoma developed in one of the affected bones and he comments as follows: "An instance apparently of an abnormal tissue in a state of ill-regulated activity which continues in this condition for many years and shows no tendency to cure."

The case which I have just reported is still under observation, and with an apparatus which protects the hip and knee the boy walks very well. His general health is excellent. Personally, I believe an incision could be made and any redundant overgrowth of this tissue could be shaved away without impairing the strength of the bone or the function of the joint, but believing as I do in the non-malignancy of the lesion, I am content to refrain from further operative interference.

The title of the paper simply illustrates my willingness to accept Dr. Barrie's view of the case and by courtesy give it precedence over my own.

5 PARK AVENUE

COMPLETE CONGENITAL ATRESIA OF THE ILEUM.

BY ROYALE HAMILTON FOWLER, M.D.

BROOKLYN-NEW YORK.

ASSOCIATE SURGEON, GREENPOINT HOSPITAL.

BABY T. was born in the Greenpoint Hospital, service of Dr. F. C. Holden, March 21, 1916. The delivery was normal and easy, no forceps. Weight at birth about seven pounds.

Vomiting commenced about fifteen minutes after birth. Vomitus was green, flaky, and thick without special odor. It continued several times during the night and the following day. The abdomen was slightly distended and tense. No visible peristalsis, no masses seen or felt. No external congenital anomalies. The rectum easily admitted the little finger, no blood escaped or appeared on the gloved finger. No masses or obstruction felt. Genitalia normal.

March 22. Vomiting still continues, same character. A soap suds enema resulted in the return of a small amount of clear fluid. An intestinal cast was expelled from the rectum about six inches long and one-quarter inches in diameter, consisting of mucus and meconium. Later a colonic irrigation was given. Two ounces of fluid are said to have entered the rectum. A considerable amount of greenish black meconium was later found upon the diaper. Several gastric lavages showed the washings consisted of the same greenish material.

March 23. Vomiting persists, the abdomen is more distended. Consultation held, operation advised for intestinal obstruction. Preoperative diagnosis: Complete

atresia of the duodenum or hypertrophic pyloric congenital stenosis. Neither of these quite explained the fact that the obstruction appeared to be a low one in the small intestine.

Operation. (Dr. Fowler.) Age of patient, 27 hours. Right rectus incision. A large amount of thin serous fluid escaped on opening the peritoneum. Small intestine presented. It was of dark color and distended six times the diameter of the neighboring loops. This distended loop of gut literally "popped" into the wound. It was blind and free, without fibrous cord connection. The mesentery down to its root was also lacking at this point. The gut above this point was less dilated than the blind pouch. The bladder was full, the stomach was distended. No stenosis or change in the pylorus. The duodenum was dilated slightly more than the commencing jejunum. In a hurried search the lower end of the ileum was not found. The appendix was normal. There was no persistence of the embryonal type of cecum. The latter was firmly attached to the posterior abdominal wall. The intestines were moderately congested. The upper free end of the small intestine was sutured to the abdominal wall and the abdominal wall closed in layers about the protruding gut. Enterostomy was then performed by the thermocautery.

March 24. Following the operation the pulse was weak, the baby cyanotic. Hypodermoclysis, two ounces given every two hours. Refuses to take the breast. Considerable brownish green discharge from the enterostomy. March 26, vomited several times during the

last two days. An abundant discharge continues from the enterostomy. Feet cold and clammy, has taken no nourishment. March 27, has continued to vomit, cyanosis more marked. Profuse discharge from the enterostomy. Patient died.

At autopsy the gastrointestinal tract was removed with its attachments to the posterior abdominal wall. It was preserved in Keiserling solution, and photographed both in black and white and by the Eastman method of color photography by Dr. Nathan Beers. In the photograph above is seen the lower edge of the liver—to the right the stomach and just below it the transverse colon. Below the stomach and to the right may be seen the upper jejunum, toward the left less dilated coils of jejunum ending in an enormously dilated blind end at the extreme left. Enterostomy was performed at this point. (This dilated loop was left outside of the abdomen.) The less dilated coils of jejunum, shown below the liver, between the blind end at the left and the commencing jejunum at the right, show partial collapse and the efficacy of enterostomy. The lower blind end of the collapsed ileum is shown transfixed by a pin, below the smaller piece of cotton. The rectum is seen below on the right tied off with a piece of string. To the left of this immediately above the glass rod the appendix may be seen.

Total length of small intestine 56 inches. The ileum ends in a small blind pouch 22½ inches from the ileocecal valve, one-half inch in diameter. The wall of this is thickened and bulbous for a distance of ¾ of an inch. It is slightly curled upon itself. The segment distal to this cul-de-sac is patent. There is a defect in the mesentery at a point opposite the situation of the atresia of the ileum. The upper blind pouch ends at a point 33½ inches from the pylorus. It is very much dilated for a distance of six inches. The widest diameter of this portion is 1¼ inches. The duodenum has no mesentery, the cecum is located in the right iliac fossa, therefore rotation of the intestine has occurred. The ileocecal valve and the pyloric sphincter show no change. The liver, gall-bladder and ducts and stomach are apparently normal. There is an accessory spleen.

Dr. J. B. Boehm, resident surgeon at the Greenpoint Hospital, who has undertaken a careful search of the literature, reports that he was unable to find a similar case. A few cases of atresia of the lower ileum have been recorded, but none in this exact location. According to Treves, the average length of the small intestine at birth is nine feet, five inches. The length of the small intestine in the above case is 56 inches, and shows a shortening of four feet, eight inches.

250 JEFFERSON AVENUE.

CARCINOMA OF THE ESOPHAGUS PERFORATING INTO THE RIGHT BRONCHUS.*

BY JOHN GUTTMAN, M.D.,

AND

I. W. HELD, M.D.,

NEW YORK.

CARCINOMA of the esophagus, according to Kraus and Ridder,¹ forms 5 to 7 per cent. of all carcinomata encountered in man, and occupies about the fourth place in frequency. Carcinoma is most commonly found in the stomach, next in the uterus, next in the breast, and next in frequency in the esophagus.

In about 50 per cent. of the cases, carcinoma of the esophagus breaks through the walls of the esophagus into the neighboring cavities, into the mediastinum, the heart, the blood-vessels, or the bronchi. While perforation of the carcinoma of the esophagus into the air passages is not very rare the diagnosis of such perforation *intra vitam* is quite rare.

The following case is of sufficient interest to justify its publication:

*Presented at the Section of Laryngology and Rhinology of the N. Y. Academy of Medicine, February 22, 1916.

S. E., sixty years of age, has been suffering from slight digestive disturbances and constipation for the last ten years. His present illness began at the end of September, 1915, when he began to cough and expectorate sputum streaked with blood. An examination by his family physician, Dr. Lesser, revealed a temperature of 101° F. and dullness, with moist rales in the supraclavicular and infraclavicular region of his right lung. The diagnosis of pulmonary tuberculosis was made, and he was sent to the mountains for rest and recuperation. After a four weeks' sojourn in the mountains at the end of October, he returned to the city much improved. In the middle of November, although not complaining of anything in particular, he was re-examined by his family physician, who then found his temperature to be 102° with the same physical signs in his chest as in September. The patient was directed to go home immediately, and to stay in bed. On his way home he was suddenly seized with a severe hemorrhage, so that an ambulance had to be called and he was removed to the hospital. There tuberculosis of the lungs was also diagnosed. Repeated sputum examinations, however, proved to be negative, and suspicion arose as to the possibility of the condition being a sarcoma of the lungs. An x-ray picture was taken; this showed a marked shadow in his upper right lung. A second radiograph a few days later showed the shadow to be much smaller, while a third exposure a week later did not show any shadow at all. It was therefore thought that the shadow was produced by a hemorrhage in the lungs, which had at this time been absorbed. The patient was thereupon discharged from the hospital as perfectly cured. At the end of December, about two weeks after his discharge from the hospital, he began to complain of cough after swallowing liquids, and shortly thereafter regurgitation of the ingested fluid with copious mucus set in. His family physician then sent the patient to one of us (Dr. G.) to find out whether such symptoms would be produced by tuberculous glands, or by tuberculous laryngitis. The examination of the mouth, pharynx, and larynx proved negative. Bronchoscopy under local anesthesia revealed no pathological condition. During esophagoscopy, however, at a distance of about 10 inches from the teeth we encountered a sudden resistance. The walls of the esophagus appeared smooth, but rigid and infiltrated, and in only one spot a small erosion was visible, which was attributed at that time to trauma induced by passage of the instrument. The lumen of the esophagus appeared narrowed down to a slit. We then withdrew the esophagoscope, and introduced a bougie. This also met with resistance at about the same distance, but by using slight force we were enabled to force the bougie through the narrow slit. On these findings we (Dr. G.) established diagnosis of a neoplasm of the esophagus and sent the patient to Dr. H. for fluoroscopic examination. The fluoroscopic examination was first made of the chest both in the ventro

cardiac space to be absolutely clear. The findings of this examination proved the absence of tuberculous affection of the lungs, mediastinal tumors, or aneurysm of the aorta.

A contrast emulsion, as first advocated by I. S. Hirsch, which consists of one tablespoonful of bismuth

FIG. 2.—Another view of the dilated esophagus and the bronchi

subcarbonate to which enough mucilage of acacia is added until a cream-like emulsion is formed, was now given to the patient. The contrast substance reaching a point on the esophagus opposite the bifurcation of the trachea stopped dilating the esophagus above. Part of the food was seen dribbling down into the bronchi, and only a very thin streak was seen below the esophageal obstruction. The patient coughed almost instantaneously as the food was seen to dribble down into the bronchi.

Figure 1 shows the dilated esophagus above the obstruction and the bronchi filled with the contrast substance. Figure 2 shows the same condition but magnified.

Figure 2 was taken in the position first described by Held and Gross (9), which consists of placing the patient with the back to the screen and the face to the tube; then his left shoulder is rotated gradually anteriorly until a light zone is seen between the spine posteriorly and heart and blood vessels anteriorly. When the patient now swallows the contrast substance, the entire course of the esophagus from mouth to entrance into the stomach, is seen. It is true that the esophagus viewed in this position shows a somewhat less distinct shadow, but we find that this can be overcome by giving the patient a more concentrated form of the contrast substance.

This at once cleared up the whole pathological condition. Now it became evident that the patient was suffering from a stenosis of the esophagus, caused in all probability by a neoplasm, with a fistulous communication with the first bronchus.

Three weeks later, on January 22, the patient died; no autopsy could be obtained.

The interesting features in this case are as follows:

(1) The onset of the disease appeared to be at the end of September, 1915, four months before the patient's death. The primary cause of his death, the carcinoma of the esophagus, had probably existed for a long time without giving practically any symptoms whatever. There was no dysphagia, no vomiting, no *fetor ex ore*, etc., up to within a short period before his death. Price and Gibb² and J. G. Emanuel³ have reported several cases of broncho-esophageal fistula, with a complete absence of the usual symptoms.

(2) The fistulous communication between esophagus and bronchus had existed for some time. As a result of this food particles passed from the former into the latter and in the course of time gave rise to bronchiectasis. The important rôle that foreign bodies play in the pathogenesis of the bronchiectasis is too well known to necessitate further re-

FIG. 1.—Dilated esophagus and bronchi filled with contrast material.

dorsal and dorso ventral position. The apices of the lungs were found to be perfectly clear. The shadow of the aorta normal, only the base of the right lung showed a distinct bronchiectasis. Fluoroscopy with the patient's right shoulder to the screen and left to the tube (first diagonal position) showed the retro-

marks. The bronchiectasis (positive evidence of which was furnished by the Roentgen examination) gave rise to small pulmonary hemorrhages and to the cough, thus obscuring the clinical picture by simulating tuberculosis.

(3) The absence of pain and the comparative euphoria at a fever temperature of 101° and 102° Fahr. is interesting.

(4) The choking and coughing spells when the patient attempted to drink is, in our opinion, one of the most characteristic symptoms of esophago-bronchial communication.

The examination with the esophagoscope, which revealed the stenosis of the esophagus with the history of paroxysms of coughing while drinking should have established the diagnosis of esophago-bronchial fistula beyond a shadow of a doubt.

(5) The superficial erosion of the wall of the esophagus was observed by Hacker⁴ and others, and was considered by them, at the beginning, to be due to a trauma caused by the esophagoscope.

(6) The immense diagnostic value of the fluoroscope, which, in fact, visualizes the whole pathological condition.

(7) We could find in the literature but one other case of an esophagobronchial fistula produced by carcinoma, and diagnosed in a living patient, by esophagoscopy and fluoroscopy, and that case was reported by Horner;⁵ a case produced by syphilis was reported by Beebe,⁶ and another case of esophagobronchial fistula caused by congenital occlusion of the esophagus was published by Losee⁷ and Finkelstone and Ellis.⁸

(8) From the standpoint of differential diagnosis, the esophagoscopic picture could have been brought about by a compression from the outside, by an enlarged thyroid, by an aneurysm, by a tuberculous lymph gland, and by a mediastinal tumor. The history of the case, the age of the patient, and especially the fluoroscopic picture made the diagnosis so positive that even a post-mortem examination while desirable was not absolutely essential for diagnostic purposes.

60 ST. MARK'S PLACE AND 3 EAST EIGHTY-FOURTH STREET

CONGENITAL ELEVATION OF THE SCAPULA.*

BY SAMUEL COHEN, M.D.,

NEW YORK.

CONGENITAL elevation of the scapula, originally described by Eulenberg¹ in 1863, consists in an upward displacement of the scapula. The condition may be unilateral or bilateral. Changes in the shape and size of the bone have been found. Associated with the deformed scapula there are one or more other anatomical defects.

The case herein reported is of extreme interest because it combines many of the phenomena found

*A case presented before the Society of Alumni of Lebanon Hospital, March 7, 1916.

separately in cases of congenital elevation of the scapula.

The patient is a boy fourteen years of age. He presented himself originally in the Surgical Department at the Lebanon Hospital Dispensary with a Colles' fracture. His family history, as far as that could be obtained, is negative.* When he was a year old an operation upon his neck was advised; but for some reason that was not performed. The boy himself remembers that at one time his head was held very much awry. It has assumed a more and more vertical position and now it is fairly straight.

The accompanying photograph shows distinctly the deformed scapula and most of the associated conditions. The left scapula lies on a higher level than the right. The upper inner angle of this bone lies above the level of the clavicle, it appears in the supraclavicular space and it is four centimeters higher than the same angle of the right scapula. The upper inner angle of the left scapula, too, is slightly farther away from the midline than the same angle of the right scapula, and slightly farther away from the midline than the lower angle of the same scapula. The vertebral border of the left scapula, therefore, instead of being parallel to the midline, as it should be, is at an angle to it. The whole left scapula, therefore, is rotated on an anteroposterior

axis. The deformed scapula, also, is rotated in the opposite direction, making the lower angle more prominent than it should be, more prominent than the same angle of the right scapula. The upper inner angle of the left scapula is slightly more rounded than normally. In shape otherwise and in size the two scapulae are practically alike and normal. The movements of the left shoulder joint are not interfered with in any way.

The left trapezius muscle is deficient, making the left side of the neck, posteriorly, shorter than the right. There is a distinct cranial asymmetry. On the front of the body there is noted a distinct facial asymmetry; the features on the left side are less prominent than those on the right. There is a torticollis; the left sternomastoid is shorter than the right. The left pectoral muscles are probably deficient, as is evidenced by the displaced nipple which is higher and nearer the sternum than its fellow. At the bottom of the sternum on the left side an exostosis can be distinctly felt.

The radiograph shows a scoliosis in the upper dorsal region of the spine, not toward the deformed scapula, but away from it. It also shows an elevation of the ribs on the affected side.

While this deformity was at first considered to

*The full photographs of fourteen members of the family were shown to the writer; these indicated no abnormalities.

be due to intrauterine causes, subsequent observation and study point toward hereditary influences. Neuhof² found a familial type of this affection. It seems that further observation is still necessary in order to verify or change the present conclusions.

The writer wishes to express his indebtedness to Dr. Charles Herrman and to Dr. L. M. Kahn for their valuable suggestions; also to Dr. Jacob Bower and Dr. K. Matthews for the excellent radiographic findings.

981 SIMPSON STREET.

IS MYOPATHY RELATED TO DISORDERS OF INTERNAL SECRETIONS?

By GRAYSON PREVOST MCCOUCH, M.D.,

UNIVERSITY HOSPITAL,

AND

S. D. W. LUDLUM, M.D.,

PHILADELPHIA.

(From the Neurological Department of the Medical School of the University of Pennsylvania.)

THIS paper aims to review what is known of the relations of myopathy and of other muscular disorders with which it is frequently associated to disturbances of internal secretion; to report a case of facio-scapulo-humeral type, associated with dystrophia adiposa genitalis, and to present the results of Abderhalden tests in a series of cases.

Related Muscular Conditions.—In discussing the etiology of progressive muscular dystrophy, the consideration of other apparently related muscular affections may prove of value. Various writers have indicated a probable association of myotonia congenita, amyotonia congenita, and myasthenia gravis with disorders of internal secretion. It is an open question whether amyotonia congenita is not identical with the simple atrophic type of progressive muscular dystrophy.¹ The coincidence of myotonia and myopathy is so common that it has been recognized as a distinct type, myotonia atrophica. Oppenheim,² Marburg,³ Foerster,⁴ and others have commented on the large proportion of cases in which myasthenia is combined with muscular dystrophy.

Lundborg⁵ has suggested that myotonia and myasthenia may be due to excessive, perverted, or deficient secretion of the parathyroid glands. After summarizing the evidence of the hypoparathyroid nature of tetany, he calls attention to the frequent coincidence of myotonia congenita and tetany, and to the resemblance of the clinical picture of paralysis agitans, on the one hand, to that of parathyroidectomized animals, on the other, to that of myoclonia. He draws an analogy between the frequent coincidence of tetany and myxedema. He contrasts the clinical pictures of paralysis agitans and myasthenia gravis and recalls the frequent combination of myasthenia gravis and exophthalmic goiter. On these grounds he suggests a hypoparathyroid origin for tetany, paralysis agitans, myoclonia, and myotonia congenita, and a hyperparathyroid source of myasthenia gravis and periodic paralysis of the extremities. Chvostek, on the basis of the clinical

contrast between myasthenia and tetany, also regards myasthenia as due to hyperparathyroidism.⁶

With tetany, paralysis agitans, myoclonia, and periodic paralysis of the extremities, this paper is not concerned. It may be of interest, however, to review briefly the evidence for the endocrinous origin of the muscular conditions frequently associated with myopathy.

Myotonia Congenita.—The combination of myotonia with tetany is reported by Orzechowski in two cases of his own and twenty-three from the literature.⁶ Faltz⁸ states that thyroparathyroidectomized animals combine the symptoms of myotonia with those of tetany. He cites Hoffman's case in which the myotonic symptoms disappeared under thyroid treatment, but the tetanic symptoms persisted. Metabolic studies lend support to a possible relation to hypoparathyroidism since the calcium balance is negative in myotonia⁹ and also in all forms of tetany, including that following ablation of the parathyroids.¹⁰ Possibly the action of sodium salts, unchecked in the absence of the normal amount of calcium, may play a rôle, since perfusion of muscle with sodium salts is said to induce the myotonic reaction.¹¹ Other evidence suggestive of an endocrinous origin is the frequent occurrence in myotonia atrophica of impotence and testicular atrophy,¹² loss of hair, and cataract.¹³ Testicular atrophy and impotence and loss of hair lend support to the theory of thyroid deficiency;¹⁴ cataract may be related to the possible hypoparathyroidism, since it is a frequent complication in tetany¹⁵ and has been produced by Erdheim in rats by ablation of the parathyroids.¹⁶ Such evidence is suggestive though it by no means proves the thyroparathyroprævic nature of myotonia.

Myasthenia Gravis.—In the case of myasthenia gravis there is no support for the hyperparathyroid view of Chvostek and Lundborg beyond the contrast of the clinical picture to those of tetany and myotonia, and the frequent association with exophthalmic goiter. On the other hand, Tobias has reported a case of myasthenia with tetany.¹⁷ Habersfield has shown that many cases of hypertrophy and cases of tumor of the parathyroids have no myasthenic symptoms; and, in two cases of myasthenia, no anatomical changes significant of excessive or perverted function were demonstrable in the parathyroids.¹⁸ Finally, Biedl's dogs with parathyroids implanted in their spleens showed no myasthenic symptoms.¹⁹

For the part played by the thyroid there is more to be said. Drinker and Drinker²⁰ sum the subject as follows: "Since 1877, when Wilkes reported the first case of myasthenia gravis, we find 197 recorded cases of pronounced complication of the two conditions (myasthenia and exophthalmic goiter). If this were all we should still be in the realm of coincidence, but the fact that comparatively few nervous diseases, with the exception of hysteria, chorea, and paralysis agitans, complicate exophthalmic goiter and that many clinicians (Oppenheim, Bristowe, Ballet, Finlayson, Liebrecht, Rothmann, Marina, Camuset, Suckling, and others) have observed some of the symptoms of Graves' disease in profound cases of myasthenia gravis and vice versa, leads us rather forcibly to the idea of a closer connection. We can, therefore, as Goldflam expresses it, 'accept a certain relation between the two diseases, because the combination of asthenic palsy with prominent or mild symptoms of Basedow's disease occurs so often, rather than speak of

a mere coincidence of occurrence.' This is also the opinion of Oppenheim. Rennie has reported a rapidly fatal case of myasthenia gravis in a jockey who had been taking large quantities of thyroid to reduce his weight, but who presented no evidence of exophthalmic goiter.²¹ Drinker and Drinker found that extract of sheep thyroid has a depressing effect on the voluntary muscle of frogs. Similar extracts of thyroid from cases of exophthalmic goiter gave an equal amount of depression and irregularity in the strength of contractions.²⁰ Administration of thyroid gland or of extract of the posterior lobe of the hypophysis increases the elimination of calcium,²² an effect which is of interest in the light of Pemberton's finding of a negative calcium balance in myasthenia gravis.²³

Adrenalin, on the contrary, tends to restrict the output of calcium and increases that of sodium and potassium.²⁴ This observation accords with the rôle Sezary²⁵ assigns to adrenal insufficiency in the etiology of myasthenia gravis. There is much in the clinical picture to support this view. Many of the cardinal signs of adrenal asthenia occur in myasthenia. Low blood-pressure is the rule; pigmentation of the skin is noted in several cases; lumbar pain in one case, and beneficial effect from adrenal therapy in many cases. On the other hand, myasthenia differs from typical adrenal asthenia in its selective action on the muscles of the face and in the mobility of the symptoms. Both conditions are often associated with muscular atrophy, though in myasthenia this is not the rule. Experimental removal of the adrenals, or serious injury to them, induces gastrointestinal disturbances, low temperature, atrophy of muscles, marked emaciation, and death.²⁶ The secretion of epinephrin is stimulated by muscular exertion.²⁷ Adrenalin is rendered inactive by passing through muscle.²⁸ Oliver and Schaefer found that it has no effect on the latent period, but prolongs the period of contraction.²⁹ Dessy and Grandis exhausted the power of a muscle to react to stimuli transmitted by its motor nerve, and restored it for a time by injection of adrenalin into the circulation.³⁰ Trerotoli³¹ found that one milligram of adrenalin induces lengthening of the ergographic curve in man.*

Important as the involvement of thyroid and adrenal may be, neither has received so much attention as the thymus. Since Weigert³² reported persistent thymus with true thymic tissue, with epithelioid cells, Hassall's corpuscles and free blood supply, with collections of lymphoid cells penetrating the smaller veins (*Durchwucherung der kleinen Venen*) associated with similar collections of lymphoid tissue and occasional epithelial cells in the muscles, the view that myasthenia is due to a lymphosarcoma of the thymus with metastases to the muscles has been widely accepted. The finding of Hassall's corpuscles in the lymphocytic collections in the muscles³⁴ and the therapeutic result from thymectomy reported by Schumacher and Roth³⁵ accord with this theory. On the other hand, though the lymphocytic infiltration of the muscles has been found in almost all recent autopsies thymic enlargement has been noted in only about 28 per cent. of cases.³⁶ In a careful review of the literature since the publication of Weigert's findings, Marburg stated that three cases had thymic tumors, three others persistent thymus, and five

others normal thymus; that the liver is affected almost as often as the thymus, and the adrenals almost as often as the liver. In two cases he excised pieces from muscles, giving the myasthenic reaction. At first sight the fibers appeared normal. But sections stained by the Marchi method showed rows of fine fat droplets looking under low power like longitudinal muscle striations. Infiltration about the vessels consisted of lymphocytes, leucocytes, and a third element, almost wholly nuclear, oval in shape, frequently showing nuclear division. The presence of transitional forms between this third cell and sarcolemma nuclei incline Marburg to regard the oval elements as young sarcolemma nuclei. He considers the muscle infiltration as neither metastatic nor lymphorrhagic, but as a regenerative reaction to the degenerative process.³ In the light of Marburg's³⁷ findings, the disturbances of internal secretion may be regarded as secondary to the foci of degeneration and infiltration present in the ductless glands. Yet such a view fails to explain why the function of one gland is stimulated and that of another depressed.

Amyotonia Congenita.—Of the etiology of amyotonia congenita even less is known. Berti³⁸ has suggested a relationship with subcretinism or submyxedema. Spiller and Smith⁴⁰ found sclerosis of the thymus and Boudouin⁴¹ sclerosis of thymus, thyroid, and spleen. But in Rothmann's case⁴² the thymus was enlarged and Hassall's corpuscles strongly developed. Adrenal,⁴³ thyroid,⁴⁴ and hypophyseal⁴⁵ therapy have all been credited with beneficial results. Yet it must be remembered that the condition tends to improve spontaneously. Thymectomy in young dogs produces muscular changes akin to those of both amyotonia and myopathy. According to Matti,⁴⁶ there is outspoken atrophy, pallor, and fatty infiltration of the muscles. The fibers range from fifteen to thirty microns in diameter compared with forty-five to seventy-five in the controls. Transverse striation is absent in places, though longitudinal striation is well developed. Some fibers are swollen and the sarcoplasm stains poorly in certain fields. There is a relative increase of connective tissue and an absolute increase of fat growing between the fibers, and of both muscle and connective tissue nuclei. The picture differs from that of amyotonia or of myopathy in the absence of large stretches where all fibers have disappeared, of high grade increase in the nuclei of the perimysium internum, of round cell infiltration, and of extensive growth of fat.

Myopathy.—In the closely related condition, muscular dystrophy, the evidence of secretory trouble is even more doubtful. In commenting on the occurrence of Miculicz's disease in myopathy, Spiller¹ says, "A relation of myopathy in some of its types to glandular disturbance possibly may be fully established some day. It is remarkable that in a case of the juvenile type of muscular atrophy reported by J. Mitchell Clarke,⁴⁷ there was simultaneous enlargement of the parotid glands. The submaxillary glands were slightly enlarged. This suggests the case of Schoenborn,⁴⁸ in which all the salivary glands were enlarged and at the same time there was hypertrophy of all the muscles of the body. Schoenborn thought the case was one of myopathy of toxic nature, possibly from glandular disturbance. Schlesinger⁴⁹ has reported a case associated with myxedema, and Rossolimo⁴⁹ obtained improve-

*In contradiction to Sezary's view is Marinesco's case,²² in which the glandular condition found at autopsy indicated hyperadrenalism.

³Buzzard³⁸ regards these infiltrations as lymphorrhages.

ment from thyroid preparation in one case. Falta⁴⁰ had a case with infantilism in which there was cryptorchism, palpable thyroid, and a broad tongue suggestive of myxedema. The case did not respond to thyroid medication. Marinesco⁴¹ found no benefit from thymus extract. Ballet-Delherm⁴² observed the combination with scleroderma. Claude⁴³ reported a case with assymetric distribution of atrophy, deficient development of bone in the extremity most severely affected, and vasomotor disorders. In another case⁴⁴ he noted the association of the facio-scapulo-humeral type, the peroneal neuritic type, and acromegaly fruste. Clarke and Atwood⁴⁵ found an enchondroma of the hypophysis. Foerster⁴⁶ speaks of the frequency of adiposity and of high sugar tolerance. One of his cases showed a lipoma of the brain at autopsy, and another was complicated with dystrophia adiposo genitalis. Another case combined with Froelich's disease occurred on Dr. Spiller's service at the University Hospital in the winter of 1914-1915. Dr. Spiller discussed the case briefly at the meeting of the American Neurological Society in June, 1915. Through his kindness, I am able to report it more fully here:

L. H., a single white woman, thirty-five years of age, was admitted to the hospital December 1, 1914, complaining of weakness in the legs. There are no other cases of myopathy in the family. There are four brothers and three sisters, all of whom are stout. The patient has never been able to wrinkle her forehead or frown. When eleven years old she was told she did not laugh as others do. She could not run as fast as other girls and could not dance, but noticed no marked weakness until her fifteenth year, when she developed a gradually increasing difficulty in rising from a stooping posture, which she accomplished only by prying herself up with her hands, claspng first her feet, then her legs, then her knees, and thus pushing her trunk into the erect position. By her eighteenth year she could no longer climb the stairs without bracing herself on the bannisters. Since her thirtieth year she has not been able to go up stairs alone. At this time she first noticed difficulty in raising her arms. Since her thirty-fourth year (one year prior to admission) she has been unable to walk or even stand unsupported.

She has never menstruated, though she has had headaches, left-sided abdominal pain, and aching of the back and thighs once a month since she was sixteen years old. The patient states that at sixteen she weighed 86 pounds. When twenty-one she began to grow stout, a tendency which has gradually increased. She now weighs 165 pounds. There are no gastrointestinal, pulmonary, or renal symptoms.

The patient is an exceedingly fat woman of good bony frame. There is slight cyanosis of the fingers. The pulses are synchronous and of fair volume. The systolic blood pressure is 145; the diastolic 95 mm. Hg. The ears are large and protruding. The bridge of the nose is flat and somewhat saddle-shaped. There is external strabismus of the left eye. There is broken up cataract in both eyes. The pupils are irregular in shape. Reaction to light is slight in the right eye and absent in the left. Ocular movements are good in all directions. There is no nystagmus. There is slight lagging of the upper lids on looking downward.

The voice is deep, almost masculine. The teeth are badly shaped; there are several decayed roots. The forehead is smooth and shiny. There is slight enlargement of the thyroid, both lobes being palpable. The lungs are negative. The cardiac outline is normal; there is a soft systolic murmur at the mitral area and the second aortic sound is accentuated. The chest and abdomen show much subcutaneous fat. The breasts are underdeveloped, the areolæ small and lightly pigmented. Axillary and pubic hair is very scant. The hands are disproportionately small, the fingers delicate and tapering. On extension of the fingers there is marked hyper-extension at the metacarpophalangeal joints and slight hypo-extension at the interphalangeal joints.

The forehead cannot be wrinkled. The eyelids can be closed, but not tightly. The lips can be puckered

only slightly. Light pressure on the forehead suffices to make the head fall backward. There is winging outward of the scapulæ, and on lifting at the axillæ the shoulders hump up loosely. The rhomboids, trapezius, latissimus dorsi, and pectorals are atrophied. There is pseudohypertrophy of the infraspinati which are plump, rounded, and soft. There is marked atrophy of the thenar eminences. The grip is weak in both hands. There is marked lordosis which cannot be corrected by elevating the legs. The legs are weak, though the atrophy is masked by subcutaneous fat. The toes and ankles can be moved and the feet can be inverted but cannot be everted. There is slight talipes equinovarus. The biceps jerk is present in both arms. The triceps, radiocarpal, patellar, and Achillis jerks are absent. Tactile pain and temperature sensations are normal.

The electrical reactions taken by Dr. J. W. McConnell show responses to both faradic and galvanic currents reduced. There are no reactions of degeneration. Immediately following galvanic stimulation the posterior portion of the left deltoid remains in a condition of fine tremor.*

A skiagram showed marked enlargement of the sella turcica. A gynecological examination by Dr. Floyd Keen showed an infantile uterus. Sugar tolerance was tested by Dr. Alonzo Taylor. The patient was given 175 grams of glucose. The 24-hour specimen of urine contained 12 grams of glucose, no acetone or other ketone bodies, indicating that there was no increase in sugar tolerance. The Wassermann test was negative.

The patient was treated with electricity, massage, and during her last eight days in the hospital with 1 grain of extract of anterior lobe of pituitary daily. Her condition remained virtually unchanged, though she thinks she gained some strength during the latter part of her stay.

APPENDIX—TESTS

+ = Positive.
— = Negative.
± = Doubtful.
Two or 3 signs indicate that 2 or 3 tests were made.
*In the case of "H. V." there is some doubt about the diagnosis. Dr. Ludlum regards it as myopathy.
**In the case of "J. W." the diagnosis is questionable.

The case combines, therefore, the adiposity, the deficient development of both primary and secondary sexual characteristics, the small hands with tapering fingers, and the enlarged sella turcica of Froelich's disease with the distribution of atrophy and pseudohypertrophy, proportional muscular weakness, diminution, and, in some cases, total loss of tendon reflexes, and the diminished response to electrical stimuli without reactions of degeneration, characteristic of the facio-scapulo-humeral type of progressive muscular dystrophy. It also shows a common complication, cataract.

*Hoffmann⁴⁷ found in a case of Schultze's prolonged contraction of the flexor communis digitorum on direct galvanic stimulation.

A series of Abderhalden reactions was done by Dr. S. D. W. Ludlum in four cases of dystrophy, one of spinal progressive muscular atrophy, one of neuritic muscular atrophy (peroneal type), and in two cases of muscular atrophy from syphilitic root neuritis. The results are given in the preceding table.

The series is as yet too small to draw conclusions, especially since several of the cases have not been tested against all of the glands. Yet the positive reactions to adrenal and thyroid and in several instances to thymus and to testis in four cases of myopathy, one case that may be either myopathy or spinal progressive muscular atrophy, and one case of neuritic muscular atrophy (the peroneal type of Charcot, Marie, and Tooth) contrast strikingly with the almost uniformly negative reactions in the two cases of muscular atrophy from syphilitic root neuritis. The negative reactions to pituitary combined with positive reactions to thyroid and thymus suggest a possible relation to hypopituitarism.

To recapitulate briefly: Myotonia congenita and myasthenia gravis are frequently associated with muscular dystrophy. Amyotonia congenita has occurred in connection with muscular dystrophy and may be identical with one form of it. There is some evidence suggesting that thyroparathyroid deficiency may bear an etiological relation to myotonia. Myasthenia is frequently associated with hyperthyroidism, hypoadrenalism, and probably with hyperactivity of the thymus. Hypothyroidism and pathological findings suggesting both hypo- and hyperactivity of the thymus have been noted in amyotonia. Myopathy has been found in association with many disorders of internal secretion, perhaps most frequently with hypopituitarism. The case reported here presents the fully developed picture of both dystrophia adiposa genitalis and the fascio-scapulo-humeral type of progressive muscular dystrophy. Abderhalden tests on a series of four cases of myopathy, one case of neuritic muscular atrophy, one case of spinal muscular atrophy, and two cases of muscular atrophy from syphilitic root neuritis showed hyperactivity of thyroid, thymus, and adrenal in the first three conditions. In the peroneal case hyperactivity of testis was also noted. The tests on the syphilitic cases were negative. Thyroid and thymic hyperfunction are frequently observed in hypopituitarism.

Whether the glandular disorders bear an etiological relation to myopathy or are secondary to it, or whether both are due to a common cause is uncertain; but the combination is too frequent to be regarded as a mere coincidence.

In closing, we wish to express our thanks to Dr. Spiller, at whose suggestion this paper was written, and through whose kindness we have been able to report the present case, and to Drs. Mills, Lloyd, and Spiller for the privilege of studying the cases on their services at the Philadelphia Hospital.

A NEW THEORY OF THE FUNCTION OF THE LYMPHOCYTES.*

BY DUANE MEREDITH, M.D.,

WICHITA FALLS, TEN.

FORMERLY ASSISTANT TO THE CHAIR OF BACTERIOLOGY, T.C.U.,
FORT WORTH, TEN.

FROM my recent study of the different defensive properties of the body, both the defense against bacteria and their products and that against injury which may occur within the body from traumatism, or the natural death of certain cells after they have fulfilled their usefulness, I have worked out the following theory as to the function of the lymphocytes. This theory is based upon the study of the filterable viruses, including the cancer organism, and covers my theory of the origin of all tumor formation.

It has been proven beyond question of a doubt that the internal secretions of certain cells of the body govern the growth of the body organs. These include the thyroid, pituitary, adrenal glands, male and female generative organs, and perhaps some of the other ductless glands. That is, they govern the normal growth of organs and the body as a whole, but do not take care of the repair of the body after accident. This process is taken care of principally through the leucocytes and lymphocytes of the blood and through their action upon the other cells of the body. To understand the function of these cells according to Erlich, as given in the last edition of "Howell's Physiology," I shall give this classification:

1. Lymphocytes: No granules in the cell substance; and, though capable of ameboid changes of form, this property is not characteristic and probably not sufficient to cause locomotion.

(a) Small lymphocytes are about the size of the red corpuscles; the nucleus is large, symmetrically placed, stains homogeneously, and the cytoplasm is reduced to a very small amount. They form from 20 to 25 per cent. of all the white corpuscles.

*Read before Wichita County (Texas) Medical Society, September 14, 1915.

(b) Large lymphocytes are two or three times as large as the preceding. Nucleus somewhat eccentric. The cytoplasm is relatively more abundant than in the non-granular cells. These forms exist only in small numbers, forming 1 per cent. or less of the white corpuscles.

2. Leucocytes: Granules of different sorts found in the cytoplasm. Cells characteristically ameboid.

(a) Transition forms (uninuclear leucocytes). Single large nucleus more or less lobulated; cytoplasm abundant and faintly granulated. The granules stain with neutral dyes and are, therefore, designated as neutrophile granules. The name "transition forms" implies that these leucocytes represent an intermediate stage between the large lymphocytes and the following variety, but this belief is vigorously denied by many competent hematologists. This form exists in small numbers, 2 to 10 per cent. of the total number of white corpuscles.

(b) Polynuclear or polymorphonuclear leucocytes. The nucleus is segmented into lobes connected by narrow strands. The cytoplasm is especially ameboid and is granular. The granules in most cases are neutrophilic and small in size. The typical cells of this kind form the bulk of the white corpuscles of the blood—60 to 75 per cent. Eosinophilic leucocytes form a subgroup of this variety. They have a similar segmented nucleus, but the cytoplasm contains numerous coarse granules that stain in acid dyes, such as eosin, hence the name.

(c) Mast cells. These peculiar cells exist in very small numbers under normal conditions. Less than 1 per cent. of the total number of white corpuscles. They have a polymorphic nucleus like the preceding group, but differ in the fact that the granules in the cytoplasm are strongly basophilic; that is, will stain only with basic dyes, such as thionin.

While Ehrlich says that he observed ameboid movement in the lymphocyte, others regard it as a motile cell, and it certainly must be to fulfill its function, as it is found in the dense tissue, as scar tissue, bone, as well as in all normal tissue, and is known as the cell of chronic inflammation where it is abundantly found, no matter what causes the inflammatory reaction.

The function of the leucocyte, according to Metchnikoff, is that of a phagocyte, being capable of taking up bacteria and other foreign material and digesting them, and it also has the function of excreting a proteolytic enzyme that is capable of dissolving dead tissue.

The leucocytes, and this includes all of the motile bone-marrow cells that are found in the blood stream in healthy individuals, are male cells, and as such perform the function, as outlined by Professor Metchnikoff, with the possible exception that eosinophiles and mast cells have the additional function of neutralizing toxins, but these take no part in the regeneration of the cells of the body. This last function is performed by the small lymphocyte. As this cell is unquestionably the male cell of the body, and brings about the regeneration of normal tissue repair, and is responsible for every true caryokinetic change that takes place within the body. It is as necessary to the body cells as the spermatozoa of man is to the ovum of the woman in the starting of a new child.

The function of the lymphocyte has never been assigned, so far as I have been able to find out from the following pathologies: Ehrlich, Ziegler, McFarland, Adami, Nichols, Brooks, Woods, Webster,

Strümpel, Da Costa, Howell, and Tigerstedt—in physiology, a fairly representative body of investigators.

That there are both male and female cells within the body is an original theory with me, and is based not only upon my work, but upon that of our foremost investigators in their latest works upon different organs and diseases, that have a tendency in clearing up this field. I got some of my most valuable ideas from the workers in the Rockefeller Institute. That male cells existed within the body is not made mention of by any of our investigators, hence what cells carry on this function in the early life of the embryo would only be guesswork, but it is probably done by some cells connected with the vitelline circulation, and later by the placenta, until the formation of the lymph channels and glands are completed. This work will have to be cleared up by our future embryologists. De Lee says that it has been proven that the umbilical veins carry more white cells to the child than the umbilical arteries carry to the placenta, and thinks this organ is responsible for their formation, and as it is well known that the small lymphocytes predominate at the birth of the child, usually being about 60 per cent. of the total white cells, it is reasonably certain that these are mostly lymphocytes.

We do have direct division of some of the cells of the body without undergoing a true mitosis, according to Adami, when these are stimulated by some external irritant, as toxins, or bacteria, or foreign material, but these cells multiply only for a few generations, and die out as soon as stronger cells can take their place. This same phenomenon has been caused by Loeb, in the case of the ovum of the sea urchin, which is normally impregnated by the spermatozoa of this animal. He was able to produce fertilization, artificially. The cells of the body that yield most readily to such a stimulus are the fibrous tissue cells, liver and kidney cells, and probably some others, under certain conditions.

How normal repair takes place within the body can be better illustrated by the death of a single cell, one that dies within the liver, for instance. Here through the enzymes liberated by the dissolution of the dead cell, leucocytes and lymphocytes are attracted, the one to remove the dead tissue and the other to repair the damage. These same enzymes acting as a foreign body stimulate the adjoining cell, which begins to swell and get ready, as it were, for the male element, just as the ovum does for the spermatozoa, and when it becomes impregnated goes through the caryokinetic change, with a division of the cell into daughter cell, to take the place of the dead cell. I do not think that it is necessary for a lymphocyte to come in actual contact with the cell that it impregnates, as this same cycle is seen in many of the lower animals, but that it does excrete from it nuclear material, when irritated, an enzymic body, which, when it comes in contact with cells that are beginning to proliferate, impregnates these cells, bringing about a true mitosis or indirect division of the cell thus impregnated.

In my early studies with pathological specimens I wondered why this small lymphocyte should be so prevalent in all tissues unless it had some specific function, as it is found in tumors, tubercles, syphilitic gumma, and all grades of inflammation. To show how this takes place in an injury where there is death of many of the cells, one has to recall the process of normal repair after an injury. I shall

endeavor to show how normal repair takes place from a cut through the skin and some of the tissue beneath it. We first have hemorrhage with the formation of a clot within the space left in the tissue by the knife, with a drawing in of the end of the blood-vessel, a blood clot closing it. Now we have a slowing of the blood current in the adjoining vessels, with the leucocytes beginning to adhere to the vessel wall and gradually pushing themselves through until, after a short time, we find the vessel fairly surrounded on the outside with these cells. This slowing of the blood stream is probably due to the action of the nerves upon the blood-vessel. These cells proceed to migrate toward the injured area. Along with the leucocytes will be found numerous lymphocytes and red blood cells. The passage of these cells are facilitated by the flow of lymph from the vessel walls. The true skin is made up principally of white fibrous and elastic tissue along with some unstriped muscle fibers that run to the hairs, beneath which lies a layer of fat cells. The blood supply to fibrous tissue is poor, as it lies dormant, but with the increased blood supply the cells begin to swell up along the injured area and to proliferate and divide by direct division; that is, if there is foreign substance left there, or if there is dead tissue cell. It has been found that cells in the resting stage, such as the fibroblast, respond much more readily to the stimulus than functioning cells. This takes place some eight hours after the injury, and these cells may continue to divide by direct division for the first twenty-four hours, but after that time they usually divide by indirect division, and it is these cells that repair the injury. Cells that are formed by direct division are very short lived and only fill in until stronger cells can take their places.

This indirect division is brought about by the lymphocyte impregnating these cells, and it is through this that the body gains its greatest resistance to bacteria, and is able to bring about the process of repair. All cells before they undergo fecundation assume the embryonal type, or nearly so (Adami). This is especially true of the fibroblast, and it is principally with these cells that all repair work is done; but it is the proliferating fibroblast and endothelial cells that are the chief phagocytes, as they will destroy leucocytes, red blood cells, and bacteria. This is brought about by the lymphocytes, as all proliferating embryonal cells undergoing mitosis are phagocytes. These fibroblasts continue to multiply so long as there is an irritant that causes them to come in heat, as it were, or to prepare them for fecundation. This gives us typical granulation tissue. After the irritating substance is removed they quiet down and resume their normal state with the formation of true fibrous tissue. Before the fibroblasts, along with the leucocytes and endothelial cells, are capable of removing all of the irritating substances, they have to have food, as the blood-vessel resumes its normal condition as soon as the pressure is as great on the outside as it is within, and as these rapidly growing cells soon use up what was liberated at first it is necessary for the formation of new blood-vessels to take the place of the old ones. Whether this is brought about by the rapidly growing cells themselves, when their nutrition is decreased to such an extent as to interfere with their function, by them throwing off an enzyme that stimulates the endothelial cells to fecundation and proliferation with the formation of new capillaries, or

through the direct action of toxins liberated from dead tissue cells acting upon the endothelial cells, is not known. This formation of new blood-vessels occurs early in an injury, while the formation of lymph vessels occurs later; the latter are probably the result of the accumulation of by-products of growing tissue cells. Where these products are altered by growing organisms or their toxins there is a lack in the development in lymph vessels. This condition we see in tuberculosis and tumor formations, as these newly-formed tissue have no lymphatics. Thus with the formation of new blood-vessels to furnish plenty of food to the leucocyte, fibroblast, and lymphocyte, nature soon closes the wound. Another reason why we say the small lymphocyte is a male cell is because of the action of the lymph gland, and what is true of the lymph gland is true also of the spleen in regard to the blood.

To understand the function of the lymphocytes it will be necessary to give the function of the lymph glands. Outside of their function of acting as filters of bacteria and their toxins, and being the seat of the development of the lymphocytes, no pathologist has gone further or shown how this takes place.

The lymph gland is made up of a fibrous-tissue capsule with numerous trabeculae extending down into the gland, dividing it up into numerous chambers. To the outer side are packed numerous small lymphocytes, while the central portion of these chambers is filled with large endothelial cells. These cells are the mother cells of the small lymphocytes. The large lymphocytes are the daughter cells of a caryokinetic change and only occur in the blood in the proportion of less than 1 per cent., unless the lymph gland is badly irritated. These cells are supported by a fine reticular framework. The lymph vessels enter the gland through the mass of small cells to the outer side, then spread out over the large cells of the central portion. Foreign bacteria and dead tissue that may be in the lymph are destroyed by these cells, which are irritated and undergo fecundation and proliferation.

Endothelial cells undergoing fecundation and proliferation are distinct phagocytes, and will destroy any cell they come in contact with except the small lymphocyte, which seems to have the power of neutralizing the proteolytic enzyme liberated by these cells, keeping them confined within a cordon of small lymphocytes. Thus the body utilizes these cells to overcome the invading host of bacteria that constantly break in, but keeps them confined where they will do no harm to the other cells of the body. We see that the body tries to overcome these cells, when one of the serous membranes is involved, by limiting their action with plastic lymph. A careful study of the location of the lymph tissue will show that it is placed where the place of bacterial invasion is most likely to occur.

The Kupfer cells in the liver and certain cells of the spleen have the same function of destroying decaying red blood cells, or leucocytes, or bacteria. Where these glands are irritated by some toxins, as in the anemias and leucemia, we have a marked increase in the small lymphocytes, large lymphocytes, and also there appears in the blood the macrophages of Metchnikoff. The presence of these cells with their parasitic properties, the inability of the lymph gland to neutralize the proteolytic enzymes liberated by these cells, and their action upon the blood-forming organs, give some clue to the causes of this type of diseases.

Again, in typhoid fever, when there is destruction of bacteria at the close of the disease, a marked lymphocytosis takes place; this is probably the result of the cells of the lymph glands being irritated by the toxins of the destroyed typhoid bacillus.

J. B. Murphy and Morton of the Rockefeller Institute have shown in their experiments in the inoculations of mice with defibrinated blood as a prophylactic against mouse tumors implantation, that in the natural immune animals there was a marked increase in the lymphocytes, while the susceptible animal showed no such increase. Here again we have the mother cells of the lymphocytes irritated by the toxin of the destroyed cancer organism with the production of a very marked lymphocytosis, as the result of the repeated divisions of these embryonal endothelial cells of the lymph gland.

In tuberculosis there is usually a slight lymphocytosis, but in acute miliary tuberculosis there is a marked decrease in the lymphocytes. This is explained by the fact that the endothelial cells forming the tubercle undergo mitosis, and attract these cells from the blood stream in such numbers that there is a decrease of them in the circulating blood from 25 to 10 per cent.

I think Dr. Carrel of the Rockefeller Institute went further than anyone else in proving that the small lymphocyte is a male cell, when he was able to grow tissue *in vitro*. He collects human blood in a paraffine test tube, centrifuges this, mixes the clear plasma with Ringer's solution, and places his tissue in this; he noticed a very slight growth.

He next conceived the idea of making an extract from tissue and adding this to his other solution; he obtained a much more vigorous growth. If he had added an extract from a lymph gland, he would have obtained a still better growth. Henry F. Smith reports in the February, 1916, issue of the *Journal of Experimental Medicine* that he has confirmed Carrel's work in a way by using an emulsion of spleen pulp upon his tissue cultures that were inoculated with diphtheria and typhoid bacilli. The culture inoculated with spleen pulp was able to overcome the bacteria with a steady growth of tissue cells, but in the culture in which spleen pulp was not used there was no growth, thus proving that the tissue cells that were supplied with a large amount of the male cells, through this spleen pulp, were able to overcome the infecting organism, while the other tissues were overcome by the bacteria.

Murphy and Morton reported 100 per cent. takes when the mice were previously x-rayed. This shows that the lymphocytes contained within the tumor were able to stimulate the cancer cell, while those of the host were unable to stimulate the endothelial and fibroblast cells so as to destroy this foreign tissue.

Then, again, this gives us our first insight into the causes of contracted kidney and liver, and arteriosclerosis. When functioning cells are overcome by toxins, the remaining functioning cells are unable to fecundate and divide, owing to their lowered vitality. These dead cells thus act as a foreign body and stimulate the supporting fibroblasts to fecundate, and those being impregnated by the lymphocytes cause the production of scar tissue, with the destruction of the remaining cells.

To me it seems that this function of the lymphocyte makes it one of the most important cells within the body. As to proof that it is the male cell, I have cited the works of the foremost investigators of the day, and find nothing that conflicts with this theory.

MEDICAL RECORD.

BRONCHIECTASIS.

It is well known that bronchiectasis is too often not suspected until some other pulmonary disease develops, and that it is found post mortem more frequently than it has been diagnosed clinically *intra vitam*. This is probably due to the fact that as a rule it is associated with other pathological conditions in the lungs. It may occur as a pure bronchiectasis due to disease of the bronchial wall and with gradual dilatation of the lumen, or as a result of a cirrhotic lung process, or in association with pulmonary tuberculosis which produces fibroid changes with infiltration and weakening of the bronchial walls. The associated fibroid condition of the lungs with the manifestations of pulmonary involvement frequently masks the bronchiectasis.

Although most frequently the disease is primarily bronchiectatic in character in the non-tuberculous types, nevertheless cavities develop later, with practically always some mucous membrane lining, and in the end resembling true abscesses with indurated cicatricial walls, of such rigidity that, despite the absence in certain cases of pleuritic adhesions, gas compression is valueless. No single germ is found in this condition, but the influenza bacillus is frequently present, especially in the smaller bronchioles, at least post mortem. Chronic, non-tuberculous suppurative bronchiectasis is commonly the result of aspiration of foreign bodies, and of septic material following tonsillectomy or the removal of adenoids, in general anesthesia, and particularly in adults. More than one-quarter of these cases have been found to be post-operative (Wessler).

The main symptoms are characteristic, appearing when bronchitis occurs, and this is usual in almost all cases before the condition has been present long. In the early stages, however, the bronchitis which precedes the development of the bronchiectasis is indistinguishable from the true condition, the first noteworthy change being the production of patches of bronchi wider than normal, with resulting stagnation of secretion, and the appearance of the main symptoms and physical signs consequent upon this. Most important, diagnostically, is the cough, with profuse mucopurulent sputum, brought up with little preliminary coughing, especially in the morning, and with practically complete remissions of from several hours' to even one or two days' duration. The character of the sputum varies, but is

usually foul, though not penetrating and pungent as in acute gangrene, with elastic fibers present even in non-tuberculous cases, and, unless associated with pulmonary tuberculosis, there is an absence of tubercle bacilli, on repeated examination, even by the Loeffler antiformin method. Periodical attacks of septic fever, loss of sleep (due to cough and expectoration), resulting disturbed nutrition, with loss of strength and weight, with insufficiency of the right heart developing in the late stages and consequent venous engorgement of the general circulation, characteristically pronounced drumstick fingers (also found in other respiratory and circulatory diseases), and even pulmonary hemorrhage, due to ulcer formation, may occur during the course of the disease. Although, as Lilienthal says, post-operative cases may recover spontaneously or under hygienic and supportive therapy, still, once established, the progress of the typical case is extraordinarily chronic, in fact, progressive. As Williamson emphasizes in the March number of the *Medical Clinics* of Chicago, "small and medium-sized moist rales heard in patches, constantly present and always heard over the same spots," are the very typical physical signs, percussion yielding little or nothing in comparison. Exploratory puncture is not only dangerous but absolutely unnecessary, since the symptoms, physical examination, and x-ray show both the presence and the location of the pus. The x-ray is of the greatest importance in localizing the trouble within the lung, but the history and examination by bronchoscope are the great aids, in conjunction with radiography, in diagnosis.

The treatment of this condition from the medical standpoint consists essentially in hygienic and supportive measures. A study of the bacterial flora in the sputum may lead one to try vaccine therapy, the employment of which in bronchiectasis, at least in the early stages, we have not yet seen recorded. But unfortunately medical treatment is too frequently useless, or at least not particularly ameliorative, not to say curative. When associated with pulmonary tuberculosis, the latter condition should be treated as its improvement or cure will help considerably to clear up the bronchiectatic state. But in the pure type, the ordinary chronic, non-tuberculous, suppurative bronchiectasis, what should one do? After all, ordinary medical treatment in these conditions, after it has been given a fair trial for months, cannot be expected to offer much hope. When this is the case, when it is certain that nothing further can be expected from medical means, should we not turn to surgery in the pure forms of bronchiectasis mentioned? Lilienthal advises us not to wait too long before surgical aid is invoked in the pure types of this disease. The case should be carefully studied. The x-ray and bronchoscope aid one in determining the location and anatomical distribution of the lesion present in any particular individual. Surgical intervention of a radical nature is contraindicated in advanced, bilateral, chronic pulmonary infection, and even in some instances of unilateral disease which is too far advanced. Zaaier of Amsterdam considers what Lilienthal refers to as the palliative operative treatment. He reports three cases clin-

ically cured by the subperiosteal resection of 13 to 20 cm. of four or five ribs, suturing in two tiers, with a compressing pad above. In a fourth case there was a return of the trouble following an apparent cure, and the author advises that in cases of failure or recurrence with this method removal of the periosteum and intercostal muscles should then be undertaken. Although according to Zaaier the deformity is slight and the danger small, particularly with local anesthesia, Lilienthal, in a paper read recently before the Chicago Medical Society (published in its *Bulletin* for March 29, 1916), declares these palliative operations to be almost as dangerous as the more radical method of extirpation, resulting scoliosis not infrequently making the patient an incurable cripple. From an experience of twenty-eight cases since 1910, he advises the palliative surgical intervention in actually hopeless cases (such as bilateral involvement, or unilateral involvement of great extent and with adhesions contraindicating operation). He recommends extirpation, by pneumectomy, when a single focus or multiple foci exist in one lobe, or even when neighboring lobes are involved but in one single infected mass. The methods of procedure, including preparation of patient, position, incision, technique of operation, and after-treatment, are important. Lilienthal tried extirpation in seven cases, completed the operation in six, and obtained cures in four; one patient, who really should not have been operated on by this method, died from an exploratory operation. On the other hand, in comparison with the results obtained by the radical method of pneumectomy, the results from twelve drainage or conservative operations gave but a single cure, five so-called improvements (nothing more than a modification of the degree of invalidism), and six deaths. The surgical treatment of selected cases of bronchiectasis before the condition has progressed too far is therefore now well-grounded and should receive proper consideration at the hands of medical men, who see these cases relatively early.

CAN THE KLEBS-LOEFFLER BACILLUS CAUSE SEPSIS?

ACCORDING to most authorities uncomplicated diphtheria and tetanus furnish examples of pure toxemia and their exciting causes cannot produce virulent bacillemia or septic metastases. As a result of this characteristic both diseases are amenable to prevention and cure by antitoxins. Some data have recently been adduced to show that in exceptional cases there may develop a tetanus bacillemia and sepsis, and similar evidence seems to indicate that the diphtheria bacillus has analogous properties. Phenomena of meningism or meningeal irritation are occasionally seen in the course of severe diphtheria. In a material of over 8,000 cases of this affection, nine cases of meningitis occurred, two of which were evidently due to the Weichselbaum meningococcus, while the rest were set down as due to mixture of infection with various ordinary forms of pyogenic cocci proceeding from the pharynx.

However, diphtheria bacilli had never been noted

as occurring in meningitis pus until Reiche reported a case to this effect in the *Muenchener medizinische Wochenschrift* for April 18. This case in a child aged five years was an ordinary example of mixed diphtheria and streptococcus sepsis which ended fatally on the fourteenth day. The disease began as a meningitis, the throat presenting nothing abnormal. The blood and spinal fluid were both sterile. At a later period there was bilateral purulent otitis media and streptococci were now recoverable from the cord. Next appeared a purulent nasal discharge, rich in virulent diphtheria bacilli. Autopsy showed a continuous pseudomembrane in the nasopharynx, nasal fossæ, sphenoidal sinuses, antra of Highmore, and middle ears. There was no break of integrity in the base of the skull. There was a purulent leptomeningitis but chiefly of the vertex, the pus containing both diphtheria bacilli in abundance and the streptococcus. Both organisms had evidently reached the meninges by the blood route, and certain peculiarities of the pus, such as a greenish hue and tendency to form a membrane, could have been caused only by the Klebs-Loeffler bacillus.

DEATH RATE AMONG NEGROES.

THE impression seems to prevail that the morbidity of the colored population of the United States is extremely high, in fact the idea is held by some that the negro, failing to adapt himself to this climate, is gradually dying out. It is true that, speaking generally, the death rate of the negro is higher than that of the white, but it does not necessarily follow that this is due to differences in the two races so inherent that no environmental modifications can change them. Assistant Surgeon-General John W. Trask of the Public Health Service recently conducted an inquiry into the subject and finds that in most communities in the United States where registration is compulsory the negro death rate is markedly higher, with few exceptions, the latter being in States with very few negroes and these largely young adults.

Incidentally, Dr. Trask notes some other facts which may have bearing on the question. For instance, the negro death rate in the country was as a rule scarcely any if at all higher than that of the urban white, and in communities where the negro had made marked social progress the death rate did not show the same degree of excess over that of the whites as it did among the negroes in less enlightened communities. Comparing the death rate per thousand among the negroes in the United States in a given year (1912) with the rate in the population of European countries with practically no negro population, the figures were found approximately the same. Thus among the American negroes it was 22.9, in Hungary 23.3, in Roumania 22.9, in Spain 21.8, and in Austria 20.5. Bearing in mind the figures 22.9 for America, we find further that twenty or thirty years ago in Boston that city's death rate average 23.5 per thousand and in New York City from 1888 to 1897 the rate was 23.6.

So Dr. Trask concludes that the death rate among negroes in most communities of the United

States is not discouragingly high and is gradually becoming lower. It is at present the same that prevailed in the most enlightened white communities twenty or thirty years ago. Furthermore it seems probable that with the economic and industrial progress of the negro the death rate will gradually lessen until it is approximately the same as that of the white.

RABBITS AND PELLAGRA.

BR'ER RABBIT enjoys considerable popularity throughout the South on account of his exploits, as narrated by Uncle Remus, but he will become still more popular if he is the means of ridding that section of the country of the plague of pellagra. The chief obstacle encountered in the fight against this disease is, as is now generally conceded, the monotonous dietaries prevalent in districts where the disease abounds and the economic reasons why these cannot be improved forthwith. The obvious thing to do is, of course, to improve the diet by the addition of meat, milk, eggs, peas and beans, but this is easier said than done. The expense incident to raising stock for food, slaughtering and storing it is considerable, and the class which is prone to pellagra is the very class which has not the capital to attempt anything of the sort. Dr. C. W. Stiles, writing in *Public Health Reports*, March 31, 1916, suggests that rabbits be raised for food. That animal's multiplying proclivities are proverbial and, the period of gestation being short and the births multiple, a few lively individuals of assorted sexes would soon colonize a community. Dr. Stiles argues that rabbits are easily taken care of and readily procurable, and their meat is quite acceptable. Even if the temptation to market them was too strong, the resultant improvement in the family finances would be such that the dietary would naturally improve and thus the same result would be obtained. Dr. Stiles' suggestion is so simple that it may be overlooked, but there seems theoretically, at least, no reason why it should not be adopted.

EUNUCHOIDS.

THE eunuchoid belongs to either sex and presents analogous characteristics, which resemble those of the male castrate. At a recent session of the Greifswalder medizinischer Verein (*Deutsche medizinische Wochenschrift*, March 2) Fischer demonstrated three cases, one of which was in a female. The two males represented respectively the tall and the fat types. The height of the tall subject was 6 feet, while his reach was 6 feet 9 inches, and in the fat subject the reach was also somewhat in excess of the height. The increased length of the long bones was offset by arrest of development in the primary and secondary sexual characters. The female case was in a girl aged sixteen, who showed the true eunuchoid proportions in the long bones while the fat distribution was that of the eunuch. The uterus, fetal in type, was anteflexed at an acute angle, and the tubes could not be differentiated from the broad ligaments. The right ovary was the size of a bean, and the left one still smaller, and both were against the pelvic wall. The dimensions of the uterus agreed with those in a child of six or eight years of age. In apparent contrast the breasts were very full from fat accumulation. Two of the three eunuchoids had subnormal temper-

ature. Polyuria, alimentary glycosuria, a special blood picture, and uniform changes in the sella turcica were absent.

PROGRESSIVE LIPODYSTROPHY.

THIS term has been applied to certain conditions in which the deposit of fat obtrudes itself as a dystrophy which may originate in the action of certain hormones on the fat currents of the body. However, there are various familiar types of obesity in which the distribution of fat is very irregular. The excessive carbohydrate eater tends to a uniform distribution of adipose. In the all around glutton the accumulation is limited at first to the abdomen and buttocks, while later he may develop pendulous jowls and a fat neck. The paunch of the alcoholic contrasts with his relatively thin legs. In true lipodystrophy we may see a slender torso with elephantine legs. This condition is not a new one, for we learn from a recent session of the Medical Section of the Silesian Society for Fatherland Culture (*Berliner klinische Wochenschrift*, March 6) that Rosenfeld described a case of "fat-leggedness" nearly a decade ago. The progressive feature of this dystrophy is at present receiving attention. In the brief references to this affection we note the absence of any allusion to another group of fat dystrophies which comprises lipomatosis universalis, Dercum's disease and symmetrical lipoma. The two groups should have much in common.

News of the Week.

City Death Rate.—During the week ending May 27, the death rate for the City of New York was 13.89 per 1,000 of population, as compared with 13.82 for the corresponding week of 1915. This difference in the rate is equal to an increase of 8 deaths, the total number during the week having been 1,487. There was an increased mortality in whooping-cough, cerebrospinal meningitis, heart disease, lobar pneumonia, Bright's disease, and nephritis; and a decrease in the number of deaths due to measles, scarlet fever, digestive diseases, influenza, bronchopneumonia, pulmonary tuberculosis, and other forms of tuberculosis. The death rate for the first twenty-two weeks of 1916 was 15.19, as compared with 15.42 for the corresponding period of last year.

Transfer of the Baltimore Quarantine.—It is gratifying to be able to announce that the campaign for the transfer of the Baltimore quarantine station to Government control, which Dr. Nydegger of the Public Health Service has carried on for the past three years, has resulted successfully, and the station is now in course of being transferred. This is the last station in the country to go under National control.

New Har Moriah Hospital.—The directors of the Har Moriah Hospital of 138 Second Street, New York, have decided to build a new hospital, the site to be chosen somewhere south of Fourteenth Street and east of the Bowery. It is estimated that the new buildings will cost at least \$400,000, and of this \$50,000 is already in hand and an additional \$50,000 has been promised.

Nurses' Home Needed.—An appeal has recently been sent out by the trustees of the Flower Hospital, New York, for \$50,000 to be used for the construction and equipment of a home for nurses

attached to the hospital. The accommodations at present provided for the nurses are both inadequate and inconvenient, being situated at a distance from the hospital wards.

Change of Name.—Announcement is made that the name of the Long Island State Hospital has been changed and the institution will hereafter be known as the Brooklyn State Hospital.

The name of the S. R. Smith Infirmary, the oldest hospital on Staten Island, which was formed forty years ago by the late Dr. Samuel R. Smith, for whom the institution was named, is to be changed to the Staten Island Hospital.

The Park Hospital (formerly the New York Red Cross Hospital), 395 Central Park West, between 99th and 100th streets, New York, has available a number of free beds, for the care of acute, non-contagious cases among the worthy poor. Admission will be made upon the application of the family physician, and upon presentation at the hospital of a letter from the physician, containing his diagnosis and the assurance that the case is a proper one for free hospital treatment.

Milk Stations Open.—The twenty-fifth season of the Straus milk stations, which provide pasteurized milk for the children in the public parks and on the recreation piers during the summer, was inaugurated on June 1 with the opening of ten stations in addition to the eight which are maintained throughout the year. These summer stations are in the City Hall, Battery, Central, and Seward Parks, on the recreation piers at Third, East Twenty-fourth, East Eleventh, Barrow, and West Fiftieth Streets, and at the Educational Alliance Roof Garden.

Medical School Graduates.—Twelve young women received the degree of doctor of medicine at the graduating exercises of the New York Medical College and Hospital for Women held at the Waldorf on June 2. At the annual dinner of the alumnae of the college, on the evening before, announcement was made of the collection of funds amounting to \$62,000 to be used for new buildings for the institution. It is hoped that a total of \$200,000 will be obtained.

The ninety-first annual commencement of Jefferson Medical College of Philadelphia was held on June 3 and the doctorate was conferred on 162 graduates. Dr. W. W. Keen delivered the valedictory address, the subject of which was "The Doctor's Duty."

Medical Schools to Merge.—Announcement has been made of the success of the plan to merge the three big medical schools of Philadelphia, the medical department of the University of Pennsylvania, the Jefferson Medical College, and the Medico-Chirurgical College, under one head, thus forming the largest medical school in the United States. Committees from the three schools are said to have agreed on the methods of consolidation, the steps have been taken, it is believed, largely on the urging of the Carnegie Foundation, the directors of which held the opinion that Philadelphia was supporting too many medical schools. The School of Medicine of the University was organized in 1765, the Jefferson Medical College in 1825, and the Medico-Chi in 1881. The total enrollment of the three schools for 1914-15 was 1,126, and the total number of graduates in 1915 was 284.

Personals.—Dr. Carroll Chase of Brooklyn, N. Y., sailed for Bordeaux on June 4. Dr. Chase will enter the hospital service in France.

Dr. Walter Baer Weidler of New York has recently been made a member of the New York State Committee for the Prevention of Blindness.

Volunteer Hospital.—From Mr. James B. Duke of New York the Volunteer Hospital at Beekman and Water Streets has received a gift of \$5,000 for the establishment of a children's ward, to be known as the Doris Duke ward. The directors of the hospital announce that because of the increase of work in the district they will shortly start work on the proposed new addition. The horse-drawn ambulances of the institution are soon to be replaced with automobiles. Last year the ambulances of the institution answered 3,000 emergency calls in the district between the City Hall and the Battery and east of Broadway to the river.

Gifts to Charities.—By the will of the late Mrs. Rachel H. Pfeiffer of New York the Montefiore Home receives a bequest of \$1,000, while the sum of \$10,000 is left for the endowment of a bed in some Jewish charitable institution to be chosen by the executors.

By the will of the late Josephine Reissiere Monges of Philadelphia bequests are made as follows: To the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, the residue of her estate, amounting to more than \$30,000, together with clocks, furniture, books, and pictures, to be devoted to the construction of private rooms "to be used exclusively for gentlefolk who have insufficient means and are not proper patients for wards."

Appeal for Funds.—An appeal for funds to be used in the maintenance of the Ris-Orangis Military Hospital, near Paris, of which Dr. Joseph A. Blake, formerly of New York, is the medical head, was recently issued in this country. The French Government placed at the disposal of those in charge of the hospital the Jesuit College buildings at Ris-Orangis and gave \$10,000 toward its equipment. It has been transformed into a modern and up-to-date hospital of eighty rooms, all well filled, and for its maintenance during the next twelve months \$60,000 will be required.

Endowment of the J. William White Professorship.—By the will of the late Dr. J. William White of Philadelphia bequests are made as follows: \$150,000 to the University of Pennsylvania, to be held in trust as a permanent endowment, the income from which is to be used for the establishment of a professorship of surgical research to be known as the J. William White Professorship of Surgical Research; \$10,000 to the University of Pennsylvania, to be held in trust and the income to be divided in three parts, to be used by the managers of the University Hospital as a prize for nurses, as a prize for resident physicians and for the purchase of Christmas presents for child patients; \$5,000 to the College of Physicians of Philadelphia.

The S. Weir Mitchell Memorial Dispensary of the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases was formerly dedicated on June 1. An opening prayer and a closing benediction were delivered by the Rt. Rev. Philip M. Rhinelander. The formal presentation of the building and its equipment was made on behalf of the donors by John Cadwalader, Esq., and the acceptance was made on behalf of the managers by C. Hartman Kuhn, Esq. An address in memory of Dr. Mitchell was made by Dr. W. W. Keen. The building cost in the neighborhood of \$40,000.

West Tennessee Medical Association.—The annual meeting of this association was held at Jackson on May 18 and 19. The following officers were elected: *President*, Dr. John C. Paris, Rutherford; *Vice-Presidents*, Dr. Thomas E. Sawyer, Martin, and Dr. Robert Mann, Memphis; *Secretary-Treasurer*, Dr. Isaac A. McSwain, Paris; *Assistant Secretary*, Dr. George McSwain, Paris.

The Late Dr. Brickner.—The following minute has been adopted: The Metropolitan Medical Society of the City of New York has learned with great sorrow of the death of its friend and colleague, Samuel M. Brickner. Dr. Brickner was a physician of unusual ability, a scientist of learning, and a teacher of rare gifts. He was not merely a wise and helpful physician, but, in the last years of his life he exemplified the finest qualities of patience and strength.

We mourn his death and by this minute record our deep sense of loss in his passing out of the circle of his associates in the practice of our calling and extend to his bereaved family the assurance of our deepest sympathy.

Gustav G. Fischlowitz, M.D., President; Harold Neuhoof, M.D., Secretary.

The Late Dr. Stein.—The following minute has been adopted: The Metropolitan Medical Society of the City of New York records in this way its great grief at the sudden death of a distinguished member of the medical profession, Richard Stein. Dr. Stein died as he lived, amidst the performance of his duty as a physician and scientist. He was a true physician, not only a man of high attainments, but a physician of highest character. He was a friend of men within and without his calling; his passing will long be mourned by great numbers of those who looked upon him as a wise friend, a trusted counsellor, a noble physician.

To her upon whom the burden of grief rests heaviest, we send the assurances of our deep-felt sympathy and we shall always recall his life and service as worthy of the finest traditions of our calling.

Gustav G. Fischlowitz, M.D., President; Harold Neuhoof, M.D., Secretary.

Obituary Notes.—Dr. FRANCIS FOERSTER, for over twenty-five years gynecologist to the German Hospital, New York, died, after a lingering illness, on June 1, aged 62 years. Dr. Foerster was born in Heidelberg, Germany, came to this country in 1872, and was graduated from the College of Physicians and Surgeons, New York, in 1883. For ten years he served as professor of gynecology at the New York Post-Graduate Medical School, and later joined the staff of the German Hospital. He was a member of the American Medical Association, the New York State and County Medical Societies, the New York Obstetrical Society, the American College of Surgeons, the German Medical Society, and the New York Academy of Medicine.

Dr. CHARLES ZEH GARSIDE, professor of pathology and bacteriology in the Fordham University School of Medicine, New York, and pathologist to the Fordham Hospital, died in the German Hospital, on June 1, aged 37 years. Dr. Garside was graduated from the College of Physicians and Surgeons, New York, in 1903, and later served for two years at the City Hospital. He was a member of the New York Academy of Medicine, the New York Pathological Society, the Harvey Society, the Society for Serology and Hematology, and the Alumni Association of the City Hospital.

Dr. PIERRE V. ROUDIEZ of Denver, Colo., died at his home on May 13, after a short illness, aged 83 years.

Dr. OTIS LEE WINGATE died at Philadelphia on May 26, at the age of 38 years. He was graduated from Jefferson Medical College in the class of 1904, and he resided for several years at Albuquerque, New Mexico.

Dr. ARTHUR S. REEBEL of Youngstown, Ohio, a graduate of Tufts College Medical School, Boston, in 1909, died at his home on May 22, after a long illness, aged 31 years.

Dr. ISAIAH T. PRICKETT of Parkersburg, W. Va., a graduate of Miami Medical College, Cincinnati, in 1876, died at St. Joseph's Hospital on May 19, aged 69 years.

Dr. THOMAS P. KENNEDY of Union, S. C., a graduate of Tulane University of Louisiana, School of Medicine, New Orleans, in 1910, died at his home on May 21, after a long illness, aged 30 years.

Dr. ANDREW M. PEABLES of Auburn, Me., a graduate of Dartmouth Medical School, Hanover, in 1864, and a member of the American Medical Association, the Maine Medical Association, and the Androscoggin County Medical Society, died at his home on May 24, aged 80 years. Dr. Peables served for eighteen months as a surgeon in the Civil War, and was one of the founders of the Central Maine General Hospital.

Dr. JAMES F. COSTELLO of Quincy, Mass., a graduate of Tufts College Medical School, Boston, in 1913, died at his home on May 24, aged 26 years.

Dr. HENRY HARDENBERGH of Port Jervis, N. Y., a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1859, and a member of the Medical Society of the State of New York and the Orange County Medical Society, died at his home on May 29, aged 81 years. He retired from active practice a number of years ago. At the time of his death Dr. Hardenbergh was the oldest physician in Orange County.

Dr. EDWIN A. GOODRIDGE of Flushing, N. Y., a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1871, formerly surgeon to the Flushing Hospital, and a veteran of the Civil War, died at his home on May 31, aged 76 years.

Dr. FRANK C. CLARKE of Catskill, N. Y., a graduate of the University of Buffalo, Medical Department, in 1873, died at Palenville on May 30, aged 64 years.

Dr. S. M. LE CRONE of Tacoma, Wash., a graduate of Starling Medical College, Columbus, in 1878, died at his home on May 17, aged 70 years.

Dr. ALBERT C. PERVEIL of Brooklyn, a graduate of New York University Medical College in 1895, died in Roosevelt Hospital on May 30, after a long illness, aged 40 years. Dr. Perveil was surgeon of the Offin River Gold Mining Company in the Congo for some time, and it is thought that while there he contracted sleeping sickness which was the cause of his death.

Dr. THEODORE COLE of New York, a graduate of New York Medical College in 1879, died at his home on June 1.

Dr. JOHN L. DURYEE of Orange, N. J., a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1868, died on June 1, aged 70 years.

Dr. HENRIK G. BLESSING, who was physician and botanist with the Nansen polar expedition, 1893 to 1896, died on May 22 in Christiania, Norway.

Correspondence.

NAUHEIM BATHS AT SARATOGA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Referring to your editorial on the Nauheim baths at Saratoga Springs, it may interest your readers to learn that in reply to an inquiry I have received a letter signed by Mr. George D. Pratt, commissioner, and Mr. J. H. Jones, superintendent, stating that "under specific prescription from a physician of good standing the commission is ready to administer mineral baths with any additions which that physician may see fit to make to our natural mineral waters and with the express understanding that the responsibility for these additions shall rest solely with physicians prescribing them." This clear exposition of the commissioner's policy removes all doubt regarding the matter of obtaining the correct Nauheim bath formula in Saratoga Springs.

The method I worked out facilitates the latter, and it would prevent any miscarriage at the hands of the attendants at the bath houses if the manager would keep on hand a supply of packages containing 12 pounds sodium chloride and 1 pound pure (not crude) calcium chloride for baths of full strength and packages of one-half and one-fourth of these quantities for the weaker baths that may be prescribed in the beginning. This calculation, made for the Saratoga bath house supplied with Hathorn No. 1 water, equals within a few ounces the average saline content of the three Nauheim springs. Such an arrangement would facilitate prescriptions of one-quarter, one-half, or full strength Nauheim baths, and these being kept on hand would prevent delay in filling the prescription. The saline solutions should always be poured into the tub before the CO₂ water is allowed to run in, as the attendants at the Saratoga baths understand. A loss of CO₂ ensues if the practice is reversed. This addition of salines is of the utmost import in cardiac cases, because they enhance absorption and prevent the escape of CO₂ from the bath water, in the artificial and probably also in the natural CO₂ bath.

That cardiac cases sent to Saratoga should always be placed under the care of local colleagues goes without saying, for each new prescription of one or more baths must be based upon the effect of the previous bath. It is, indeed, a blessing to our patients suffering from organic heart affections, to be at last able to obtain baths of which they have been deprived for two years. Greater still will be this boon offered by the wisdom of our State authorities to those whose means have hitherto precluded their participation in the therapeutic advantages of the great German Spa

SIMON BARUCH, M.D.

THE X-RAY TREATMENT OF TINEA TONSURANS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Owing to the fact that we failed to receive the issue of the MEDICAL RECORD for March 18, 1916, our attention has but recently been called to a letter and published in your issue of the above date in which Dr. H. G. Adamson criticises our article on the "X-ray Treatment of Tinea Tonsurans" published in your issue of August 7, 1915. Adamson

thinks he was not given sufficient credit for his publication on the same subject in the *Lancet* for May 15, 1909.

We began to treat ringworm of the scalp with the x-ray soon after the publication of Sabouraud and Noiré's articles in 1905. For several years we employed a static machine, a "hard" tube, the platinocyanide of barium pastilles, and the Sabouraud radiometer. With this technique, however, we never attempted to depilate the entire scalp. When we read Kienböck's article in 1907 we attempted to follow his technique, but our efforts were not crowned with success. We never succeeded in successfully depilating the entire scalp until we had carefully studied Adamson's excellent article in 1909. Adamson's explanation of the method was so clear and concise that we had no further trouble so far as concerned the placing of the tube and the measurement of the head for the five-exposure method. However, not yet being satisfied, one of us (MacKee) visited Howard Pirie in Montreal (about 1912 or 1913) and obtained personal instruction. In the meantime we had discontinued the half-distance method and established the skin distance as advocated by Hampson in 1911 and we utilized the Holznecht radiometer, instead of the Sabouraud instrument, and adopted several other modifications. Later, of course, the Coolidge tube displaced all other therapeutic tubes. Therefore, the technique used by us was not based upon Adamson's work alone, but was the sum total of the work of many other observers, as was mentioned in our article. In this article we began by stating that "there is nothing original about the method, it being the result of the work of many investigators in the same field—Sabouraud and Noiré, Holznecht, Kienböck, Adamson, Sequeira, Hampson, Pirie, Corbett, Coolidge, Macleod, and many others." Later, in the article, we said that "this method of treating the entire scalp by five exposures was originated by Kienböck and is exceedingly accurate, as shown by Adamson, Pirie, Sequeira, and many others." The part of our technique that deals with the measurement of the head and the placing of the tube is the Kienböck-Adamson method and in the preparation of our paper we employed Adamson's article as a guide in explaining this part of the technique. We thought that in disclaiming originality and mentioning the names of the men to whom we were indebted for the technique and in including their articles in the bibliography we were giving sufficient credit. We certainly had no idea of belittling Adamson's work and now regret exceedingly that we did not definitely state that we had depended upon his article for certain parts of the technique employed by us. We shall have occasion to refer again to the x-ray treatment of tinea tonsurans in another communication and will take pleasure in giving Adamson full credit for his work.

Adamson seems to think that our statement, "there is nothing original about the method," refers to his lack of originality. We referred, of course, and fail to see how anybody can misconstrue the meaning, to our own lack of originality. We acknowledge gladly that Adamson modified and improved Kienböck's five-exposure method, that he proved the accuracy of the method by successfully treating a large number of cases, and that his article brought this to the attention of the medical world and stimulated dermatologists and Roentgenologists in all parts of the world to perfect the

technique. We acknowledge also that we made liberal use of his article in the preparation of our own paper. And to be perfectly fair to other authors we must also admit the liberal use of articles by Hampson, Holz knecht, Macleod, and others already mentioned. If the technique employed by us, which we, at the clinic, designate as the Kienböck-Adamson method (a phrase based upon the title of Adamson's article "A Simplified Method of X-ray Application for the Cure of Ringworm of the Scalp: Kienböck's Method") is to be given a name that will give credit to all who have been instrumental in its evolution, it will have to be designated as the Sabouraud-Noiré-Kienböck - Adamson - Holz knecht-Benoist-Coolidge method, and even this long title would not give full credit.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SHAKESPEARE AND MEDICINE—MUSEUM OF THE SOCIETY OF MEDICINE—DERMATOLOGY, CHEMOTHERAPY.

LONDON, May 13, 1916.

SHAKESPEARE is just now the absorbing topic of study and conversation. It is therefore only natural for his references to medicine to be again studied, though it may be thought that nothing new is likely to reward the most diligent student. Sir St. Clair Thomson, however, took it for the subject of his oration at the Medical Society, remarking that it was only right amid the tercentenary commemorations, for the profession to pay its tribute of recognition, for probably no matters were more frequently dealt with by our greatest master at any rate after the great poetical subjects of love, hate, ambition, and war. And there was a special reason why the Medical Society of London should take a particular interest in the most many-sided man the world had known, for its library contained the only authentic record of his death. That is in the commonplace book of the Rev. John Ward, Vicar of Stratford-on-Avon, and that was begun only 32 years after the death of the poet. In one of its volumes occurs the following entry: "Shakespeare, Drayton, and Ben Jonson had a merry meeting and it occurs drank too hard, for Shakespeare died of a fever there contracted." We need not suppose that Shakespeare ever studied medicine, but he certainly had a comprehension and knowledge of it which was most remarkable. His profound knowledge of human life and human nature explained why he will always be, said the orator, one of our greatest masters of medicine. His astonishing acuteness of observation, his familiarity with the ways and thoughts of frail humanity, his discrimination of disease according to age, sex, and circumstances, his sensitive regard for our "brutal life," his human sympathy and his knowledge of that part of physiology and pathology which might be studied in the daily life of the street, the market, the tavern, the court, the camp, or the town illustrate the poet's medical and scientific insight.

Shakespeare's familiarity with many technical medical matters was surprising—he employed terms which no modern playwright would know how to introduce. The diseases referred to were many—among them ague, rheumatism, plague, pestilence, fevers, measles, leprosy, sweating sick-

ness, and many others. Their mere mention was not much, but the flashes of genius revealed that he had such acquaintance with the science of his time and knowledge of human life and character as to make him one of the greatest masters of medicine. By the marriage of his eldest daughter to a medical man Shakespeare would have had the opportunity of acquiring some knowledge of the practice of medicine in his time. There are six representatives of medicine in his plays—none of them a surgeon. Quacks and mountebanks were numerous in his day and of course were mentioned. The diseases named were rather numerous, but what seems more important, as showing the extent of the poet's observation, is the surprising insight revealed here and there into the character and progress of some patient's malady. He had a clear knowledge of the opinions held in his time on various pathological questions and reasonable views on such medical and sanitary problems as were then discussed.

The Wellcome Medical Museum showed a number of Shakespearean exhibits at the Medical Society on the 1st instant—articles of *materia medica* mentioned in the plays and references to the uses made of them at that period. They were, so to say, on a par with many other subjects treated by the great, some would say the greatest or most comprehensive, mind in all literature. There were portraits of Shakespeare, of his house at Stratford-on-Avon, of the Glove Theatre, a copy of the bust on his tomb, a photo of a London apothecaries' shop of the period, oil paintings, portraits, a cross made from Shakespeare's crab tree, medicine jars, book-plates, and other memorials.

At the Royal Society of Medicine the Section of Dermatology has been to the front with a discussion on chemotherapy. At the Harveian Society, Backward Displacements of the Uterus. For this condition it was stated in the course of the conversation that 100 different operations had been employed. One member described two he had successfully used. Another remarked that congenital cases were common, but seldom caused any symptoms and were of no importance, if without complication.

OUR LETTER FROM ALASKA.

(From Our Special Correspondent.)

THE ESKIMO MEDICINE MAN.

ST. MICHAEL, April 5, 1916.

FROM the earliest times the subject of abnormal states of health and their treatment has been shrouded in mysticism with the Eskimo. They do not believe in healing through the medium of herbs or any form of medicine and they have the greatest horror of any form of surgical interference, but believe that certain persons are born with the gift of calling into play certain invisible powers by means of which the disease is driven out of the patient's body. These certain persons are the Medicine Men and the invisible powers are believed to be and are called Spirits by the Eskimo.

There are three distinct classes of natives inhabiting Alaska; the Indian of southeastern Alaska, the Aleut of western Alaska (in the region of the Aleutian Islands), and the Eskimo of northwestern Alaska. All three classes have about the same belief in regard to the medicine men but differ somewhat in their method of carrying out their line of treatment. They have a profound belief in the actions

of good and evil spirits in the prevention, cause, and alleviation of disease.

The present letter is based on observations among the Eskimos, and the medicine man is described as seen to-day in this portion of Alaska.

There are about 18,000 Eskimos (Innuits) in Alaska and they inhabit principally the coast, so it is not surprising that their food and habits are associated with the sea. The natives are gathered in small settlements called "villages," each village having a chief and one or more medicine men. There is also in each village a council house called the "Kashim" or "Kasga," which is open to every one alike for work or play. It is the common meeting place where the natives gather for their dances and "pow-wows" and is also the place where the medicine men treat the sick.

As above stated the medicine men are born and not made. They usually descend from families long known in this vocation, although occasionally a medicine man develops from other sources. In this same connection it may be of interest to note that there are a few medicine women.

Shamans, conjurers (tungaks) and medicine men are looked upon as mediators with the invisible world. They claim to be able to call the spirits into their environment, to see them, and to converse with them. They also claim that there are several kinds of spirits and that each spirit has a separate and distinct power of its own. The medicine man here tells me that there are five and that each one has the power to heal a certain kind of a disease (he recognizes five diseases); that when he calls the spirits and the wrong one comes, he must drive this one away and continue calling until the right spirit comes and that this may take as long as ten hours or as short a time as ten minutes. The writer thinks that the prosperity of the sick one is in direct proportion to the length of time required to call the *certain* spirit.

No two medicine men are alike because they associate with different spirits, however there is always rivalry in a village where there is more than one medicine man. One tries to get rid of the other and this results in ill feeling. As soon as the ill feeling becomes manifest, the Eskimo stamps the one with the most manifest malice as a fraud and the then preferred medicine man attempts to shorten the life of the "fraud" so, as a rule, we find but one active in a village, but the sick will often go from one village to another seeking treatment.

The sick may be treated at home or in the kashim, the latter being much preferred by all and believed to be more effective. In order to understand thoroughly this procedure it is necessary to know the plan of the kashim. It is a building constructed in the side of a bank if one can be found, about 20 x 20 feet, with a 10-foot ceiling. The sides and top are built of logs and are covered with dirt. In the center of the flat top there is a hole about 2 feet square and covered with a seal-gut covering. This is the only opening through which air and light can enter. The seal-gut window or covering is translucent and, as it is usually fastened down tight, there is little or no ventilation. All around the interior, about 4 feet from the floor, there is a shelf upon which the men sit (the women sit on the floor under the shelf). The floor is of dirt or boards; the center boards can be removed, exposing a hole 18 inches square. This hole is about 5 feet deep and is the inner opening of a tunnel, which tunnel leads to another vertical hole, which in turn leads to the storm

entrance through which all persons must pass on coming into and passing out from the kashim. Some of the modern kashims have a door from the storm entrance, thus avoiding the underground passage, but the older natives and those far away from civilization believe that the crooked passageway will keep out evil spirits, therefore they will not allow the ground level door. The walls are as black as tar from smoke. This smoke comes from the seal oil lamps the Eskimos use and from the fire that they build in the inner vertical hole after all persons have entered.

When the Eskimo is taken sick and desires the services of the medicine man, the medicine man is notified. He in turn notifies the whole village, stating the hour, day, and place for the performance. At night, just after dark and in the kashim, is preferred. The natives collect in the council house and seat themselves, the men on the shelf and the women on the floor. The spectators are made up principally of men; however, all ages and sexes are at times present. The medicine man makes his entrance through the underground passage. He is nude with the exception of a rain parka and a pair of short reindeer muclucs. A parka is a one-piece garment with hood and sleeves and slips over the head and falls to the knees. A rain parka is a parka made of seal gut. When finished it is translucent and will turn rain. This garment rustles like paper and is used by the medicine men on account of this property. Reindeer muclucs are short boots made of reindeer skins with the hair on them.

After the medicine man enters the kashim he calls for the patient. The patient is brought in, usually lowered through the opening in the roof, and placed in the center of the room. Selected men then sing (accompanied by the tom-tom of improvised drums) the medicine songs of this particular medicine man. The medicine man begins his dance, shaking the rain parka violently. From time to time he rapidly shakes his head from side to side, making a peculiar noise with his lips—"bluba luba luba lub—a!" The dance consists of standing in one place, leaning first on one leg and then on the other, throwing the arms around violently in a manner to show off the muscles and making various gruesome facial expressions. There is nothing artistic or pretty about the dance. The rustling of the parka and the songs are to call the spirits. From time to time the medicine man will stop and converse with a spirit. If this is the wrong spirit he will tell it to go away and the performance will begin all over again. This is kept up until the right spirit arrives. He then tells the audience and patient that he sees and is conversing with the invisible spirit. He will ask what is the matter with the patient and after a pause will state that the spirit says that this sick person did so and so, describing something that happened possibly many years ago, such as killing a female reindeer just before calving, or slapping a certain child (usually mentioning some act of which the medicine man knows). He will then ask the patient, "Is that so?" The patient will say "Yes," and the audience is then spellbound. The medicine man again converses with the spirit and asks what will heal the patient. After a few moments' pause he will turn to the sick man and tell him what to do to be healed. This treatment consists in prohibiting a certain kind or kinds of food, as, for example, the eating of seal oil, whale blubber, or dried fish; it may also forbid "the use of the knife." By this expression is meant that he must not chop any wood and at times this ap-

plies to the whole family. Sometimes the medicine man will hold a piece of fish or something else to eat, in his hand and ask the spirit to give this piece of food the power to heal the sick and will then make the patient eat it.

After the medicine man has finished his instructions there is much singing and rejoicing and the sick man is taken out of the kashim through the opening by which he was brought in. This ceremony may last from a few minutes to an all-night performance, regardless of how sick the patient is.

The medicine man usually states that the sick person will rise from the bed at a certain time. If the patient gets worse or cannot get up at that time the medicine man claims that his instructions have not been carried out and will at times become very much enraged about it or he may administer another treatment. The fees of these native doctors vary a great deal. Some few will not charge as they claim that in charging for their treatment they anger the spirits. However, this is not the rule as they get all they can. They may charge ten pounds of fish, so many gallons of seal oil, a dog, sleigh, furs, or anything. They get as much as they can and many of them do not work at all. The medicine man, next to the chief, is the most important and most respected Eskimo in the village. He is sometimes a "sleight-of-hand" performer and if successful is always one of the brightest of a settlement. This is necessary in order to gain the native confidence, as they look upon him as supernatural. The natives consult him and pay him for other things than treatment. For example, they consult the medicine man about the coming fishing, whaling, and sealing seasons and will often pay him so many furs to ask the spirits for a good catch. He also presides over the "Feast of the Dead," which will be described in a subsequent letter.

Progress of Medical Science.

4. The Problem of Ringworm in Children. E. L. Oliver.
5. Results of Open Air Treatment of Pneumonia in Children. A. R. Cunningham.
6. The Problem of Tuberculous Infection in Children. Harold W. Dana.

1. **Pediatrics as a Specialty in the Smaller Cities.**—Alexander C. Eastman points out that owing to the large percentage children constitute in the general physician's practice, the pediatricist must, of necessity, come into daily contact with the general practitioner, and he is obliged to become very circumspect in defining the limits of his specialty. The general physician may be glad to turn over a feeding case to the specialist, but at the same time be very loathe to give up a case of bronchitis. Because of the large educational propaganda concerning child welfare, people are demanding more and more special training in the physician who cares for their children. This is daily making the chance for the pediatricist's success much greater, but it is also complicating his relationship with the general practitioner. Much of the work in the smaller cities must be clinical in character, the scientific research work coming to us from the medical centers. The educational work is, however, just as important and should be carried on just as thoroughly in the small as in the large city. Pediatrics is primarily a specialty of preventive medicine.

2. **The Management of Gonorrhea.**—J. Dellinger Barney says that their experience with gonorrhea in the Genito-Urinary Clinic of the Massachusetts General Hospital has led them to agree on the following standard as a cure of the infection. The patient must meet these requirements at least once, preferably twice or three times, at intervals of at least two weeks and not less than a month after treatment. In the male there must be absence of gonococci; a negative gonococcus fixation test; the urine must be clear, and there must be no pus in the prostate or vesicles after three examinations, or pus present, but a negative blood test. In women they require a negative gonococcus fixation test, absence of clinical evidence of the disease in the lower tract, and a negative pelvic examination. In female children they require absence of gonococci, little or no pus in the vaginal smear, and a negative gonococcus fixation test. The writer believes that the average general surgeon or practitioner is incompetent to undertake the treatment, and especially to determine the cure of a gonococcus infection of the urethra, and that it is only proper that the State Department of Health should cooperate in seeing not only that the layman who wishes private treatment can get it from a reliable physician, but also that he should be able to know where to turn for this information. Public health authorities should keep on file a list of such physicians throughout the State who by their training and experience and hospital and teaching connections are competent to handle venereal disease.

4. **The Problem of Ringworm in Children.**—E. L. Oliver reviews the older methods of treating ringworm of the scalp and concludes that they are inefficient. He finds that the treatment of this disease by the x-rays, according to the method of Sabouraud and Noire, has proved to be highly efficient. In Paris it has shortened the course of the disease from two years to three months. The objection to the use of the x-rays in ringworm, on account of the possibility of producing permanent baldness, owing to inability to measure the rays properly seems to be answered by the introduction of the Coolidge tube, with which the amount of rays absorbed can be measured with great accuracy. Radiologists as well as dermatologists have been slow to grasp the importance of the x-ray treatment of this disease, but it is to be hoped that before long all cases will be treated by this method, which should make it much less frequent in the future than in the past.

6. **The Problem of Tuberculous Infection in Children.**—Harold W. Dana calls attention to the large proportion of children (90 to 95 per cent.) infected with tuberculosis during childhood and that from this early infection most of the active tuberculosis of later life is supposed to spring. He believes that the general practitioner has not been interested in the diagnosis of these cases and he has not awakened to the importance of such cases in the fight against tuberculosis. In fact he tends to deny the existence of such cases. In dealing with this problem there are certain things that are possible to do: we can probably abolish that part of the infection with tuberculosis which is acquired through the use of milk as a food; we can diminish the contact between children and active cases of tuberculosis; we can follow up any child exposed by association with any known case of tuberculosis; we can, to a greater or less extent, pick out those children who have become infected; and we can watch these infected cases to prevent them from becoming active cases, treating those whose general condition fails to improve by more energetic measures. Such cases should be sought for by the school physician, and when found should be followed up by the school or district nurse, who can take

such patients to the local tuberculosis dispensary at stated intervals for examination. The writer emphasizes the fact that the x-ray does not distinguish, in general, between active cases needing active treatment and the latent or healed cases.

7. Addison's Disease of Syphilitic Origin. Philip M. Schaffner and Tasker Howard.
8. The Curatelle and Modern Psychiatry. George W. Jacoby.

1. **Hysterical Mutism.**—G. Hudson Makuen believes that hysteria is essentially a disease of the mind. He reports several cases and says that hysterical mutism is a somewhat rare affection; it occurs at all ages, in all races, in both sexes, and even in animals. Hysterical mutism is usually of sudden onset and is the result of some severe psychical or emotional shock. It is characterized by the complete absence of the physical representations necessary to the production of speech. Heredity is an etiological factor so far as it furnishes the neuropathic or psychopathic soil for the development of the affection. The mutism generally occurs in conjunction with other hysterical phenomena, although it may be the only hysterical symptom. Hysterical mutism may occur in conjunction with organic nervous diseases which themselves simulate hysteria, and it can be distinguished from them only by actual discovery of the pathological conditions giving rise to the particular affection. Hysterical mutism differs from hysterical aphonia in that the former evinces a more extended disability of the mechanisms of speech, and it differs from aphemia or motor aphasia in that the mutism is absolute. If physicians were better practised in the art of psychotherapy there would be fewer so-called miraculous cures reported outside the pale of the regular profession.

2. **The Treatment of Muscular Rheumatism.**—William Fitch Cheney considers this subject and says that the remedies of most avail are the following: (1) Rest. Nature usually enforces this management if the attack is sufficiently acute. Sometimes absolute rest of the whole body in bed is demanded, as in lumbago; sometimes rest of one portion, as an involvement of the deltoid. (2) Heat. Cold increases the pain and heat is always grateful and gives relief. It seems probable that the virtues alleged for certain antiphlogistic pastes depend even more upon their retention of heat than upon their chemical constituents. (3) Purgation. He believes with others that there is a close relation between abnormal intestinal chemistry and attacks of muscular rheumatism. Relief is afforded by thoroughly emptying the bowel and best by some mercurial. One other drug particularly efficacious is colocynth. (4) Salicylates: They are as rational remedies for muscle rheumatism as for joint rheumatism. Just at present aspirin is the one most commonly prescribed. (5) Opiates. It should be thoroughly understood that all opiates are out of place because they check elimination by skin and bowel and because they have in general bad effects that outweigh the good.

3. **The Treatment of Tuberculous Adenitis by Röntgen Rays.**—Russell H. Boggs says that cases of tuberculous adenitis formerly were referred to the Röntgen ray treatment on account of the operation leaving unsightly scars, but today this is not the chief

reason. It is because operation is followed by frequent recurrence, as well as more danger of producing general tuberculosis. Besides, many believe the end results of radiotherapy are much better. Radiotherapy stands on a different plane than it did two years ago. The same massive radiation is not indicated in the treatment of tuberculous adenitis as in the treatment of malignant disease. The Roentgen ray is the best method of treatment when the glands have become widely scattered and are broken down. Where there is pulmonary involvement, the writer believes the Röntgen ray, together with good hygienic treatment, is the only method to be considered.

4. **Chorea: Its Treatment.**—Morris Grossman tells of the value of muscular relaxation and reeducation, in addition to general treatment, based on the study of fifty cases, with a detailed report of one case of chorea mollis. He offers the following conclusions: (1) Relaxation and reeducation have a distinct value in the treatment of chorea. (2) The course is favorably modified and the danger of complication lessened; the duration of the disease is shortened by their use. (3) Residual chorea and other conditions of muscular unrest are obviated. (4) We reduce to a minimum the drain on the motor centers, due to prolonged and continuous muscular activity. (5) With this systemic exercise treatment, we increase the mental stability and will power of the patient, thereby diminishing the danger of subsequent tics and other functional neuroses that flourish in such a soil.

1. **A Study of 1,153 Cases of Scarlet Fever, with Special Reference to Their Sequelæ.**—Dr. Louis I. Dublin, Statistician of the Metropolitan Life Insurance Company, presents this study. These patients were all policy holders of the company, and their whereabouts and subsequent physical condition could readily be traced in the years subsequent to their having the disease. Nearly 80 per cent. of all the cases were among children between two and ten years of age. The greatest disposition to the disease is found among children from three to seven years of age, 55.2 per cent. of the total being found within these years of life. The period eleven to fifteen years presents an appreciable number of cases, but after this age the cases are few. Not only are children at the youngest ages more susceptible to

scarlet fever, but it appears that these children take the disease in the severest form. The lethal rate for the 1153 cases is 7.8 per cent. The younger the children the higher has been the death rate. The lethal rate also varies considerably with time and place, depending on the severity of the epidemic. The ninety deaths that occurred in this series showed complications in sixty-two cases; in eleven of these there was a distinct kidney involvement. In tracing the history of those who survived there were only eighteen deaths in the following four years; three of these showed a record of endocarditis; there were five deaths from respiratory diseases, and four from tuberculosis. The remainder were scattered among a number of causes having no relation to the scarlet fever. Strangely enough, there were no deaths from kidney disease. Apparently among the survivors of the primary disease, the kidneys were not sufficiently impaired to cause early death. The sequelæ of scarlet fever are apparently not an appreciable factor in the mortality of the survivors, but it should not be overlooked that the disease itself still constitutes an important factor in child mortality. The disease has not shown the same amount of decrease in the last fifteen years that has been observed in connection with other infectious diseases, the death rate in the registration area being about 10 per 100,000. A study of these figures with reference to seasonal distribution shows that from January the frequency of the disease rapidly rises until May, when the maximum number of cases occurs. Thereafter there is a rapid drop in the number until September, which is marked by the minimum. The largest number of deaths occur during April and May and the fewest in September.

3. A "Group Study" Plan for a Diagnostic Team Acting as a Laboratory for the Profession.—Fayette Watt Birch states that the type of group study as now practised in general hospitals is unsatisfactory. The assignment of patients to different departments for treatment is often determined by the patient's complaint without previous investigation by the various departments, which is comparable only to the methods of the general practitioner. Realizing these limitations the profession in the vicinity of San Francisco three years ago organized the San Francisco St. Luke's Hospital Clinical Club for the purpose of remedying such conditions. After trying various plans the following method was adopted: A section was organized consisting of ten men, each having special training along some particular line. The members of the profession refer obscure cases to this section for diagnosis. These patients are placed in the hospital for observation, and each member of the diagnostic team makes an individual examination and a written report of his findings. At noon each day the team meets to discuss the cases. If the case is not clear at the first consultation, further investigation is recommended, and any new discoveries are reported the following day. This method of procedure is continued day after day until some conclusion is reached. The physician who referred the case is asked to be present at all the consultations. Finally, the patient is referred back and a written report of the findings and recommendations for treatment are mailed to the attending physician. All of this work is done for a fee commensurate with the patient's income, though the amount collected is not sufficient to pay for the time of the clinicians. The results to be expected from such a scheme are: The general practitioner will gladly accept it; the good influence of the family physician will be preserved; medical men in the community will take advantage of the daily discussions and gradually broaden their point of view of medicine; this method of group study will maintain the advantages

of specialism and do away with the disadvantages. Clinical reports from this work bearing on these predictions are now being prepared for publication.

7. Free Tumor Diagnosis as a Function of the State Public Health Laboratories.—Leverett Dale Bristol publishes the results of an investigation in regard to the existing facilities for the laboratory examination of specimens of suspected cancerous tissue, the information having been collected through a questionnaire sent to the directors of the various State public health and hygienic laboratories, and in some instances to the State boards of health. This investigation shows that twenty-four States have facilities for the diagnosis of suspected cancerous tissue, while twenty-four do not attempt such work. On the basis of the data collected the following recommendations are submitted as worthy of consideration in the campaign against cancer: 1. So far as consistent with local conditions, facilities should be offered under public auspices in each State for the diagnosis of tissue suspected of being cancerous. Preferably, these should be made free of charge. 2. The logical place for the doing of such work is the laboratory of the State health department. It is not to be supposed that such work will be given the preference over other work now being done by these laboratories. 3. To cover this work, in those States which have no such facilities, additional money should be appropriated. 4. Judgment must always be used by surgeons in the removal of suspected cancerous tissue for diagnosis, and the value of a microscopic diagnosis should appear to outweigh the risk involved before such a procedure is adopted.

9. The Supernumerary Ureter.—A. R. Simon and H. O. Mertz report a case which serves to emphasize the frequency of supernumerary ureter, the surgical significance the anomaly may assume, and the possibility of its recognition as a factor in the production of a pathognomonic condition early in the process. The authors point out that an otherwise benign condition may be rendered malignant through the association with a supernumerary ureter. The recognition of this condition is possible in every case. The clinical history of a constant incontinence associated with periods of normal urination at once suggests the existence of a supernumerary ureter with an extravesical opening. When the opening is intravesical this symptom does not obtain. Many such anomalies will at once be recognized by the cystoscope, and there is always some irregularity in the bladder picture. Should the opening of the third ureter be among the folds of the trigon or vesical neck chromo-ureteroscopy may be necessary, and mucus covering the opening may prove confusing and add to the difficulties of diagnosis. In the case reported there was a complete duplication of the right ureter, with separation of the two pelves, the cephalic one being rudimentary. There was evidence of infection of this supernumerary pelvis and in this case the anomaly had a direct bearing on the progress of a pathological process, namely, a small papilloma situated on the posterior margin of the trigon.

10. The Treatment of Gonorrheal Folliculitis by Cauterization with the d'Arsonval Current.—Edgar G. Ballenger and Omar F. Elder report several typical cases selected from a series of fifty-four patients treated with the high frequency current for persistent or recurrent urethritis. Some had been treated for as long as six years by a number of physicians and specialists, but the discharge and urethral shreds still continued. Two or three treatments were the average required after the authors had learned the value of inserting the electrode to the bottom of the pocket and applying the current until the mucosa overlying it

turned white. A number of these patients returned home and allowed their physicians to continue mild irrigations. During the two or three weeks interval it was most gratifying to note the improvement in some of these patients who had been treated for years unsuccessfully by the usual measures. The authors state that in suitable cases they have never been able to secure such definite and prompt results by any measure or remedy hitherto advised for this class of patients. Acute and subacute conditions naturally should not be treated in this manner.

11. **The Duration of the Nursing Period in Women of the United States.**—A. Graeme Mitchell presents an analysis of about 3,000 cases taken from the records of the Children's Hospital in Philadelphia during the past fifteen years, from which he concludes as follows: 1. There has been no decline in breast feeding in the last fifteen years. 2. The women of the poorer class compare favorably in the period of lactation with the women of the more prosperous class in this country. 3. The women of this country compare favorably in the period of lactation with European women. 4. The average period of lactation in children entered at the hospital was six months. 5. Twenty per cent. of the women did not nurse their children; 80 per cent. nursed one week or longer; 55 per cent. nursed three months or longer; 42 per cent. nursed six months or longer; 34 per cent. nursed nine months or longer; 27 per cent. nursed a year or longer; 9 per cent. nursed eighteen months or longer, and 2 per cent. nursed two years. 6. For the reason previously pointed out, namely, the greater susceptibility of artificially fed babies to gastrointestinal and nutritional disturbance, the infants brought to the hospital were, in the large majority of cases, bottle fed at the time of their entrance there. The conclusion is inevitable that the figures given represent the minimum of lactation.

12. **The Etiology of Typhus Fever in Mexico (Tabardillo).**—Peter K. Olitsky, Bernard S. Denzer, and Carlos E. Husk present a preliminary report of work begun in February, 1916, in Matehuala, Mexico, and interrupted in the early part of March because of the necessity of Americans leaving the country. They state that the organism found in the blood of typhus patients is an obligate, anaerobic, Gram-positive bacillus which in morphology and cultural characteristics, including acid production in various carbohydrates, is identical with the *Bacillus typhi exanthematici*. The injection into a guinea pig of a colony taken directly from the blood culture tube proved the organism to be pathogenic. Agglutination tests performed with serums taken in different stages of the disease showed negative results during the early part of the illness, an occasional positive reaction at or near the crisis, and uniformly positive results after the crisis. In cultures made from lice taken from the clothing of typhus fever patients, the same organism was obtained. The injection of lice into guinea pigs produced a febrile reaction, and at necropsy the characteristic splenic lesion was found. In cultures from the spleen, an organism was recovered showing the morphological characteristics of the *Bacillus typhi exanthematici*.

3. **The Visual Standards Used in the Medical Examination of Recruits in the British Army and Continental Armies.**—J. V. Paterson and H. M. Traquair recall the fact that, owing to the difficulties attendant on the provision of spectacles and their use by men in active service, glasses have been prohibited altogether in the British army. A recruit who failed to pass the test without glasses was finally rejected, no matter how good his corrected vision might be. At that time and during the early stages of the present war the standard was 6/24 with each eye, or 6/6 with one eye and 6/36 with the other. With the increasing need for men a modification was introduced in September of last year requiring 6/24 in each eye, or 4/24 in the right eye with 6/60 in the left. The use of correcting glasses was permitted in home service and garrison service at home and abroad. The continental powers take the view that it does not matter very much what a recruit's vision is without glasses provided that he gets 6/12 vision in the better eye with spectacles. After collecting data with reference to sight tests in other countries the writers conclude that the present sight test for general service for recruits for the British is by far the highest in Europe, and excludes from the fighting line large numbers of men who are freely used as combatants in the armies of the chief continental powers. In view of the present want of men there is urgent need for the immediate adoption of a remodeled sight test based on corrected vision, on the lines of the military visual standards in use on the continent of Europe.

4. **Spinal Anesthesia with Special Reference to the Use of Novocaine.**—C. Colgate Holman has used a 5 per cent. solution of novocaine and mannitol, the dose for an adult varying from 6 to 8 cg. of novocaine, in 300 cases in which the site of the operation was below the level of the umbilicus, as hernia, hemorrhoids, varicose veins, etc. He says the symptoms sometimes occurring during the operation are faintness, often accompanied by nausea or vomiting during the first ten minutes. This was usually relieved by one-half an ounce of brandy or a hypodermic injection of strychnine. Serious symptoms never occur in patients under fifty years of age. Bache and retention of urine appear to be less common than after a general anesthetic. Headache is often troublesome during the first forty-eight hours. The author emphasizes the fact that spinal anesthesia is a method which must be employed with scrupulous care and attention to detail. It is more suitable for use in hospitals, where the nursing staff is familiar with the technic and the after-treatment than it is for casual operations in private practice. Whether novocaine has any special advantage over stovaine he is not prepared to say. Its lower toxicity is neutralized by the fact that a somewhat larger dose is required. It seems to be generally admitted that it is less irritant to the tissues.

7. **Ulcerative Stomatitis.**—Kenneth Goadby states that ulcerative stomatitis is appearing sporadically among the troops of France as well as in some of the English camps. The disease is characterized by the gradual onset of general malaise, red congested fauces, and acute inflammation of the gum margins; mastication and deglutition are painful, the cervical lymph glands are enlarged, the tongue furred, and the breath fetid. In the course of two or three days the gum edges become necrotic and a white false membrane may develop in the throat, the removal of which leaves a raw bleeding surface. The necrotic process may spread

to the cheeks. A smear preparation made from the gums, cheeks, or throat, and stained by Giemsa's method shows innumerable bacteria of two morphological forms, *Bacillus fusiformis* and spirochetes. Dilute chromic acid relieves the pain and promotes the removal of the necrotic tissue. Its use should be followed by a wash of chloreton and glycerin. Potassium chlorate, 10 to 15 grains with perchloride of iron and magnesium sulphate should be given internally. The disease commonly yields to this treatment. Ulcerative stomatitis is easily differentiated from scurvy, pyorrhea alveolaris, pneumococcal ulceration, and lymphatic leucemia by the white necrotic gums, the pain, and above all by the smear examination.

2. A Case of Congenital Atresia in the Duodenum Treated Successfully by Operation.—N. P. Ernst reports this case because there is only one other instance of this condition known to him in surgical literature in which a surgical operation was successful. He says that Petrograd Theremin reports having found nine cases with this deformity among 150,000 children and he himself has found two cases among 41,000 children in the Royal Lying-in Hospital at Copenhagen. The child under consideration was operated on eleven days after birth. The incision was made a little to the left of the middle line and was between 7 and 8 cm. in length. After the anterior sheath of the rectus had been laid bare, Mosetig batiste was sewn to the edges of the skin with continuous silk suture so that the integuments were completely covered. On opening the peritoneum, the duodenum was uniformly of about two fingers breadth as far as it could be traced to the upper side of the transverse mesocolon. But below the colon where the intestine reappeared at the flexura duodeno-jejunalis, it was seen to have collapsed to the caliber of an ordinary lead pencil. The remaining portion of the small intestine showed no stenosis. The writer made a duodeno-entero-anterior anastomosis; that was, a coil of small intestine about four inches below the flexura duodeno-jejunalis was drawn up in front of the transverse colon, and united to the duodenum about the junction of the pars superior and pars descendens. The child was little affected by the anesthetic or by the operation which lasted about an hour and a quarter. The patient took 35 c.c. of ether. In reviewing the literature the writer notes that in an astonishing majority of the cases only enterostomy has been performed, and it has always resulted in sudden death, associated with an enormous rise of temperature. It cannot be supposed that failure was due in every instance to defective personal aspies on the part of the surgeon; we must therefore direct our attention to the special source of infection in the child itself. There is risk from two sources, the skin and the contents of intestines. The integuments of the child during the first weeks of life are always infected from the umbilical wounds and the delicate skin cannot stand any strong disinfectants. In order to eliminate this danger the writer first dressed the umbilical wound with cotton wool moistened in 1 per cent. solution of silver nitrate, before the putrefaction

of the cord and, what was more important, sewed the Mosetig batiste to the margins of the wound.

4. Dressings Used in a Casualty Clearing Station.—A. Don writes his observations after ten months' experience in a clearing station, where the various methods of dressing wounds that have been suggested from time to time have been tested and their efficacy in cleaning damaged tissues, in preventing the spread of infections, and in adding to the comfort of the patients, has been compared. He concludes that it is not so much the antiseptic dressing used as its intelligent application that matters. Almost any one of the methods tried, hypertonic solutions, hypochlorous acid, iodine, methylated spirit of glycerin, carbolic acid, sterile or double cyanide gauze, hydrogen peroxide, or continuous irrigations, would give average good results, but there were cases in which one application was more suitable and more easily applied than any of the others. The surgeon in a casualty clearing station should never become an enthusiast in any one method of dressing, as he is then a danger to his patients and an embarrassment to his colleagues, to whom freedom of choice is as necessary to secure their intelligent interest as a change of method of dressing may be to the patient.

5. Acute Urinary Infection with Paratyphoid B. Bacillus.—C. Worster-Drought and Alexander Mills Kennedy report this case of acute urinary infection with the *B. paratyphosus B.*, which presents little in common with ordinary paratyphoid infection as hitherto recognized and presents several additional interesting features. There was a pyuria due to pure infection with *B. paratyphosus B.* The usual signs of paratyphoid fever were absent. A perusal of the literature shows that it is by no means common to find paratyphoid bacilli in the urine during the course of an ordinary attack of paratyphoid fever. This patient was successfully treated with autogenous vaccines and hexamine. The patient had not been abroad.

7. The Therapeutic Value of Hypochlorous Acid.—Raúl Flores Córdova publishes the results of experiments made during the past nine months to determine the antitoxic and antiseptic power of hypochlorous acid *in vivo*. He presents tables showing the efficacy of 10 c.c. doses of the hypochlorous acid solution in certain artificially produced infections and toxemias. These show that in rabbits 10 c.c. intravenous doses of 0.5 per cent. solution of the acid, even when repeated two or three days in succession, produce no ill effects, that they may delay or prevent the onset of symptoms due to the injection of the animals with diphtheria and tetanus toxins and with cultures of *Bacillus perfringens* and *Staphylococcus pyogenes aureus*, the rabbits recovering from the infection or remaining healthy. He concludes that hypochlorous acid intravenously administered is to be regarded as of therapeutic value; the antiseptic apparently delays the development of the bacteria and destroys their toxins. It is suggested that the destruction of the toxins is in the nature of a protein coagulation.

Complete Syphilitic Alopecia.—Lloyd Thompson calls attention to the fact that complete syphilitic alopecia is not mentioned by most text-books, or is dismissed with the statement that it is a rare condition. He refers to several instances that have been reported in the literature and reports a case. The most striking feature in this case was the absolute complete alopecia, there being not a single hair on the entire body. Even though the Wassermann test, which at first was strongly positive, became negative under treatment, he still continued to show a condition of complete alopecia.—*Journal of the American Medical Association*.

Book Reviews.

THE TREATMENT OF ACUTE INFECTIOUS DISEASES. By FRANK SHERMAN MEARA, M.D., Ph.D., Professor of Therapeutics in the Cornell University Medical College in New York City. Attending Physician to Bellevue Hospital, New York. Price, \$3.50. New York: The Macmillan Company, 1916.

THE chief faults of textbooks on treatment are that they are often mere compilations and that the methods of treatment are outlined in a broad, general way that leaves much to the imagination of the student or practitioner who uses them. These faults are avoided in Dr. Meara's book. Based entirely on his own wide experience it describes tried remedies and methods. In addition all methods are described in detail, even to the proper making of a bed, so that the work is also a manual of therapeutic technique. It contains thirty-five chapters, each devoted to a single disease, and while the author's practice of detailed description has led to a good deal of repetition, the space so used is not wasted. At the end of each chapter there is a summary of its contents, convenient for ready reference or review. It is a pity that such a useful volume has suffered so much from inadequate proof-reading. There are many instances of obscure or even ungrammatical construction which would have been eliminated by a more careful inspection of the proof. On page 28 Rosenau is made to defend the doctrine of the transmutation of the streptococci; it should read Rosenow, of course. In the chapter on Diphtheria, hardly enough importance is given to the Schick test, which is merely mentioned. It is, however, a valuable book and can be recommended especially to students.

INFANT HEALTH. A Manual for District Visitors, Nurses, and Mothers. By J. (SHAWNET) CAMERON MACMILLAN, C.M.B., A.R. San. I.; Lecturer (First Class Diploma) Sick Nursing and Popular Health, Edinburgh; Inspector of Midwives and Health Visitor, Oxford; Formerly Senior Health Visitor, Aberdeen. Price, 75 cents. London: Henry Frowde, Oxford University Press; Hodder & Stoughton; New York: Oxford University Press, American Branch, 1915.

THIS is a small manual of 128 pages in which there are described in simple language the physiology and hygiene of pregnancy, and the care of the infant. There is a foreword of endorsement from Sir William Osler and one cannot but agree with him that this book is "full of sound knowledge and common sense"—a virtue that is sadly lacking in many similar books of greater size and pretension.

A MANUAL OF HYGIENE AND SANITATION. By SENECA EGBERT, A.M., M.D., Professor of Hygiene and Dean of the Medico-Chirurgical College of Philadelphia; member of the Academy of Natural Sciences of Philadelphia. Sixth Edition, Enlarged and Thoroughly Revised. Illustrated with 141 Engravings and 5 Plates. Price, \$2.25. Philadelphia and New York: Lea & Febiger, 1916.

IN this edition due attention has been given to changes and advances in sanitation during the past few years. At the same time, since the author's purpose is to provide a textbook, he has exercised a wise conservatism regarding new ideas. He has added an entirely new chapter on Industrial Hygiene and Occupational Diseases, embodying in a general way present views on these subjects. He gives special attention to the changing views regarding air pollution and ventilation, water purification and sewage disposal, military hygiene, and to the demonstrable achievements in life-saving and health conservation in recent years. The book is admirably adapted for use as a text-book in high schools or colleges, or for the lay reader who wishes a succinct and comprehensive view of this subject.

AN INTRODUCTION TO BACTERIOLOGY. For Nurses. By HARRY W. CAREY, A.B., M.D., Former Assistant Bacteriologist, Bender Hygienic Laboratory, Albany, N. Y.; Associate in Medicine, Samaritan Hospital, and City Bacteriologist, Troy, N. Y. Price \$1.00. Philadelphia: F. A. Davis Company, 1915.

THIS little work is based on the lecture notes used by the author in teaching bacteriology to nurses during a period of eight years. There is no attempt to do more than present such of the principles of the science as are necessary for the nurse to know. The author is to be congratulated on having performed a difficult task with much skill; and the volume, while small and unpretentious,

is authoritative and well written. The book is commended to the notice of those in charge of our training schools for nurses.

MEDICAL LECTURES AND APHORISMS. By SAMUEL GEE, M.D. Fellow of the Royal College of Physicians, Honorary Physician to H. R. H. the Prince of Wales, and Consulting Physician to St. Bartholomew's Hospital; with Recollections of Samuel Gee by J. WICKHAM LEGG, Hon. D. Litt. in the University of Oxford, F. S. A., London; Sometime Assistant Physician to St. Bartholomew's Hospital, Lecturer on Pathological Anatomy, and Demonstrator of Morbid Anatomy in the Medical School. Price \$2.00. New York: Oxford University Press, American Branch, 1915.

THIS is the fourth edition of some of the more important lectures, papers, and articles published in his lifetime by Dr. Samuel Gee, together with a collection of aphorisms culled from his books and lectures. The fact that this publication has passed through four editions in a comparatively short time is witness to the interesting character of this record of personal experience. The "Recollections of Dr. Samuel Gee," as presented by J. Wickham Legg, picture him as a man of prodigious learning, not only in medicine, but in philosophy, history, and literature. The value of the book lies perhaps more in the delineation of a personality embodying the ideals of the highest type of physician than in the value of the medical knowledge with which most physicians conversant with medical literature are already familiar.

BANDAGING. By A. D. WHITING, M.D., Instructor in Surgery at the University of Pennsylvania; Surgeon to the Germantown Hospital and to the Southern Home for Destitute Children; Assistant Surgeon to the German and the University Hospitals, Philadelphia. Price, \$1.25 net. Philadelphia and London: W. B. Saunders Company, 1915.

IT is refreshing to find a book on bandaging that is just what it purports to be—namely, a book that teaches bandaging and does not also dabble in the diagnosis and treatment of fractures and dislocations, or present an incomplete, and hence more or less useless, discussion of subjects belonging to the realm of minor surgery. In this book Whiting is concerned solely with bandages and the methods of their application. The various materials used for the roller bandage and the best ways to prepare them for use are first discussed; then the cardinal principles in bandaging are enunciated; the fundamental bandages—circular, spiral, reverse, figure-of-eight, recurrent—are described and illustrated; and finally all the special types of bandages in common use in the various regions of the body are taken up in detail. There are also short chapters on the use of the many tailed and handkerchief bandages, these latter being especially useful in emergencies.

While some of the descriptions might profitably be clarified a bit, as, for instance, that concerning the application of the Velpeau, as a general rule the reader can scarcely mistake the directions, especially as the illustrations are often sufficient in themselves to indicate the course which the roller must take. We fully agree with the author in the statement that the muslin roller should be used by one who is learning the art of bandaging; and would add that while bandaging has not yet declined to such an extent as to be called a lost art, it is unfortunately true that the larger percentage of doctors and nurses of the present day and generation put on so-called bandages of which graduates of twenty or more years ago would be ashamed. Even if the young doctor has no pride in the matter, he should understand that a neat, comfortable and skillfully applied bandage makes an impression on the average patient and is thus an asset that will often put extra dollars in his pocket. This is a valuable book for those who wish to become proficient in the art of bandaging.

SEXUAL IMPOTENCE. By VICTOR G. VECKI, M.D., Consulting Genito-Urinary Surgeon to the Mount Zion Hospital, San Francisco. Fifth Edition, enlarged. Price, \$2.25. Philadelphia and London: W. B. Saunders Co., 1915.

THE previous edition of this book appeared in 1912. We note that the section on psychoanalysis contains double the amount of matter in comparison with the fourth edition; and the entire text on psychohygienic treatment has been increased by eighteen pages. In his latest preface the author calls attention to advances in instrumentation. He thinks the meddlesome surgery of the ovary of past days may be repeated in connection with the colliculus seminalis and seminal vesicles.

Society Reports.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, N. Y., May 16, 17, 18, 1916.

(Special Report to the MEDICAL RECORD.)

(Continued from page 1024.)

SECTION ON GYNECOLOGY AND OBSTETRICS.

Tuesday, May 16—First Day.

DR. GEORGE GRAY WARD, JR., NEW YORK, IN THE CHAIR.

A Further Report on the Technique of Abdominal Cesarean Section.—Dr. WILLIAM M. BROWN of Rochester read this paper. This subject had been presented by him before, when he had proposed a modification of the Davis operation into an extraperitoneal one. The present technique had been evolved on account of the evil effect of manipulation of the intestine, which accompanied most abdominal surgery. Every operator recognized the need of packing the cavity with gauze to keep the uterine contents from spilling into it, and also the need of keeping the abdominal firmly against the uterus. Assistants experienced great difficulty to hold these together till the child was safely delivered. It was found that patients who suffered from most shock, distention, and pain were the ones who had had most traumatism and handling in the peritoneal cavity. To avoid the slipping down of the uterus into the pelvis before the incisions were closed, Dr. Brown had devised at first a method of temporary suturing of the uterus to the abdominal wall, so that an assistant could be dispensed with. This prevented emptying of the uterine contents and protected the viscera from handling. It was at first feared that excessive hemorrhage might result from this method, but it was found that the bleeding was more easily controlled than in pelvic delivery. Later a procedure had been introduced which simplified the procedure still more; this was to use from four to six of the ordinary towel clamps of Moynihan or Backhaus, and clamp the uterus firmly to the abdominal wall, instead of using sutures. Dr. Brown gave an analysis of 15 cases treated in this way, in which there had been no deaths, and recovery had been remarkably comfortable and free from vomiting and distention. His conclusions were therefore, that (1) fixation of the uterus to the abdominal wall before delivery possessed distinct advantage to the patient, protecting both from infection, and from subsequent pain and discomfort; (2) patients who underwent this operation did not suffer more hemorrhage than under the old form of operation or of pelvic delivery.

Dr. MILLER of Syracuse said that nothing particular was gained by fastening the uterus to the abdominal wall. Infection was not likely here, it might do harm in the endometrium, after the placenta had been removed and would be more serious than in the peritoneum.

Dr. BRYAN said that he had used a similar technique, but he had better results since he had been doing the Davis operation with high incision, and he had paid very little attention to the contents of the uterus and whether they escaped or not. He made a special point of telling the assistant to keep his finger in the upper angle of the uterine wall and let the operator do the rest. He had attempted to suture the uterine wall to get a mechanical grip, but it cost extra time and traumatism. If one succeeded, one had not accomplished much.

Dr. BROWN, in closing, said that he had one case of infected uterus in a hysterectomy case. He did not know the patient had elevation of temperature, and she was already on the operating table and he was not told until the operation was finished. He was impressed with the fact that while the woman had a severe sepsis, chills lasting 25 minutes, temperature 106 deg., there was no infection of the peritoneum whatever, it was a pure septicemia. She got perfectly well.

The Influence of Luetic Invasion in Gynecology and Obstetrics.—Dr. J. WESLEY BOVEE of Washington, D. C., read this paper by invitation. He stated that prior to 1905 the diagnosis of syphilis was based entirely on clinical evidence. The discovery of the *Spirochæta pallida* in that year, and the Wassermann test in 1907, made scientific diagnosis of the disease certain. Arsenic

having been found in the endometrium and menstrual blood, its use promised well and it had been found efficacious in treatment; Ehrlich's announcement of "606" in 1909 was therefore received with rejoicing. While this had not proven entirely specific, it was undoubtedly of great value. The foremost evidence then of the presence of syphilis rested upon the finding of *Spirochæta pallida*, although its absence did not prove absence of the disease. The Wassermann reaction might be stated to be about 84 per cent. specific, though not absolutely diagnostic. Care in the technique might make it more certain, and reliable tests were very desirable, especially in the negative histories and "denied" class. The disease was found to be about eight times as frequent as admissions would state. There was found to be an alarming prevalence of lues among those who denied having it, or who presented no symptoms of it. Morrow and Neisser stated that 5 per cent. of the German population, and 2 per cent. of the population of the United States had been infected. In 619 cases collected from gynecological and obstetrical clinics by the reader, there was a probable total of 38 per cent. infections; about 60 per cent. of these were white women. Luetic infection in females was much more obscure and easily overlooked or mistaken for other conditions than in the male. Cervical chancre closely resembled erosions and infiltrations. In one case seen, there was marked resemblance to cervical cancer. Local manifestations of luetic invasion of the female genital tract were slight, evanescent, and disappeared without leaving trace, and commonly escaped detection. Tertiary lesions of the cervix, however, were sometimes seen. Possibly spermatozoa carried spirochaetes into the ovaries and tubes, but thus far this was unproven. Dr. Bovee then considered the relationship of lues, as regards, which he said was highly important. He discussed the probable routes of infection from mother to child, and also the reliability of Colles' law, which he said should be subject to revision. Dr. Bovee felt that there was no such thing as a healthy mother with a syphilitic child, and *vice versa*. Infection was latent in one or the other. He felt that once a diagnosis of lues was established treatment should be as vigorous as was compatible with safety. It would seem beneficial perhaps to regard all patients as at least mildly luetic and to apply antiluetic treatment. Short of this activity patients were not receiving due care on the part of the obstetrician. Should compulsory diagnostic laws be enforced, immeasurable benefit might be hoped from them, and the capacity of insane asylums would not be so severely taxed. Tuberculosis was a harmless disease as compared to syphilis.

Dr. T. J. WATKINS of Chicago said that all gynecological and obstetrical cases should have the Wassermann test. Two papers had appeared which brought out very emphatically the need of this test. A man who had made examination of 4,000 cases found that of those who had a positive Wassermann 50 per cent. were women in whom syphilis was not suspected. The importance of that was very evident. In a paper recently read before the American Gynecological Society it was stated that the Wassermann test was found positive in 50 per cent. of unsuspected cases. Recently in Chicago they had been making a Wassermann test of all ward cases and had been very much impressed with the frequency of the positive reaction where it was not suspected.

Dr. G. G. WARD of New York said the matter was of interest in regard to the question of Colles' law which they had been led to believe was proven incorrect. At a recent meeting in Washington, however, Dr. William Whitridge Williams read a case which seemed to prove that this law might hold good. He had a case in his service of a negro woman who had had 11 labors, under his control. She had had repeated Wassermann's but all negative. The first five labors were perfectly normal, the sixth was twin birth, and one child was markedly syphilitic and one not. This was probably a case of superfecundation. Subsequent labors under observation gave no evidence of syphilis. The woman never showed syphilis. If the woman had two lovers at the time of conception, it would be the strongest evidence that there was reason to believe in the validity of Colles' law.

Diagnosis in Gynecology; What a Routine Physical Examination of the Female Pelvis Should Be, and What It Should Accomplish.—Dr. THOMAS J. WATKINS of Chicago read this paper by invitation. He apologized for presenting an elementary subject to the meeting. He felt, however, that standardization of methods was very necessary. Palpation should mean comparison of pal-

pation of one part with another. Such comparisons must have some value. Kidneys should be palpable in a very large number of cases, except where there was heavy deposit of fat. They should be palpated by putting one hand under the ribs in the usual position, elevating slightly, and putting a delicate vibratory pressure, just as one would engage the uterus or ovary between the hands. If one was not certain, the hand should be shifted to a point where no palpation was obtained, and then by going back. Palpation of an enlarged lobe of the liver, or of an enlarged gall-bladder, had to be carefully distinguished from the kidney palpation. Dr. Watkins found the normal appendix a thing of the imagination, but of the chronic appendix he said that, on palpation, there should be more tenderness over the appendix than over the corresponding point on the opposite side. It was often important to let the patient do the palpation, as the amount of pressure that could be borne could be judged and there was no stimulus to contraction of the muscles. The facial expression of the patient was also important.

Dr. MILLER of Syracuse said he had listened also to Dr. Watkins' paper with pleasure, but he would like to go a little further than Dr. Watkins in the subject of abdominal palpation. Dr. Watkins had told them the necessity of appreciating the position of these organs in their normal and pathological positions. The touch should be educated to appreciate these. This work was not easy and could only be acquired by those who were constantly doing it. To them it was simple and familiar. Cases were constantly seen, however, that varied from the supposed condition. Many diagnoses erred. There was a page in the *American Journal of Obstetrics* where there was a picture of a hand and in the index finger there was placed an eye. If it were possible, the speaker said he thought that surgeons should have an extra eye in the index finger, so that they could reach conclusions in pelvic palpation.

Torsion of the Pedicle of Ovarian Cysts Complicating Acute Appendicitis.—Dr. ROSS G. LOOP of Elmira read this paper. This condition, he said, was first mentioned by Rokitawski, in 1841, and in 1855 thirteen cases were reported. A large literature had since grown up on this subject, dealing mostly with conditions in pregnancy and the puerperium. It was three times as frequent in pregnant as in nonpregnant women. Operations had been reported on children as young as three years. As a complication of acute appendicitis, torsion of an ovarian cyst must be so common that it is not reported, or it must be very rare. Dr. Loop had been able to find eight cases in the literature and he could add four cases from personal observation. In all the cases the appendix was clearly and primarily involved. The diagnosis of cyst should be made before acute symptoms supervened. The causes of torsion were many: the tendency for organisms to grow spirally; the length of the pedicle, the freedom from adhesions, the heavy lobular state of the cyst, all were predisposing causes. Emptying or filling of bladder or rectum, violent peristalsis, increased pressure, coughing, vomiting, lifting, falls, or jolts might all cause rotation in a cyst, which often was insecurely balanced. Muscle spasm, vomiting, and distention, so often accompanying appendicitis, were frequent features that would favor torsion. The results of sudden strangulation were gangrene, infection and peritonitis, without any increase in the size of the cyst. The cyst became edematous, dark, with thrombosis of the veins, with more or less bloody contents.

Wednesday, May 17—Second Day.

Results and Technique of Vaginal Subtotal Hysterectomy for Prolapsed Uterus and Cystocele, Associated with Fibroid Growths or Fibrosis Uteri.—Dr. HIRAM N. VINEBERG of New York presented this subject. In a method described before the New York Academy of Medicine in February, 1913, Dr. Vineberg said he had dealt with amputation of the body of the uterus at the internal os, and the use of the cervical stump to hold up the bladder by anchoring it to the subpubic fascia. He claimed that this method possessed several advantages over total hysterectomy, in supporting the bladder. It was also attended by less hemorrhage. At that time ten cases had been thus treated, but since then twenty additional cases had been operated upon. The technique was as follows: (1) Longitudinal incision of the anterior vaginal wall, extending from near the urethral meatus to within an inch or an inch and a half of the cervical os; (2) separation by sharp or blunt dissection of the vaginal walls from the underlying bladder; (3) pushing of the bladder up from the

uterus and base of the broad ligament by gauze dissection; (4) transverse incision of the vesicouterine peritoneal fold; (5) delivery of the body of the uterus through the vaginal incision; (6) if the ovaries were to be preserved a ligature was passed round the ovarian ligaments and the tissues cut between the ligature and the uterus. If they were to be removed, the ligature was passed around the infundibule pelvic ligament; (7) a ligature was passed at the level of the os internum; the body of the uterus was amputated at the desired level by a wedge-shaped incision, the thin edges of the wedge toward the cervix; the edges of the wound then brought down by continuous cat gut suture and the raw area of the cervix sutured laterally in the same way; (8) the cervical stump was then sutured to the subpubic fascia and anterior vaginal wall. Further modifications of this operation would be the shortening of the utero sacral ligaments to prevent the cervical stump from pushing downwards. Of 32 cases 25 had given excellent results. One was a failure.

Technique of Vaginal Plastic Operations for Cystocele and Prolapse of the Uterus.—Dr. R. T. FRANK of New York said that this was an attempt to standardize technique in order to obtain more uniformity of results. The technique was described which in ten years had given most uniform results and which was most readily taught to house surgeons. The operation for cystocele was as follows: Anterior lip of cervix seized with volsellum and pulled to vulva; mucosa seized with artery forceps half inch below mucosa; mucosa incised between the two fixed points and reflected on both sides for one-half inch along line of incision superficially; neither deep or wide reflection being permissible; narrow flaps on each side seized with two forceps by assistant at lowest angle of wound, bladder freed from cervix in median line by snips of scissors; the bladder freed by pushing firmly upward against the cervix until lateral fibers become plainly demarcated; after exposure of these bladder pillars, vaginal flaps to be separated more widely; a thin line of fascia continuous with the pillars to be preserved. The repair was to be done as follows: Two transverse sutures of medium chromic cat gut passed, taking in first one pillar then the cervix, then the opposite pillar; upper suture passed at lower border of peritoneal reflexion, the next one-half inch below it; pillars united firmly in the median line by tying, thus raising the bladder to a higher level and making it flat instead of bulging. For rectocele the repair was as follows: After exposure, the rectum should be pushed away from lateral structures, with the finger. The approximation should take place at the descending rami of the pubis. The rectum should be held aside and a mass of tissue grasped and a heavy chromic cat gut suture should be passed, taking in lateral fascia and underlying muscle on one side, then forming a partial purse string suture, grasping the rectal fascia between rectum and mucosa, around the upper part of the rectocele, and again grasping the lateral structures on the opposite side, the suture being tied. The rectum was thus firmly held fixed and back. The gap in the mucosa should then be sutured with interrupted silk sutures as this region later became less accessible.

The Usefulness and the Definite Limitations of the Pessary Treatment of Retroversion and Prolapse.—Dr. R. L. DICKINSON of Brooklyn read this paper. He said that the pendulum had swung from one extreme to the other in the treatment of retroversion, in former times it had swung too much towards pessary treatment, and now it swung too much to the surgical side. One often heard sweeping condemnation of pessaries but it could be safely said that there were a great many cases of retroversion, that were practically symptomless, that could well be left alone. In the group that might be taken care of by pessaries could be included: (1) The retroversions of early pregnancy; (2) postpartum retroversions; (3) "bad risks"; (4) a few cases where retroversion affected the bladder. To the operative class belonged the cystocele and rectocele group. Dr. Dickinson said that he was more inclined than formerly to operate upon elderly women. They stood operation well and might have twenty years to live after an operation. They should be given a choice of operation or be told that they would have to wear a pessary for the rest of their lives. Working women as a rule should be operated upon. They had no time to keep coming to the physician's office to be examined. In the case of young girls it was better to do an operation rather than give them the "office habit." There was distinct use for a pessary for a few months after operation, until the organs had had time to recover tone.

Dr. J. RIDDLE GOFFE of New York said that the usefulness and the definite limitations of the pessary in the treatment of retroversion and prolapse had been very clearly and convincingly presented by Dr. Dickinson. In his mind and in his practice the pessary had a definite place in the treatment of these conditions, but speaking broadly, it was only a temporary device, to be discarded and supplanted by operative procedure when the time and place served. Age was rarely a contraindication for surgical procedure in a woman who was able to be upon her feet. He found that old women stood vaginal operations surprisingly well, and the age of women in the sixties or seventies, in itself, did not forbid the surgical procedure. Passing to the discussion of Dr. Vineberg's paper, Dr. Goffe said he had a very limited experience with the operation described, and then more for the purpose of testing it out than because of its appeal to him as a rational and desirable operation. He was a great stickler for following Nature, in her arrangement and physiological function, in dealing with all human organs and indeed with every part of the body.

Dr. THOMAS J. WATKINS of Chicago said the pessary was tending to go out of use on account of its abuse. It had a very important field, even if a limited one. As regards prolapse operations, he felt that Dr. Dickinson had mentioned a very important thing in regard to cystocele and rectocele, that was that conditions got worse especially menopause so that rectocele and cystocele conditions should usually be corrected before they became extensive, so that operative procedures in this class of cases gave better results. In regard to the transposition operation, considering the results after 8 or 10 years, the more he studied the subject, the more and greater problems he encountered. There was, he felt, no one operation that was best for prolapse of the uterus or of the bladder. Operative procedure should be modified to suit the case. In the transposition operation there was danger of protrusion of the fundus. That might be the fault of the operator, the fault of the selection of the case, or the fault of the technique. If one removed the uterus, and sutured the broad ligaments and thus supported the bladder, there might be failure of good union and the cystocele would recur, then it was impossible to do anything for that patient short of obliterating the vaginal canal. If, however, one did transposition operation, it was easy to do a second procedure to correct any difficulty.

Dr. E. MONTGOMERY of Philadelphia said that he heartily agreed with Dr. Watkins that the operation should be adapted to the condition rather than that the patient should be adapted to the operation. There was no one operation adaptable to every class of patient.

Dr. H. S. CROSSEN of St. Louis said that he wanted to express appreciation of the papers and demonstrations he had seen presented that morning. He was especially pleased to see the subject of the pessary so clearly demonstrated by Dr. Dickinson. There was just one class of cases that he had hoped to hear Dr. Dickinson speak of, but he had not. That was the class of cases in which there was no shelf left for support. The ball pessaries would slip out in half an hour. The Smith pessary and other forms would slip out. In that type of case he had used the double horse shoe pessary. This should come into the hands of the general practitioner. It would be more and more used when understood.

Dr. J. W. BOVEE of Washington, D. C., said that the further one got away from any one particular operation, or from any one form of treatment, the safer one was. Those that were addicted to one form of operation would find that they would have to use pessaries after operation, not as some noted surgeons had done, shortly afterwards as precautionary measures, but months later as reputation-savers. He felt that the best time to use a pessary was before operation. A large proportion of cases could then be helped. If the pessary was the right one it should not give symptoms. If it gave pain, it was not the right one.

Dr. R. R. SMITH of Grand Rapids said that he indorsed most heartily what Dr. Dickinson had said in regard to the indications for the use of the pessary and of operations in cases of retroversion; especially what he had said in regard to cases which should be left without treatment in any form. In young girls and young married women before child-bearing there was nearly always a neurotic element and the less attention called to the pelvis the better. In older women operation alone should be used in certain complicated cases. But it would be well to bear in mind one thing. In

women during the child-bearing age there should be no operation done which would interfere with this important function.

Dr. LEROY BROWN of New York said there were two ways of dealing with large uteri: Taking a wedge out of the uterus and bringing it down so that it would not protrude from the vagina, and Dr. Vineberg's method, of taking the uterus up in the anteroposterior diameter, and making it shorter instead of narrower. There was only one objection to this, and that was that by passing the structures anterior to the anterior wall, there would be a predisposition to pushing down of the cervix, as Dr. Vineberg mentioned occurred in two or three cases. The cervix should be well imbedded so that there could be no fulcrum action. He would not recommend such an operation in complete procidentia. He felt that the operation which would give the best result would be complete hysterectomy, sewing together the broad ligaments and putting the bladder on the top of them.

The Genital Reflexes and Their Role in the Production of Symptoms Arising in the Pelvis.—RICHARD R. SMITH of Grand Rapids, Mich., said that the study of function had recently become as interesting as that of pathology, and that the relationship of both must be considered, so that the capacity of a crippled organ for work and recovery of its functional equilibrium might be estimated. Careful study of the physiology of the pelvic organs led to establishment of a fact, sometimes neglected, that perfect function depended upon integrity of the parts and also upon certain ductless glands, constitutional conditions, and the behavior of the nervous system. It would be the work of the future to distinguish between disturbances due to disease or injury to the pelvic organs, and the so-called functional disturbances. There were rich fields for investigation, such as the menorrhagic conditions associated with hyperthyroidism, the amenorrhoea of tuberculosis, or conditions arising from disturbance of the nervous system. He would particularly deal with the latter group. The genitourinary reflexes might be divided into two groups, first, those belonging to the spinal and sympathetic system, second those of the higher cerebral centers. The first group were automatic, simple and unconscious, and were designated as subcortical, and the latter were psychic. The first group of reflexes were able to maintain normal generative functions, for women with transverse lesions of the cord were able to menstruate and conceive, and had normal labors. Dr. Smith then dealt with various sympathetic reflexes, such as contraction of the anus and perineum which was protective in character, contraction and retraction of the uterine musculature and production of secretion from the Bartholinian glands. The psychic reflexes belonged to the higher development of the brain. Their stimuli was physiological, the psychological beginning when the impressions had reached the cortex. Perceptions varied with the quality of stimuli. Only exaggerated processes reached consciousness. The mental make up and sum total of experience determined mostly the manner of the reflex. The purpose of some reflexes was clear, such as contraction at the fear of some object, or the production of the secretion of the Bartholinian glands, but some reflexes were more obscure, such as blushing under embarrassment, or violent movements of the intestines under fright, or cessation of menstruation after shock or grief. These were all conscious reflexes, but some were not under the direct control of the will. The mechanism of emptying a full bladder illustrated the employment of both psychic and subcortical impulses. The application to gynecology was this, that the mental make up of the patient might produce irrational ideas and distortions in the presence of a perfectly normal pelvis. It was the misrepresentation of very slight functional disturbances which led to a lot of harmful and useless surgery. When but slight lesions were present the mental picture must be considered as the direct cause of symptoms arising from the pelvis. The stress of patients living under emotional unbalance produced great exhaustion and fatigue, even under conditions that would seem to be conducive to normal life.

Gynecological Surgery in Hysteroneurasthenic Patients.—Dr. H. S. CROSSEN of St. Louis said there were three questions to be asked. (1) Was operation indicated? (2) If indicated, what was the preferable time for operation, before or after the course of neurologic treatment? (3) When operating should more or less conservatism be practiced than in an individual with a normal nervous system? In regard to the first

question he said that where the pelvic condition was seriously depressing the general health through blood loss, or pain due to lesion, the lesion should be removed, irrespective of the co-existing nervous disease. Cases had to be carefully studied as there were two types to consider, first, those in which the chief symptom was pelvic pain, with a lesion which accounted for this; and second, those in which the symptoms were extra-pelvic, but were supposed to be due to intra-pelvic lesion. In markedly neurasthenic patients, where pain was of secondary importance, operation was contraindicated; but, if prolonged treatment with all ordinary measures failed to relieve pain, then operation was indicated. In the second group operation would relieve only in so far as nutrition was affected by the lesion, and in so far as general nervous irritation might be allayed. To the second question as to when operation should be performed Dr. Crossen said that when it was necessary sooner or later, it had better be done before neurological treatment. Rest in the hospital might give a good start to the recovery of the patient. But, if the influence of the lesion was questionable, the neurologic treatment should come first as, with treatment, operation might be rendered unnecessary. This treatment should be by a competent neurologist. As regards to the amount of conservatism necessary in operation on these nervously unstable patients, the safest rule to follow was "Radicalism until the last ovary is reached and then great conservatism." Instability of the nervous system made the complete removal of the ovarian influence exceptionally hazardous, consequently, every effort should be made to preserve an ovary or a functioning part of it. This rule should be modified in regard to young patients or when a patient had very strong wishes on the preservation of menstruation. When menstrual function was accompanied by so severe and prolonged pain as to indicate elimination of the function, hysterectomy with preservation of an ovary was better than with double oophorectomy.

Practical Aspects of the Internal Ovarian Secretion.

—Dr. W. P. GRAVES of Boston said that he intended in this paper to point out certain matters of clinical importance in the bearing of physiology of the pelvis on modern gynecology. The importance of the ovarian secretion was shown in its influence on the external genitalia. Ovarian extract was shown to have great effect on castrated animals, though it was not known exactly how this influence was exerted, nor the exact source of the important element in the substance, whether from the whole ovary or from the corpus luteum. The importance to the gynecologist was its relation to deficient genital development as hypoplasia and infantilism, and secondly natural cessation of ovarian function, namely, atrophy. In considering the general bearings of this subject from the standpoint of gynecology Dr. Graves came to the following conclusions: (1) That in genital atrophy there might occur abnormalities of great importance to the gynecologist. (2) That circulatory disturbance of the external genitals, such as kraurosis and furunculosis of the vulva, might be greatly relieved or cured by the administration of ovarian extract. (3) That ablation symptoms were, in the great majority of cases, markedly relieved by administration of ovarian extract. (4) That after hysterectomy, vasomotor symptoms followed transplantation of ovarian tissue and also leaving of the whole ovary in situ, occurred similar in degree and frequency to those following total ablation of the ovaries. This condition and (5) functional amenorrhea in the young were often relieved by the administration of ovarian extract. (6) In the experience of the writer, extracts of the whole ovary were more efficacious than extracts of the corpus luteum in organotherapy.

A Review of Five Hundred Cases of Pelvic Infection with End Results.—Dr. JOHN O. POLAK of Brooklyn read this paper. He said he found the end results of pelvic infection very illuminating, in regard to records of conservatism, operative and non-operative. They had made a careful study of cases treated surgically and non-surgically, with regard to etiology, clinical course, pathological findings, condition on discharge, and anatomic symptomatic cures, after re-establishment of pelvic function. Cases included: Non-operated cases; cases operated on for sterility, after symptomatic cure; cases where infected structures were removed, but with preservation of menstrual function; cases in which uterus and tubes were ablated; and last, cases in which panhysterectomy and double salpingo-oophorectomy was done. Study of results of conserva-

tion of ovaries, with resection or suspension had caused them to swing toward more radical treatment, because it had been found that it was useless to conserve ovulation without menstruation, and that a conserved ovary behaved badly in cases of pelvic infection. It tended toward cystic formation and pain, and the trauma and circulatory disturbance disturbed the functional activity. Another important point was that no operation should be undertaken during the acute stage of infection, or when exudate was present. Bacteriology of the infection was important as different organisms had different histories. Gonococcus and streptococcus infections differed widely, the former causing suppurative salpingitis, oophoritis and peritonitis, the latter lodged almost always in the parametrium. In non-operative cases, patients suffering from post abortive infections, the women were very ill on admission. They were put in a high Fowler position, a rectal tube was inserted, ice bags were applied to the lower abdomen, and absolute gastric abstinence was enforced. Later, whenever possible, the patients were kept in the fresh air. Some cases required drainage by posterior colpotomy. Of 104 patients 101 recovered. Another class of 168 women wished to be cured of sterility. They presented a similar history, of poor health since marriage, and if they had been pregnant, birth was followed by pain, leucorrhea, or some menstrual anomaly. Examination of the husband generally showed evidence of former indiscretion with presence of infective cocci in the prostatic urethra. In few of the women were gonococci found. Sterility, dyspareunia, and leucorrhea were the symptoms. Of the 168 cases, only 20 could be relieved of sterility. The next class consisted of 107 women, with gross pelvic masses, in whom infected structures were removed, yet menstrual function was conserved. Eighty of these women remained well. Others returned for reoperation for metrorrhagia, menorrhagia, or cystic ovary. The fourth group comprised 89 cases, in some of whom a portion of the ovary was conserved. These results were among the most disappointing, and 15 had been reoperated, as headaches, flushes, sweats, etc., and burning pain over the ovary had followed. The final class comprised 22 women in whom such pathological destruction had taken place that any conservation was out of the question. These women all recovered. Climacteric symptoms were prominent in four; the others had good general health. One important conclusion from this work was that total extirpation was better than conservation of vitally impaired structures.

Infection of the Uterine Appendages; Its Sequelæ; Its Non-sacrificial Treatment.

—Dr. E. E. MONTGOMERY of Philadelphia said that infection of the appendages was favored by any condition that favored congestion of the pelvic structures. These conditions lowered resistance of the tissues and promoted nurture of the infecting elements. The infection spread by the mucous surface, accentuated by the disturbing influence of menstruation. The most usual organisms were gonococcus, staphylococcus, streptococcus, colon bacillus, tubercle bacillus, pneumococcus, and influenza bacillus. The gonococcus was most superficial in its effect, but prepared the ground for other organisms, and was thus more baleful in its work. Nature endeavored to protect herself by closing up the tubal ends against the invader. Sometimes the infection was so virulent as to prevent this, sometimes so slight that it did not take place. The peritoneum was sometimes directly infected through the wall, causing an extensive abscess involving the tube and ovary. Such effects necessitated the sacrifice of the organs. Causes of infection might be impure sexual relations, want of care in labor or abortion, or severe pelvic inflammation from infection, in which sometimes relief could be obtained by drainage through the vagina. In these acute infections the plugged up tube became a sac filled with serous, bloody, or purulent contents. All the adjacent structures might become involved, and the ovary might become a mere abscess cavity filled with pus. Should such a case fall into the hands of a surgeon who advocated prompt surgical treatment for all pelvic inflammation, sacrifice of the appendages would be made. This procedure would break down the barriers raised by nature and even more dangerous extension might take place. The limited number of gynecological beds in hospitals and the urgent desire of patients to go home, frequently hurried the resort to surgery, but the frequent cases of women who had had pelvic peritonitis justified careful revision of the procedures. It required moral courage to contest the brilliant results obtained by surgery,

but preservation of function was of highest importance to the woman. To do this absolute rest, promotion of elimination, establishment of early immunity and perfect cleanliness were essential. If pus collected in the pelvis it could be reached by vaginal incision and drainage. Finally even in abdominal exposure the structures should be preserved unless absolute destruction and extensive invasion existed.

Resection of the Pars Interstitialis in Diseases of the Fallopian Tubes, with the View of Preserving the Uterus.—Dr. L. K. P. FARRAR of New York read this presentation. Dr. Farrar said that to the thoughtful surgeon, one of the most difficult problems that gynecology presented was what to do with diseased fallopian tubes. If drainage through a vaginal incision, or if salpingostomy could be performed, that should be done, but if one or both tubes were hopelessly diseased their removal would seem imperative, and that of the uterus also, because the stumps of the tubes left would be a source of metritis and discharge, or the site of intestinal adhesions. Also, without the tubes, the uterus served no purpose. The stump of the fallopian tube, or the pars interstitialis, might be the seat of various growths or polypi, due, according to Chiari, to old gonorrheal salpingitis. It seemed true, owing to the pouch-like form of the pars interstitialis, that it was a source of continued infection, most frequently gonococcal. This was not always the case. Many uteri recovered after resection of the tubes. Possibly with the removal of the primarily infected part, the immunes developed in the rest of the pelvis were able to take care of the rest of the infection, but this could not always be hoped for. Therefore, resection of the entire tube was considered. The operation consisted of the following steps: (1) Preliminary curetting and disinfection of the uterine cavity; (2) laparotomy incision, inspection of ovaries (oophorectomy only to be done where imperative); (3) ligation of the ascending branch of the uterine artery; (4) excision of tube down to the uterine mucosa; (5) closure of wound with interrupted sutures. Twelve cases were quoted with good results and return to menstrual habit. The question then was was the uterus a useless organ after removal of the tubes? Dr. Farrar stated that a definite cycle of changes took place in the uterine mucosa in the menstrual cycle. Menstruation rightly considered, was the ultimate excretory expression of the internal secretory phenomena which occurred in the whole organism, and not only a local function of the uterus and its adnexæ. As Vigne expressed it, it exercised "a therapeutic effect on the health." The whole system had been planned for this periodic outlet and with difficulty the life of woman learned to adjust itself to its loss. Dr. William Polk, in 1893, in opposition to Lawson Tait and Robert Battey, had protested against the removal of the tubes and ovaries. He had defended his position with a broad knowledge of pelvic surgery and deep discernment into the needs of his patients. To quote the closing of the discussion he had said, "I can say that the woman has the right to have the operation tested. None of the patients I have operated upon has died. . . . The operation is a simple one, and I can assert that it is efficacious. . . . My wish is simply to give the woman a chance to retain organs which she values if we do not."

Renal Tuberculosis.—Dr. HENRY DAWSON FURNISS of New York read this paper. He said the presence of pus or red cells in the urine of women with leucorrhea, or bloody discharge, was not apt to be attributed to the right condition. Every such symptom should be accounted for. Sins of omission were many, and he had known patients who had had symptoms for years, which should have suggested correct diagnosis. Of 33 personally observed cases, in 20 per cent. there was history of other tuberculous lesions, of these 15 per cent. were associated with pulmonary tuberculosis. In 50 per cent of cases cystitis was the first symptom; in 15 per cent. microscopical hematuria, this was followed by cystitis. He thought that the hematuria was vesical rather than renal in origin. Renal or ureteral colic pain was seen in 15 per cent. of cases. The cystitis was found to be the most distressing symptom, and engendered loss of sleep from frequent urination. Nephrectomy was advised for this, before extensive bladder involvement had taken place. Pyuria was present in every case. Tubercle bacilli were found in slide in 85 per cent. of the cases. This appeared high, but was probably an understatement. Very early and very late lesions often showed no tubercle bacilli. A method of Crabtree of centrifuging urine at low

speed to throw down the pus cells, and the supernatant fluid at high speed, rendered finding of the bacilli easier. Temperature did not seem to play an important part in this infection. The affected kidney was rarely found enlarged. In all except early cases there was bladder involvement, characteristic of tuberculosis. By the time patients applied for treatment the lesions were advanced enough to show characteristic changes. These were redness and induration of the ureteral orifice, often with nodular irregularities. With progress of the disease the induration increased, the meatus became more involved, the trigonum retracted, the ureter shortened. Later ulceration occurred and finally the whole bladder became lined with granulation tissue. In cases of long duration the ureter was involved, and in catheterized urine the finding of tubercle bacilli was evidence of tuberculosis of at least one kidney. General health of these patients was usually good. Most cases were nephrectomized, with ligation and division of the ureter. The percentage of post operative fistulae was about the same whether drainage was used or not. Perhaps undrained cases gave better results. It seemed better to excise the ulcer through an extra incision, extraperitoneally. Only one death had occurred as a result of operation, but this was a case complicated with pulmonary tuberculosis. About 30 per cent. of post operative fistulae had been reported, but this did not seem detrimental to the health of the patient, even though it lasted for as long as two years. Patients with long involvement seemed to do better and to have developed better immunity than those who had had the disease for a short time. After the operation there seemed to be a typical tuberculin reaction, exacerbation of other tuberculous processes, and rise of temperature, this being apparently due to liberation of tuberculous material into the body. About half of the patients seen were between 20 and 30 years of age. It was essentially a chronic disease and seemed to be rather frequent. The prognosis in operated cases was good.

Thursday, May 18—Third Day.

Some Mistakes in the Diagnosis of Ectopic Pregnancy.—Dr. C. C. LITTLE of Geneva, N. Y., said that this was a condition that was rarely recognized, and in spite of the fact that some writers asserted that it was a condition in which the diagnosis was written all over the face of it, it was a fact that diagnosis was frequently not made until rupture had occurred. Very divergent opinions had been expressed on the subject, some asserting that 40 per cent. of hospital cases were diagnosed incorrectly and that 50 per cent. of private physicians failed to recognize the symptoms, until after hemorrhage had occurred. It seemed, however, certain that physicians were not sufficiently alert to discover the condition which was frequently mistaken for acute appendicitis. The cases could be recognized as acute abdominal conditions. There was abdominal pain, vomiting, rigidity, and often overdue catamenia. Often other conditions, such as pyelosalphingitis, hydrosalphinx, gallstone disease, or cholecystitis were mistaken for ectopic pregnancy. In some cases of ectopic pregnancy the symptoms were not so severe as in acute appendicitis. It behooved the physician to think about, write about and talk about these cases, to find out just what were the characteristic symptoms. Considerable suspicion should be attached to a menstrual flow from five days to a month overdue, and the character and amount of the flow should be observed carefully. Pain was present in 80 per cent. of all cases, and a great diversity of symptoms which made diagnosis a difficult matter. This should, however, not be deferred until the classical rupture symptoms occurred, but when the symptoms were mild and before the disease had become urgent.

Dr. MILLER of Syracuse said that the subject which had been presented was of too great importance to pass by without making some comments upon it. It had given him great pleasure to listen to the paper. In the first place, in discussing this subject, he had come to feel that certain diseases were like pictures hung in memory's halls. They were so vivid on account of associations with them that they would be recognized under all conditions. The picture given by Lawson Tait was one of the noblest things ever given to the surgical world. Although ectopic pregnancy was a frequent condition, there were many physicians who had never met with a case, in the course of a long experience. That was because many cases had not been appreciated and some deaths had taken place without the discovery of the true pathology. The conditions found localized in the pelvis would never be known by any one symptom

at all times, and one saw cases where there were no symptoms until after hemorrhage had taken place, and then early death might ensue. It would depend upon which part of the tube gestation had occurred and the patient might die before interference could take place. Physicians of the present day were better educated to recognize the symptoms than in the past, although the specialist saw more of these cases than other men because the cases were referred to him when met with. The fact that the ordinary physician received two dollars for diagnosis of these cases, instead of one hundred dollars as did the specialist, was no reflection on the diagnostic ability of the general practitioner. Nor was it a reflection on the hundred dollar man. A man had to do the best he could for the patient and money should not enter the question. It was a very difficult matter to diagnose ectopic pregnancy before rupture, although there might be certain characteristic symptoms. If the patient was under observation, and then rupture occurred, the physician might well know that something definite had taken place, but clinical pictures differed so materially that the physician had to reach conclusions by physical findings. Finding a lump on one side of the uterus might mean salpingitis, or it might mean ectopic gestation. In the presence of ectopic pregnancy there might be a rise of temperature, but the temperature taken by mouth did not record a very low grade of temperature, and a low grade inflammation in the tube might be due to salpingitis. These two conditions might well be found in association, the ectopic pregnancy on the one side and the salpingitis on the other. Unfortunately the case was often not brought to the attention of the physician until after rupture. Thus there were in the pelvic physical findings, confirmed by clinical history—a condition threatening the life of the patient which could not be absolutely foretold. Where there was lateral enlargement, there might be pain and spotting, but sometimes all symptoms were absent. The condition, however, might be very serious, and when there was doubt it should be put up to the patient that she should have operative work, if it was salpingitis the operation would do no harm; if it was ectopic the life would be saved and the patient would recover. He said he had operated on one hundred cases without any mortality, and then unfortunately the next three cases died.

Accidental Hemorrhage and Its Treatment.—Dr. JAMES K. QUIGLEY of Rochester, N. Y., discussed in this paper the opinions on the frequency of this condition and its treatment. Many writers considered it very infrequent, but in a small service he had had experience of four cases. In these cases there was a coincident albuminuria. Williams in 1915 published a monograph reporting two cases, in which he found microscopical infiltration of the uterine wall with blood, due to arterial changes with thrombosis. It seemed probable that toxemia caused both hemorrhage and a nephritis, the latter being the effect rather than the cause. The symptoms were usually sharp, constant, abdominal pain, sometimes followed by collapse. When the hemorrhage was concealed, and not free, it seemed to occasion more shock to the patient. The uterus was extremely tender and the fetal heart difficult to locate. Rupture might occur into the amniotic sac. The danger of a post partum hemorrhage later was present when the patient might die in shock. The operator should be ready to pack the uterus, as, in the external hemorrhage cases, the shock was proportional to the blood loss. In these cases the mortality was the highest for both mother and child, of any obstetrical complication, being variously estimated by different writers, but apparently averaging 80 per cent. for the mother and 73 per cent. for the infant. Cesarean section often proved the best means of delivery in these cases, but in very severe uterine bleeding hysterectomy had sometimes to be resorted to in order to save the patient's life.

Dr. G. G. WARD said that he would like to say a word on this subject. He had had a case a few months before of external hemorrhage. The patient was a primipara, 27 years of age, in poor general condition. She had evidence of Graves' disease, though it was apparently quiescent. She had slight exophthalmos and enlarged thyroid. She was waiting in the hospital until term and at term she started in labor. The head was engaged in the pelvis, when almost immediately she started in with a profuse hemorrhage of great quantity. She was attended by an assistant, who thought it was a case of placenta previa, but there was no evidence of this; it was purely external hemorrhage. On careful consideration of all the circumstances—the woman

being a primipara, and having no dilatation of the small canal—Dr. Ward decided to do cesarean section. The case had a good result, the child and the mother both recovering. The cause was found to be an interesting one. It was due to shortening of the cord, not a short cord, and the cord was wrapped about the body three times. There was a typical "battledore placenta," and the hemorrhage was mechanical, the cord being so short that it caused a pull on the edge of the placenta where the hemorrhage came from. If operation had not been quickly done in this case, and if they had waited to deliver the child by the vaginal route, both child and mother would have been lost.

Dr. WILLIAM BROWN of Rochester said that he would like to call attention to one point of diagnosis in a doubtful case. Most of the grave cases were definite, but Williams called attention to the milder cases where bleeding was going on. That was one of the most valuable diagnostic aids. These cases, after extreme hemorrhage, might still have slow pulse, out of proportion to the degree of hemorrhage. Here, if a hemoglobin estimation was quickly done, it would be of great value. Moderate bleeding would bring down the hemoglobin to 60 or 70 very quickly.

Dr. QUIGLEY said that he was glad Dr. Brown spoke of hemoglobin estimation. Blood pressure was also important. He had not taken time to mention the mortality in ten cases of cesarean section. All the mothers recovered, and the fetal mortality was 50 per cent., which was better than the average.

The Treatment of Procidencia Uteri.—Dr. GEORGE CHANDLER of Kingston said that treatment for this condition was often of no avail unless aided by a suspension apparatus. The uterine ligaments were powerless to hold up the perineum. He had been doing the operation of Kocher, as modified by Murphy, in the Trendelenburg position, with a low transverse incision in the crease above the pubis. The recti abdominis were separated to the pubic bone; the uterus was pushed up from the outside through the vagina; if very small it was pulled up and turned to the right. The peritoneum was sewed tightly round the vagina to shut off the peritoneal cavity. The skin and superficial tissues were pushed upward from the fasciæ, the fasciæ were stitched together with cat gut, and skin and superficial tissues with silk worm gut. The uterus was let fall into this bed, and sutured, and the incision was closed. The tubes and ovaries might be freed from the uterus and dropped back into the pelvic cavity. Following this operation the patient might have pain in the bladder for some weeks, but the technique was very simple and the repair good. It was necessary to do the operation as near the pubic bone as possible in order to avoid future hernia. This operation had given good results after two and a half years. It should not be done until after the menopause and not in a fleshy woman.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held April 7, 1916.

DR. JOHN DOUGLAS IN THE CHAIR.

Chronic Intestinal Stasis.—Dr. FORBES R. MCCREERY presented a patient upon whom he had operated one year ago for chronic intestinal stasis. He stated that this patient was 41 years of age, unmarried, and had never had a normal movement of the bowels. Since having typhoid fever six years before her condition had been worse. Two years previously she had been sent to Saranac Lake for tuberculosis. She complained of abdominal pain, weakness, emaciation, shortness of breath on exertion, chilly and feverish sensations, and night sweats. Physical examination showed some old signs of tuberculosis, but no active lesion and no heart lesion was found. There was a slight goiter, but no exophthalmos or other signs of Graves' disease. Gastroptosis was present. The urine contained large amounts of indican, but was otherwise normal. The stools showed a very high grade of intestinal putrefaction, the predominating organism being the bacillus of Welch. The blood examination showed hemoglobin, 78 per cent.; red cells, 5,256,000; white cells, 9,200; polymorphonuclears, 79 per cent. Sigmoidoscopic examination showed only congested mucous membrane. The pelvic examination was negative. The eyelids and ankles were puffy. The patient was put on a low protein diet, given colonic irrigations of different solutions, boric acid, nitrate of silver, sugar, etc. Cultures of

lactic acid bacteria and Russell's emulsion were also given. After six weeks of this treatment she had improved immensely. The improvement, however, did not last, and except when receiving colonic irrigations she had no evacuation, save as the result of drastic catharsis and with great pain. Having become convinced that the cause of the stasis was a mechanical one, x-ray photographs were taken by Dr. Archibald H. Busby. These showed retention of the bismuth in the upper part of the sigmoid after ninety-six hours and after purge and irrigation. One quart of bismuth was then injected by rectum. It did not pass into the descending colon, but remained in the sigmoid. Operation was then decided upon and the abdomen was opened through a left rectus incision. The sigmoid was voluminous, but there was no constriction or point of obstruction found. There was, however, a peritoneal fold extending from the iliac fossa to the sigmoid and in effect shortening the outer leaf of the mesosigmoid about 2 inches. This was divided at right angles for a depth of about an inch or an inch and a half. The incision immediately gaped into a diamond-shaped figure, showing the tension that had existed. This was sutured at right angles, the result being to lengthen the fold 2 inches, or in fact to obliterate it entirely, making the mesosigmoid about 4 inches at the site of the fold, as elsewhere. A somewhat deformed appendix was removed. No other lesion was found in the abdomen or pelvis. The wound was closed and the patient made a very satisfactory convalescence. In about ten days she began to have spontaneous movements, and up to the present time, a period of one year, she had required no laxatives. All of her symptoms had disappeared, her general condition had improved, and she was now able to lead an active and a useful life. Dr. McCreery exhibited the x-ray photographs showing the condition before operation in this patient.

Dr. FRANK C. YEOMANS said that the case reported merited discussion, as it represented the type that went from one physician to another and made the rounds of the hospitals without obtaining relief. Cathartics of all varieties were prescribed, but no thorough examination was made to determine the point or points of intestinal delay or stasis. Serial radiograms were of prime importance as an aid in diagnosis, and even more helpful were the radiosopic findings. The speaker said he had had many cases of sigmoidal stasis. For proper treatment distinction must be made between cases of disturbed physiology due to abnormal size of this segment of the bowel, its atony or displacement, and delay due to purely mechanical conditions, as from bands, adhesions, etc. Only recently he had had a patient in whom the only lesion was strong adhesions between the abnormally long sigmoid and the right tube and ovary. Division of the bands gave prompt relief. Further aid in the diagnosis could also be frequently obtained from the employment of the sigmoidoscope when introduced 10 inches or more. Then by maneuvering the tube from side to side definite pain was produced by the traction on bands or points of adhesion.

Submucous Lipoma of the Ileum Causing Ileocolic Intussusception.—Dr. ANTHONY H. HARRIGAN reported this case. The patient was a man 50 years of age, and was admitted to the Fordham Hospital on December 22, 1915, and discharged on February 2, 1916. The family history was negative. He said he had had no diseases of childhood and denied any venereal diseases. There was no previous history of serious illness and no history of a similar attack of gastrointestinal disease. He was moderately alcoholic. His present trouble began two weeks before his admission with sharp, cramp-like pain in the abdomen. The pain was localized in the epigastrium and radiated to the right iliac fossa. At the onset the attacks were infrequent, occurring but two or three times a day. They increased daily in frequency until, on the day of admission, they occurred every half hour. The pain increased in severity. The patient vomited on the day of admission. He was admitted to the hospital late in the evening and was examined by the admitting physician and the senior interne; they made the diagnosis of chronic appendicitis, for there was apparently at this time a temporary lull in the symptoms. Dr. Harrigan saw the patient on the following morning. The examination revealed a well-developed man suffering from severe abdominal pain from which he was crying aloud, and seemed to be intermittent in character. He pointed to the epigastrium as the origin of his pain and to the lower quadrant as the point where the pain radiated and ceased. He was perspiring freely and was suffering greatly. The abdomen was moderately distended, but there was no

rigidity. There was found a definite and tender mass in the right lower quadrant which laid obliquely and appeared to be about 4 inches long and 1 inch wide. The rectal examination was negative. The specific gravity of the urine was 1028; there was a trace only of albumin and a few hyaline casts. The eyes, throat, heart, and lungs were negative. The liver, spleen, and kidneys could not be felt. The leucocyte count was 14,600; polymorphonuclears, 85 per cent.; the lymphocytes, 13 per cent.; the large mononuclears, 1 per cent. His temperature was 100° F., pulse 104, and respirations 28. Immediate operation was decided upon, although no definite diagnosis had been made. Two possibilities were discussed: (1) Acute gangrenous or perforative appendicitis; (2) a perforated gastric or duodenal ulcer. Upon operation the appendix was easily delivered and presented a normal appearance. A mass was found occupying the right iliac fossa and pelvis. This was delivered and found to be an intussusception of the ileum into the colon. The terminal ileum was edematous and appeared about three times its normal size. The small intestine could be felt lying in the cecum and ascending colon. Palpation of the cecum revealed the presence of a movable body within the lumen. The intussusception was reduced by traction with difficulty. Several feet of intestine had been involved. The invaginated intestine, at first quite dark, quickly assumed a normal color. At a point about 2½ feet from the ileocecal valve could be felt the round body previously felt through the cecal wall, and this laid within the lumen of the ileum. It could easily be pushed up and down. The bowel was held by an assistant and opened transversely. A small, soft, submucous pedunculated tumor was found attached to the mesenteric border. The excision was simple and the base was sutured with catgut. The intestine was closed with interrupted linen. The abdomen was closed without drainage. The postoperative course was extremely stormy. A severe pneumonia nearly proved fatal. He spent a few weeks in the Burke Foundation at White Plains. He had now returned to work and was feeling all right. The tumor measured 6.5 x 6.5 inches. The pathological diagnosis was lipoma. Dr. Harrigan believed that the best paper in English was the one by Dr. Stetten in which were reported sixty-six cases of lipoma, intussusception taking place in 60 per cent. The most recent article was by Huesel, who reported seventy-one cases of gastrointestinal lipomata. Intestinal resections had been done several times on the supposition that malignant disease existed.

Fecal Concretions of the Appendix Demonstrable by the Roentgen Ray.—Drs. JOHN DOUGLAS and LEON THEODORE LEWALD made this presentation. Dr. Douglas said that concretions in the appendix, formed as they were of hardened, more or less inspissated fecal matter, were rarely opaque to the Roentgen ray, and were therefore usually not demonstrated by radiographic examination. If bismuth or barium had been previously given for gastroenterological examination a persistent residue in the appendix might sometimes be due to the coating of the concretion with the opaque substance. When, however, on account of the inflammatory reaction of the tissues calcium salts were deposited on the surface of the fecalith it might become demonstrable. The condition was similar to that occurring in cholelithiasis. Gallstones forming as a result of pure cholesterol precipitation caused no shadow; those in which infection and resulting inflammation of the gall-bladder had caused a deposit of calcium salts to coat or become mixed with the cholesterolin became opaque. Dr. Douglas said the following two cases were reported to demonstrate the possibility of such a fecalith being mistaken in a radiogram for a ureteral calculus on the right side, unless the radiogram were taken with opaque ureteral catheters in the ureters; even this did not afford an infallible means of differential diagnosis.

CASE I.—This patient, 21 years of age, a painter, had been ill for three weeks before admission to the hospital with pains in the right iliac region, vomiting, and fever. The pain had persisted up to the time of his admission to St. Luke's Hospital. At this time his temperature and pulse were normal. His leucocyte count was 15,000, with 78 per cent. polymorphonuclear cells, which on the following day fell to 10,000, with 66 per cent. polymorphonuclears. Physical examination revealed slight rigidity and tenderness in the lower part of the right inguinal region. On rectal examination a sense of resistance was felt in the right side of the pelvis above the prostate and there was a slight mucopurulent discharge from the rectum. Radiograms

showed a shadow in the right side of the pelvis and a diagnosis of acute appendicitis with abscess which had probably perforated into the rectum was made. On operation it was found that the appendix had sloughed off about 1 cm. from its base and a fecalith about 2 x 1.5 cm. in diameter was found in the cavity below the cecum between the rectal wall and the right pelvic wall.

CASE II.—Dr. Douglas presented this patient, 23 years of age, who was admitted to St. Luke's Hospital with a history of acute appendicitis of three days' duration. On operation a gangrenous appendix was found which had perforated but still contained a large, hard fecalith. A spreading peritonitis was present. The concretion was so hard that its density was compared with that from Case I and that of two ureteral calculi which had been demonstrated by radiographic examination before removal from the other patients. This concretion would also have appeared on a radiographic plate.

Dr. Douglas reviewed the literature, which showed that only a few isolated cases resembling these had been reported. After briefly reviewing these cases, he said that they showed that in a small number of instances a fecalith of the appendix might be demonstrated by radiographic examination and that this fact must be taken into consideration when making a diagnosis. Usually the passage of opaque ureteral catheters would be of the greatest assistance in differential diagnosis, but two cases reported by Eastmond and Seelig demonstrated that even with this assistance a mistake might be made. As a further aid in the Roentgen diagnosis the writers suggested that when the shadow was above the crests of the iliac bones a lateral stereoscopic radiographic examination be made, preferably with an opaque ureteral catheter in the ureter on the suspected side. The Roentgen examination combined with an opaque meal or enema might be of further assistance in showing the relationship of the suspicious shadow to the appendix or cecum. Finally there was a possibility of one encountering a left-sided appendix, due either to a non-rotation of the colon or to a complete transposition of all the viscera. Dr. Douglas exhibited the two specimens.

Dr. LEON T. LEWALD showed the lantern slides of roentgenograms and specimens for comparison with ureteral calculi.

Postoperative Heatstroke.—Dr. ALEXIS V. MOSCHCOWITZ read this paper, in which he said that he had been on active service at the Mount Sinai Hospital regularly every year from 1899 to 1914 and he had often had the impression that, particularly during the hot weather, some of his patients suffered from a mild insolation. Several such cases were reported in detail. The literature dealing with the symptom complex, caused either by exposure to the direct rays of the sun or to high degrees of artificial heat, was exceedingly voluminous. The references appended to Steinhauser's monograph, "Nervensystem and Insolation," Aug. Hirschwald, Berlin, 1910, covered over twenty-two closely printed pages, and in addition the statement was also found that only the newer literature, approximately that after 1880, had been considered. However, even with such a wealth of material there existed no unanimity of opinion regarding the disease. After a very careful study of the more important contributions to the subject, Dr. Moschcowitz had arrived at the conclusion that their knowledge as to the etiology, symptomatology, pathology, and treatment of the disease was in a chaotic state. If this was true of heatstroke or sunstroke in a general sense, a disease so common as to be at times epi- or en-demic in nature, how much more likely was it to be true of that small and selected group which particularly interested them at present, namely, post-operative heat or sunstroke? Barely twelve cases, scattered through more than fifteen years, were all that was available for study. The most prolific contributors to the subject of insolation had been the military and naval surgeons of the United States, Great Britain, and Germany. All appeared to be agreed that there existed various forms of insolation. All writers differentiated clinically at least two forms, "sun or heatstroke" and "heat prostration"; a few authors described as well a third form, "heat exhaustion." Sunstroke was characterized by the following: There was always a history of direct exposure to the sun, an abrupt onset, with complete loss of consciousness. The skin was as a rule hot, dry, and flushed. The body temperature was very high, the pulse full and of high tension. On the other hand, in heat prostration these symptoms were either lacking or their exact antithesis

was present. Thus they found that there was no history of direct exposure to the sun, but a history of being confined in a close, poorly ventilated room, and perhaps to exposure to artificial heat. The best examples of this form of insolation occurred in stokers on steamers, and might occur even when the outside temperature was far below what was usually termed hot. The onset was gradual and consciousness was usually retained. The skin was not dry, hot, or flushed; on the contrary, it was cold, clammy, and pale. The temperature in these cases was variable, but never attained the height it attained in cases of sunstroke, rarely going over 102° F. The pulse was weak and thready. Assuming that the symptomatology discussed was correct, it should follow that cases of postoperative insolation were not cases of heatstroke but of heat prostration. For the sake of argument he mentioned the following hypothetical case: A patient was operated upon for an acute gangrenous appendicitis with abscess. Six hours after operation the temperature might be either normal, subnormal, or slightly elevated. The skin was cold, clammy, and pale. The pulse was weak and thready. The operation took place on a hot day. On the day following the operation the condition either persisted or had improved. Ultimately the patient recovered without any sequelæ or died within the first forty-eight hours. No one ever thought of making any other diagnosis than that of mild postoperative shock or post-operative reaction; yet the history and course were characteristic of so-called heat prostration. He wondered how often these cases were overlooked. Was it not possible that this was the most frequent form of postoperative insolation, more particularly as it was the form which was most likely to occur in the absence of direct exposure to the sun. Cases of postoperative insolation had been recorded in Boston, New York, and Philadelphia, and it was possible to account for the greater frequency of heatstroke in these three cities by the fact that they were more compactly built up and many of the inhabitants lived crowded together in tenements. Again, the people had not been instructed how to dress properly during the summer; they wore too much, too heavy, too dark, and too woolly clothing, all of which were conducive to the production of heat insolation. The real hot days of the year were in the very smallest minority in New York City; the great majority of the days of the year were either cold or verged at least upon coolness. On this account surgeons had learned to fear so much the occurrence of post-operative pneumonia; they tried to avoid it by instructing their nurses to cover well the patients in the operating room, upon the transportation to and from the operating room, and upon the arrival in bed. He believed that this needless superheating of the patient was conducive in a great measure to the occurrence of post-operative insolation. Dr. Moschcowitz believed that whenever the atmospheric conditions were favorable for the production of insolation, all operating room activities should cease with the exception of those of an urgent nature. In all cases operated upon during a hot wave the greatest regard should be had for the comforts of the patient. All needless swathing in blankets and the use of hot-water bottles was to be prohibited. Coolness and the lightest of covers were then indicated. Motor fans were desirable. Cooling drinks should be permitted much earlier than was generally the custom after operations. In heatstroke the temperature was so high that every effort should be made to reduce it and recourse must be had to physical measures rather than to the coal-tar products. The best was hydrotherapy in the form of sponge baths with iced water, ice caps applied to the head, enemata with ice water, etc. This form of treatment, however, would be contraindicated in that variety of insolation which they called heat prostration. The exact opposite form of treatment was here indicated. In a certain number of cases of insolation there had been found a peculiar degeneration of the blood which manifested itself by a laking. This suggested the possibility of venesection and blood transfusion, provided a suitable donor could be found at short notice.

Veronal Habit.—Otto Glaser asserts that the continued use of this drug, even in small doses, may lead to an intoxication of the cerebellum and the vestibular apparatus. The veronal when continually or too frequently used produces habit through its causing a condition of euphoria or well being. It inhibits the functions of the intestinal tract as well as those of the kidneys.—*American Medicine.*

SOME OF THE LARGER PROBLEMS OF THE MEDICAL PROFESSION.*

By RUPERT BLUE, M.D.,

WASHINGTON, D. C.

SURGEON-GENERAL, U. S. PUBLIC HEALTH SERVICE, PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.

THE profession of medicine enters into and touches every human activity from the first kindling of the vital flame until life's candle flickers out. The joys of being and the sorrows of life, the travail of labor and the relaxations of idleness, the opulence of riches and the meagerness of poverty have running through their web and woof the fine blue thread of the calling which has as its ideal the physical salvation of mankind. Throughout the nearly seventy years of its existence the American Medical Association has clung with unfaltering fidelity to the doctrine of the prolongation of human life and the relief of the miseries of man. In peace and in war, in prosperity and in public calamity, in crowded city and on isolated frontier, despite all opposition, it has moved steadily forward toward the goal of health, recognizing neither creed nor sect, neither school nor system, but solely the sacredness of its objects. The catholicity of its principles, the high altruism of its ideals, and the broad basis of its humanity have preserved it inviolate against the attacks of those who would revert to primeval incantations, ignorance, and chicanery in the prevention and remediation of disease. The passage of the years is marked by a trail of discarded superstitions on the one hand and by the monuments of scientific progress on the other, and the very obstacles which have been thrown into the path which we have trod have proved stepping stones to higher ground.

To-day, as we look back over the achievements of this association, we receive inspiration from the work of those who have gone before us. The researches of our medical forebears are a priceless heritage, entailed for all future generations. But as we review the triumphs of the past and plan fresh victories for the future, our happiness in the joy of this pleasant reunion in the bonds of scientific fellowship is not without its note of sadness.

Since our last annual meeting death has called from our midst a number of the strong men of the profession of medicine. In the loss of that lovable and kindly gentleman, Dr. Edward L. Trudeau, the world has been deprived of a great leader in the anti-tuberculosis movement. In the death of Surg.-Gen. George M. Sternberg our profession and the nation have lost an officer eminent in science and a

pioneer in the field of military hygiene. In the passing away of Dr. Henry B. Favill the country has been robbed of a powerful intellect which was being more and more devoted to the cause of good government, clean politics, municipal improvement, and sanitary progress. In the untimely death of Dr. William L. Rodman the Association has been bereaved of its president, and America has lost a distinguished surgeon and a public-spirited citizen. We would also remember at this time the members of our profession and Association who, through love of their fellow men, volunteered to serve mankind in those countries unhappily divided by war and stricken by pestilence, and who by so doing sacrificed their lives to the ideals of our profession.

By reason of their relation to the Association, we glory especially in the accomplishments of Rodman and Favill, and extend our condolences to their sorrowing relatives and friends with whom we mourn. In the solemnity of this moment let us take inspiration from their lives, that their ideals may pass on to us, and that we may more faithfully discharge our duties to mankind.

The limitation of time does not permit the recitation of the scientific accomplishments since our last meeting, neither does it suffice to enumerate the fields of activity which lie fertile before us. The movement for race betterment, the increase of child hygiene, and the restriction of child labor deserve and receive the approval and assistance of this body. The necessity for the advancement of the campaign for mental hygiene, the cure and prevention of tuberculosis and cancer, and the improvement in the collection of vital statistics, particularly morbidity statistics, is so great as to require no argument.

Medical and Sanitary Education.—Since its inception the American Medical Association has endeavored in every way to raise the standard of medical education, and as the result of its labors there has been constant improvement, particularly in recent years. Not only are the graduates of to-day better qualified in the science of medicine than those of ten years ago, but they have a broader grounding in the general sciences as well. These are decided improvements, but should not satisfy us. As an Association, we should continue to urge and adopt every means which will better qualify medical men for their calling. Improved laboratory and hospital facilities are now being made available to medical students in greater degree, and the standard of medical practice is accordingly raised. Not enough attention is being paid, however, to the subject of hygiene, in either undergraduate or postgraduate courses. Thus far the members of the medical profession have been looked to as the natural conservators of individual and community health. With the increasing interest in this subject, however, and the facilities for giving instruc-

*President's address before the American Medical Association, at the Sixty-seventh Annual Session, Detroit, June, 1916.

tion in public health work being established in institutions other than medical schools, there is likelihood that in the future medical graduates will have sharp competition in a field which they should naturally occupy. The time is at hand when localities and States will demand the services of full-time health officers, and the medical profession should look forward to meeting this requirement. It is suggested, therefore, that the Council on Medical Education and the profession generally give greater attention to this growing need.

Medical and Sanitary Preparedness.—The American Medical Association, as a national body, has come to bear an important relation to everything medical which affects the nation as a whole. It has, therefore, interested itself in the improvement of the medical departments of the Army and the Navy and the Public Health Service.

The medical department of the Army is charged with the duty of preserving the sanitary condition of the Army and with certain important functions of administration and organization. In its relation to the people of this country by far its most important activity is along educational lines. Some thirty to fifty thousand young men join the Army each year, and a similar number annually pass back to civil life. During the period these men remain in the Army they come into direct contact with the medical department. Their ideas and standards as to housing, food, clothing, ventilation, and lighting are all materially influenced by their sojourn in the Army, and even more definite impressions are acquired from the medical department with reference to such matters as disease and its treatment, preventive medicine, temperance, and recreations. At almost every point in his new environment the recruit comes into contact with the ideas and teachings of the army medical department, and he returns to civil life with a much broader and more enlightened view of hygienic principles.

The great lesson of the European war which we as medical men should take to heart is the importance of thoroughly preparing the medical and sanitary forces in time of peace, so that they may be ready to take their proper place and to efficiently relieve the sick and wounded and prevent disease in time of actual conflict. Not only must the land forces be put on the footing of highest efficiency, but it is perhaps even more important that the medical department of the Navy receive the active support of the entire citizenship. The multifarious character of the duties of the medical corps of the Navy requires officers of broad training. This Association should continue in the future as in the past to afford to the medical departments of the Army and Navy every assistance in its power.

The problems which confront the Public Health Service are of a different character from those of the strictly military arms of the Government. This organization is rapidly expanding to meet its duties in the protection of the health of the civilian population of the United States. The crying need of the Public Health Service at the present time is men and money. Congress has never been slow in imposing functions on the Public Health Service, but it has been extremely conservative in the matter of appropriations and increased personnel to discharge the added duties. As yet Congress has not seen fit to establish a national department of health, and pending the creation of that much-needed department, the Public Health Service must perform the public health duties of the nation. It is incumbent on every citizen of this country who is interested

in the conservation of human life to assist and cooperate with the Public Health Service.

Enlargement of Usefulness of Hospitals.—One of the extremely important matters in which this Association should take an active interest is the utilization of hospitals in order that they shall not only have greater application in the relief of illness, but be of greater utility in times of national stress.

In many general hospitals there is opportunity to increase efficiency through organization. It is probable, for instance, that the most accurate knowledge of the distribution of certain preventable diseases could be obtained by regular reports from hospitals and dispensaries if these were comparable. Moreover, it should become possible in greater degree to admit many cases of illness, such as tuberculosis and venereal infections, now excluded, but which profoundly menace the public health. Hospitals are public servants and as such should be utilized to the fullest extent, not only in the relief of illness, but also for educational and public health purposes.

Improvement and Standardization of Remedial Preparations.—Further effort should be made to determine the availability and use of remedial preparations. The remarkably valuable work of the Council on Pharmacy and Chemistry is well known to you. As a result of its untiring efforts for more than a decade, our knowledge of useful remedies has been increased, the pharmacopeia improved and the physicians' armamentarium made more serviceable. Much, however, remains to be done. The determination, for instance, of the value of biologic products used in the prevention and treatment of the diseases of man and the elimination of those which are without worth is a matter of urgent need, meriting the earnest consideration of this Association. While it is the province of the federal government to promulgate standards for these preparations, the determination of their therapeutic value is a function of the medical profession.

In the enforcement of the law regulating the propagation and sale of viruses, serums, and toxins, it is possible for the Public Health Service to guard against the sale of contaminated preparations. It insures to physicians the full strength of those preparations for which standards have been devised, but it cannot guarantee the potency of preparations for which standards have not been fixed, and which practitioners generally are being urged to use in greater degree. In order to determine this potency, the medical profession has a duty to perform.

By encouraging therapeutic research along broad lines through hospitals and clinical laboratories, the Council on Pharmacy and Chemistry would facilitate the standardization of useful biologic preparations and restrict the exploitation of doubtful ones, thereby saving millions of dollars annually to the country. I would accordingly suggest that this be made the subject of intensive study, thus supplementing the researches already under way in respect to other preparations.

Through its helpful attitude, the medical profession has contributed to the enforcement of the anti-narcotic law. As a result, a multitude of data are being recorded to show not only the public health importance of the control of habit-forming drugs, but the additional measures that are necessary to this end. I doubt if any of us here present comprehend fully the social and sanitary significance of this vast problem and the relation of individual practitioners thereto. It should be our

earnest effort to aid in restricting the use of narcotics for other than medicinal purposes, and thus aid in overcoming an evil of the gravest menace. While as an organization we may not influence specific legislation, it is entirely within our province to strive to mold public opinion, which will beget wise laws and proper provisions for their enforcement.

Health Insurance.—As a result of recent workmen's compensation laws and the increasing interest in the health of wage-earners, the subject of health insurance is rapidly coming to the front. This is a question which we as a profession will be called on to face in the not very distant future.

Studies of the economic and sanitary conditions affecting the health of the industrial population have shown the urgent need for more effective methods for the relief and prevention of disease among the 30,000,000 persons who comprise this group. The unskilled, low-paid workers in every community have an excessive morbidity and mortality rate, which is largely accounted for by their economic status and living environment. A large proportion of this class have incomes insufficient to maintain healthful standards of living, much less to provide adequate medical and surgical care. This places a serious handicap on the medical profession, as well as a financial burden on the poorly paid wage earner, which neither should be wholly required to bear. The public, industry, and the workers themselves are at least partially responsible for the faulty conditions, and in consequence should share in the remedial measures.

To meet the situation, there are unmistakable signs that health insurance will constitute the next great step in social legislation. Experience has shown that an adequate health insurance system should distribute the cost of sickness among those responsible for conditions causing it and thereby lighten the burden on the individual. Financial incentive may thus be given for the inauguration of comprehensive measures for the prevention of disease. I would accordingly suggest that the American Medical Association continue the studies, which have been so splendidly begun, of the results of health insurance in all its aspects in this and in foreign countries, so as to decide on a program which would properly coordinate any proposed health insurance system with existing agencies for the cure and prevention of disease.

Industrial Hygiene.—Closely allied to this is the study of industrial hygiene, a subject which will receive careful consideration in the Section on Preventive Medicine and Public Health at this session. Too many safeguards cannot be thrown about the health of operatives in industry, but we should consider the problem as it relates, not only to the workshop and factory, but to home conditions as well. Factory sanitation will fail of the highest accomplishment unless the workman is educated in the hygiene of his body and the sanitation of his home. The relation of the wage to disease, the housing problem, and the health training of operatives are therefore matters which I would commend to the attention of the Council on Health and Public Instruction.

Rural Sanitation.—Rural sanitation is a matter of even greater importance. Over 53 per cent of the population of the United States dwells in communities of less than 2,500 inhabitants, in many cases under most insanitary conditions. This is a menace not only to the health of the rural dweller,

but also to that of the urban resident. The next great point of attack against infectious diseases is the small town and village. The work which the Public Health Service has been carrying on in co-operation with State and local health authorities in rural counties shows not only the necessity for increased and more widespread activity in this direction, but also that great good may thus be accomplished at relatively little cost. It is incumbent on this Association, possessed as it is of the machinery for popularizing health movements, to undertake a definite campaign for bringing health education to our rural population. If this is well done there will be a direct result in the reduction of typhoid fever, malaria, and hookworm disease in the country and an increased safety in the food supplies of cities. I cannot too strongly urge on this body the necessity for intensive efforts toward the improvement of rural sanitation.

Public Health Organization.—In the accomplishment of this purpose, however, we cannot stop with the sanitary enlightenment of the country inhabitant. Much he can and must do for himself, but lasting good cannot be accomplished in the absence of adequate State and local health organizations. An examination of existing laws and regulations shows that some of the States have an abundance of public health legislation. In fact, in many instances the powers and duties of the sanitary authorities far exceed the appropriations for their execution. Still others have defective laws and low appropriations, while some have little law and almost no appropriations.

In many instances considerable improvement in organization will be necessary before health authorities can functionate properly. These defects are being remedied, and many States are rapidly approaching a high degree of efficiency in their public health administration. In the counties and small municipalities, however, the greatest need for reform exists, and this Association should cooperate to the fullest extent in creating a public sentiment for thoroughly prepared, adequately salaried, full-time health officers. Indeed, it should not only create such sentiment, but, as previously stated, it should take active steps to provide without delay a large share of these public servants. The production of well-qualified men for such positions is not keeping pace with the demand. Sanitation is as much a specialty as is surgery, and simply because a physician is a successful practitioner is no guarantee that he will make a qualified health officer.

Through improved medical education and the cooperation of health departments with universities, properly qualified physicians should become available to meet this growing need. It is important also that States and localities should be able to secure the services of sanitarians without reference to legal residence. It is equally as important that medical hygienists, as well as physicians generally, should be able to practise their profession anywhere within the confines of our country without undue restriction as to academic examinations. It is not at all improbable that this thought imbued our late president in founding the National Board of Medical Examiners. This body, which promises so much benefit both to the medical profession and to the American public, stands as a monument to the industry and clarity of vision of our lamented colleague, Dr. William L. Rodman. I would commend to the Council on Medical Education the study of the problem of devising some uniform means of

certifying and training prospective health officers.

The great effort of the future must be in the direction of the improvement of the internal health of the nation. We are possessed of an adequate coast defense against disease from abroad, and what we must now do is to control those diseases which are already with us. In this we require the qualified health officer and the educated public. A part of this education may be secured by the printed and the spoken word, but the great agent in public education is demonstration. This association is in a position, touching as it does every stratum of society in this broad land of ours, to carry this work forward to ultimate fruition. This is an obligation on our profession, a sacred duty laid on the followers of the healing art. Though we minister to the sick and bind up the wounded, though we bring sight to those who see not and alleviate the suffering on the bed of pain, yet our duty is not done until we have put forth our best endeavor to the end that sickness and pain and blindness be not. Poverty and ignorance, squalor and intemperance, cruelty and greed, these are the enemies which we as individuals and as a profession must combat. As citizens who would maintain our nation in a condition of preparedness against its greatest enemy, disease, it is our duty not only to perform our legal obligations as physicians, but to bend our every energy to the prevention of disease. No selfish or half-hearted service will suffice. Nothing short of whole-souled devotion to this duty will satisfy the ideals which have been passed down to us by generations of self-sacrificing, public-spirited physicians who love their fellow men. The American Medical Association represents the crystallization of these ideals. If it permits no self-seeking interest to dominate its actions, if it maintains its plane of high altruism, if it devotes itself with strength of purpose to the betterment of the public weal, it will prosper in the future as in the past, serene and sure in the satisfaction of work well done. Let our deliberations be so imbued with that broad spirit of charity and brotherhood that the name of the physician shall be revered.

THE NAUHEIM METHOD.*

By SIMON BARUCH, M.D.,

NEW YORK.

CONSULTING PHYSICIAN TO KNICKERBOCKER HOSPITAL; HYDROTHERAPEUTIST TO SEA VIEW HOSPITAL FOR TUBERCULOSIS; CONSULTING HYDROTHERAPEUTIST TO BELLEVUE AND ALLIED HOSPITALS, NEW YORK CITY.

My reasons for presenting the Nauheim method as a subject for discussion are

1. The success of this method of managing cardiac diseases has been established, during the most enlightened period of the history of medicine, not by the statement of patients, which are often unreliable, but by observations of specialists, who have demonstrated their confidence by continuing to send their patients to this mecca of heart cases.

2. The mineral springs of Saratoga and certain California springs furnish the most important component of the waters that have made Nauheim famous, viz., carbonic acid gas, and require only the addition of certain salines to be equal to those of Nauheim.

3. I have been surprised to discover that the large proportion of baths, ordered as Nauheim baths, are given with simple carbonic acid water

*Read by invitation before the N. Y. State Med. Assoc. at Saratoga Springs, N. Y., May 17th, 1916.

from a cylinder of gas or artificially produced, by mixing a definite solution of bicarbonate of soda with either muriatic acid or sulphite of sodium cakes, or formic acid. The salines are either omitted or a few pounds of salt, or a natural brine or sea water, or, as in one institution, sodium chloride and bicarbonate of soda, which actually counteracts the desired irritating action of the salt, misrepresent them.

4. It is my aim to obviate this unfortunate substitution, which may be due to the prevailing lack of agreement upon the rationale of the Nauheim method, by offering an explanation of the action of certain elements of the latter, which, though novel, has a rational basis.

5. My warrant for venturing upon this subject may be found in the historical fact that the method consists, as is well known, of the application of baths, in which the patient is submerged entirely, excepting the head, in water containing carbonic acid gas and certain salines, chief among which are the chloride of calcium and sodium, which in concentrated form would produce a decided hyperemia. These baths are given methodically, according to the indications of each case and the effect of the bath, and they are accompanied or followed by certain passive or resisting movements, which offer a systematic but mild exercise of the principal voluntary muscles of the body. Success of the Nauheim method depends upon faithfully following a method.

Artificial CO₂ Bath.—In 1896 I brought from Germany the Sandow tablets, consisting of cakes of sodium sulphite, and a package of bicarbonate of soda, for the artificial preparation of carbonic acid baths. In 1902 I visited the Virchow Hospital at Berlin. Here Dr. Laquer used the "Zeo" bath, which consists of a solution of formic acid and a package of bicarbonate of soda. From experiments in the Vanderbilt Clinic I ascertained its advantages, not being corrosive and more quickly prepared. The CO₂ bubbles were more abundant and the consequent hyperemia of the skin more pronounced. Neither one of these preparations had ever been used in this country, as far as I know.

In 1896 I visited Nauheim for the first time, and since then I have made two visits, the last being in 1913. It has been my good fortune to come in contact with Drs. Heineman, Groedel, Schott, and Honan during these visits. The Nauheim method has passed through a gradual evolution in regard to its theory and practice. Without entering into details, I desire to emphasize that the entire series of baths and exercises is a methodical training of the insufficient heart to enable it to resist definite attacks made upon the cutaneous periphery by the baths and exercise alternating with rest. Indeed, we have here the same principle which I have so frequently dwelt upon in the application of water in health and disease, viz., that water below the temperature of the skin produces an effect upon the blood vessels and nerves of the skin, which I have termed "neurovascular training," by means of which the heart and central nervous system are raised in functional efficiency, so that the organs supplied by them are restored to normal activity, which has been disturbed by toxic agencies, or by products of abnormal tissue change, due to faulty modes of living. Precision is demanded for this achievement.

In the most recent publication of Prof. J. M. Groedel, this veteran of Nauheim confirms my view

when he writes, "We have it in our power to put into action the excitations which drive the heart to higher activity by gradual approach. We may stimulate the heart to a greater or lesser degree, within definite limits, through the intensity of the thermic excitation, namely, low temperature of the water."

Formerly the Nauheim doctors began with baths of indifferent temperature, about 34° C. (93.2° F.), with small saline and carbonic acid content. This was followed slowly by a gradual decrease of the bath temperature, until 30° C. (86° F.), while at the same time the saline and carbonic acid content was increased and the duration of the bath raised from eight or ten minutes to fifteen or twenty minutes, giving at first the bath two days in succession or every second, third or fourth day. Recently this course has been abandoned for a more individualizing scheme, which is based upon the actual effect of each bath, or small series of baths, upon the patient and the type or character or the cardiac insufficiency.

In Nauheim no treatment is administered for the higher grades of circulatory insufficiency in persons who, for instance, when at rest or under the slightest movement, suffer from dyspnea or who present large dropsical effusions. I have in mind a case of the former type in which I advised against a journey to Nauheim, but was not sustained by an eminent specialist, who had advised him to consult me about the Nauheim trip, although I had endeavored to neutralize his obstinacy by telling him that he would return in a coffin. He arrived in Nauheim, but was advised not to remain longer than necessary to recuperate from the journey. He did arrive home in a coffin—dying one day before the ship arrived.

It was the merit of Beneke to select cases that were promising and to discourage others from remaining in the vain hope of recovery. His successors, though not so rigid, have followed this course, with the result that Nauheim has established a reputation for the amelioration and cure of heart disease. Let me counsel colleagues practicing in Saratoga to follow Beneke's example.

Rationale of the Nauheim Bath.—This may be divided into two essential elements, (a) effect of the carbon dioxide, (b) that of the salines.

Action of Carbon Dioxide.—From experience on my own person, together with observations made upon many other individuals in Bad Nauheim and in Saratoga Springs, the following are the notable objective and subjective effects: On entering a bath with Hathorn No. 1 water, at 90° F., my first impression was one of decided coolness, with contraction of the scrotum. This coldness disappears so soon as bubbles of CO₂ gas begin to accumulate upon the skin. A prickling sensation begins, sometimes painful, or touching in the scrotum, which feels as if covered by a very thin layer of dry varnish. If these bubbles are disturbed on large surfaces, coolness is again felt, quickly, however, replaced by warmth, so soon as the gas bubbles again are seen on the skin. The skin shows decided hyperemia wherever it is in contact with the gas bubbles. Decided warmth is felt, together with a sense of comfort and bien aise, that is not felt when plain cold water produces reaction redness. In fact, the latter only reaches such intensity of redness after very cold procedures in vigorous subjects, but never the same intensity of warmth. Certain it is that I have never seen a patient in the condition

which is met in the majority of cardiac cases that could bear a cold procedure with plain water of sufficiently low temperature to produce a hyperemia equal to that which the most depreciated cardiac case can be trained up to bear with the CO₂ bath of 90° F.

Local Action of CO₂ Water.—The hyperemia, which is invariably manifested when the individual lies in a CO₂ bath, by redness of the skin, cannot be due to reflex action, through the vasomotor system, because it is confined only to the parts exposed to the CO₂ water. A careful study of the experiments and observations made by others confirm my conviction that the hyperemia is due to a specific mechanico-chemical irritation by the CO₂ gas. (Oxygen bubbles in the Ozet bath do not produce hyperemia.)

Ottfried Miller and his school have demonstrated by painstaking observations the absence of decided vasomotor action, because of absence of resistance at the periphery. There is no plethysmographic volume increase in the arm made red and hyperemic by CO₂. This has been successfully refuted by Arthur Hirschfeld of Brieger's Clinic, who shows that Miller's plethysmograph rested partly in the bath water. Nevertheless, both agree upon the most important fact that the peripheral arteries are contracted slightly. May this not be due to the constringing action of the absorbed CO₂ upon their muscular coats, which come in direct contact with the gas? More of this later on. The almost invariable slowing of the pulse and its somewhat heightened tension find in this theory a more rational explanation.

Another undeniable effect of the CO₂ upon the skin is a heightening of cutaneous sensibility, which has been referred to. I regard this phenomenon as explaining the intensifying effect of CO₂ on temperature sensation, whether below or above the point of indifference, which averages in a plain water bath for ambulant patients about 33° C. (91.4° F.), and in persons warmed by lying in bed previous to coming in contact with plain water 35° C. (95° F.). O. Miller states that this neutral point in the CO₂ bath for ambulant patients is about 34° C. (93.2° F.). Despite the fact that the skin feels a sensation of warmth, the action of the CO₂ bath is equivalent to that of water of lower temperature in its influence upon the vasomotor system.

The first time I had occasion to utilize this singular fact was in a case of typhoid fever I saw with Dr. Joseph Fraenkel of New York several years ago. The doctor had been advised by two consultants against using a cold bath and to rely upon alcoholic stimulants to rescue the patient from desperate toxemia, which blunted all reflexes. Believing that it was imperative to arouse the reflexes by refreshment with cold water, and fearing to advise the Brand bath, a tubbing in water at 80° F. was advised, with the Nauheim salts, to add a chemical to the thermo and mechanical peripheral excitation. Though there was not the slightest visible response to the cold water, and none even to an affusion at 50° F., the patient's pulse improved in tension and frequency, and she slept for three hours after the first bath and awoke from an unconscious state of several days' duration, during the fourth four hourly bath, the pulse improving after each one. (Ueber Reaction nach kalter Prezeduren—Congress fuer Naturforscher und Aertzte in Karlsbad 1902.)

This experience was repeated in other consultations, so that I no longer hesitate to order certain cold baths, from which I formerly refrained in de-

preciated cases, when fortified by CO₂ gas. My experiments have demonstrated the enhancement of sensibility in the peripheral nerves by CO₂ baths, so that the clinical fact above mentioned is accounted for, and we are able to deduce from them a phase of therapeutic action of CO₂ baths in cardiac insufficiency that has been hitherto obscure.

These effects are combined with the following: the bubbles of CO₂ gas, which in the bath envelop the body, as it were, in a network, isolate the portions so protected against extremes of temperatures, so that the beneficial results referred to above are attained. Temperatures that would be obnoxious, either above or below tolerance, are borne with comparative comfort when the water contains CO₂ bubbles.

The systemic effect from absorption of CO₂ is more important, in my estimation, than is generally believed. Indeed, it is the one positive fact undisputed by all authorities. Ottfried Miller and his aids mention it, but do not appear to realize its importance. (Sammlung Klinischer Vortraege No. 711-14, 1915.)

The absorption of CO₂ through the skin and its activating of respiration has been indisputably established by the valuable investigations of Filehne and H. Winternitz of Erlangen (Deutsches Archiv f. klin. Medizin Bd. 72). H. Winternitz regards this action as specific in CO₂, being absent in other cutaneous irritants, and he affirms its increase in the presence of salt solutions. This is a neglected but important fact, which explains what hitherto has been obscure, as I shall show in the superiority of the Nauheim over other CO₂ waters.

In commenting upon my new rationale of the Nauheim bath, Professor Groedel protests that there is already a fatal increase of CO₂ in many cardiac cases. In rebuttal I would point to the fact that we deduce from animal experiments with toxic doses of drugs our most valued therapeutic results from safer doses of the poisons. Moreover, the cyanosis present in extreme cardiac failure is due more to the absence of oxygen than to accumulated CO₂. That CO₂ circulating in the blood in excess stimulates the respiratory center is a well-known physiological fact, an increase of 2 per cent. causing a ten-fold energy of respiratory activity in health. (Burton-Opitz.) Starling (*Lancet*, 1905) gave CO₂ the first place as the hormone or chemical regulator of respiration.

Therapeutically this enhancement of respiratory activity becomes of immense import, in that it must influence favorably the entire intrathoracic circulation, more especially the venous flow. The right heart is unloaded and the diastole prolonged, all of which must bring great relief from stases, which, by their production of edemas and retention of toxins from faulty tissue change, give the bedside clinician most anxiety, and but too often close the scene. I am disposed to regard this action of the absorbed CO₂ as most important in temporarily restoring lost cardiac equilibrium. That it requires judicious adaptation of the bath to each individual case is evident. It is remarkable that other clinicians do not lay more stress upon this demonstrated action of CO₂.

Distribution of blood as manifested by blood pressure, pulse frequency, volume and tension, has been a bone of contention among investigators. Ottfried Miller and other laboratory reporters claim some increase of blood pressure, while Groedel, Jacob and others who practise with natural CO₂ baths do not

find increase of blood pressure to any extent. Nevertheless, all report almost invariably an improvement in the pulse, evidencing bettered cardiac conditions. My own observation made with Saratoga waters, published in the *N. Y. Medical Journal*, confirm their view.

This difference in the observations of equally reliable clinicians may be explained as follows: The action of water, air and CO₂ gas upon the skin is determined by the temperature conducting capacity of these agents. Air and CO₂ gas differ materially in the *capacity of absorbing* temperatures (cold and heat), and water *absorbs* temperature with far greater rapidity than either. The point at which the skin is indifferent to water, air or CO₂, as ascertained by changes of blood pressure, is 34° to 35° C. (93° to 95° F.) for plain water, and it is lower for atmospheric air, in ordinary humidity, 20° to 25° C. (68° to 79° F.), and for CO₂ gas it is still lower, viz.: 13.5° to 14° C. (57° F.). According to Senator and Frankheimer (*Therapie der Gegenwart*, 1904) air, water and CO₂ gas differ still more positively in *conductivity* or capacity for transmitting temperature to objects. Taking the conductivity of air to be 100, that of CO₂ gas is inferior (almost one-half) to that of air, and almost infinitesimal when compared to water (1 to 54). Therefore, CO₂ conducts its own temperature so slowly to the skin that it must be warmed, by the temperature of the water, long before the skin can be affected by it; for example, if the temperature of the water at 90° F. were conveyed to the skin in one-tenth of a second, the CO₂ temperature would require 570 seconds (9 minutes) to reach the skin, were it not held in the water. This being the case, the water, which absorbs temperature readily, is endowed with the temperature indifference of CO₂ but slightly. The water temperature always dominates, because of its great conductivity, both in the low and high-temperature baths. This confirms the results of my clinical observations.

In my estimation, a potent influence upon the circulation has been overlooked by all observers, viz.: the direct stimulation of the heart muscle by absorbed CO₂. We have experimental warrant for such cardiac stimulation in the fact that animals poisoned by CO₂ die with the heart in systole.

Blood Pressure.—Weiss & Kommerell (*Ueber die physiologische Wirkung der Kohleusaure*, Volkmann's Sammlung, 711-14, 1915) have made some interesting experiments on the difference between the plain and CO₂ bath, to which I have added, as I shall show, some data of importance.

In a CO₂ bath the body is covered by a net or jacket of gas bubbles or pearls, which are warmed by the water. This would explain theoretically the remarkable dualism of a neutral bath in CO₂ water and its tendency to lower blood pressure, despite the atonic condition of the peripheral (capillary?) vessels, but Ottfried Miller has shown practically that "while there is at first a rise in blood pressure for fifteen minutes, that later, in ten minutes, the pressure falls step-like, all of which is due to warming action of the water, upon the CO₂, which is raised above its normal point of indifference (neutral temperature)," when the bath is prolonged.

The sensory excitation depends upon the number of gas bubbles and the duration of the bath. This demonstrates a chemico-mechanical excitation. In the laboratory they use artificial CO₂. I believe that a natural CO₂ water acts differently, because the bubbles are finer and it contains more dissolved

CO₂. The artificial, on the contrary, contains more free CO₂ gas, which escapes more easily, as is proved by the presence in the layer of air above an artificial CO₂ bath of 17.25 per cent., while the air above the natural CO₂ bath shows only 0.89° CO₂ (Beerwald & Von Heyde, Balneological Congress, 1909).

Moreover, experiments made under my direction by Mr. Herbert Ant, State Chemist, of the Reservation Commission, at Saratoga Springs, last December, show that the total gas available from a CO₂ bath, prepared with hydrochloric acid, 12 oz. and bicarbonate of soda, 8 oz., is less than 11 per cent. actually found by chemical experiments, of which only 3 1/3 per cent. to 4 2/3 per cent. is supersaturation. Recently a CO₂ bath made with 1 1/2 lb. bicarbonate of soda and 2 1/2 lb. hydrochloric acid, produced 17 per cent. CO₂ gas, immediately after solution (6.75 per cent. supersaturation). At Nauheim, the presence of at least 25 per cent. of gas as supersaturation is considered essential. In Saratoga, the Hathorn No. 1 water, when first drawn into the tub, ranges from 33 to 35 per cent. supersaturation, and when the patient is actually taking the bath, there is still from 25 to 27 per cent. of gas, ascertained by the Haertl shaker.

The contrast effect between the CO₂ gas and water, which Groedel dwells upon as important for thermic excitation, therefore must be more pronounced in the artificial bath, with which Ottfried Miller and his school experimented, namely, that produced by hydrochloric acid and bicarbonate of soda, as in the natural bath.

There are other elements in this problem which must influence the physiological action of the artificial carbonic acid bath; first, uncertainty from the size of the tub, which ranges, according to the exact measurements, from 45 to 75 gallons. The calculation of artificially prepared carbonic acid should be made according to the size of the tub (which differs from 45 to 75 gallons), otherwise it will be too strong or too weak; second, the fact that in the artificial bath, carbonic acid gas is rapidly evolved and passes off and its temperature cannot be quickly equalized with that of the water, would change the physiological action, unless the bath is longer than is regarded as safe. On the other hand, in the natural CO₂ bath, as given in Saratoga, Nauheim, Marienbad, Kissingen, and Franzensbad the carbonic acid being in age-long contact with the water is received by the skin, of the same temperature as the water and in the same percentage, furnishing an unvarying action, which is reliable for therapeutic purposes, whether the tub is small or large. *There cannot be any doubt, therefore, of the superiority in therapeutic effect of the natural carbonic acid water over the artificially prepared in cardiac diseases.*

Vasomotor Effect.—I have already mentioned that the hyperæmia of the skin is not due to vasomotor action, because it is only discovered in parts that are exposed to the CO₂ bath. It is possible that Groedel's idea that the contrast action, produced by the difference of the temperature between parts covered by the CO₂ and other uncovered parts may produce some excitation of the sensory terminals.

But the main vasomotor action ensues when, as I have shown long ago ("Principles & Practice of Hydrotherapy," Wm. Wood & Co., 1908, page 50), the bath temperature is reduced below the neutral temperature (which is about 34° C. or 93.2° F.) for CO₂ water. The lowest temperature prescribed by

Groedel and others, being 30° C. (86° F.), must produce some reflex vasomotor effect by excitation of the peripheral nerve endings, which fulfils my hydrotherapeutic law, viz.: the degree of difference between the water temperature and skin temperature governs the intensity of the peripheral excitation, and therefore of the reflex vasomotor, action. A carbonic acid bath of 93° F. (neutral) would be indifferent to the skin, while a bath of two to seven degrees lower, which is not uncommon in Nauheim, would produce thermic nerve excitation.

In commenting on my new theory of the action of carbonic acid baths, Groedel writes that "It is unnecessary to assume a direct effect from absorbed CO₂ gas upon the involuntary muscle fibers, in order that there should be an irritant action. The mechanical irritation of the gas bubbles, upon the peripheral nerve endings would suffice for this purpose; secondly, it is questionable whether or not we have here a thermic excitation through cold, in a bath of 32° C. (89.6° F.), to which I should reply that a difference of 3.4° C. between the bath water and the skin is certain to arouse a thermic excitation in the sensory terminals of the latter and produce reflex vasomotor action. Replying to the first, there is no such mechanical action from bubbles in the oxygen bath, in which reddening of the skin is absent.

Specific Action of CO₂ Water Upon the Cutaneous Muscular Structures.—Experiments made in Bad Nauheim and in Saratoga Springs have convinced me that a CO₂ bath produces on the unstriated muscular structures of the skin a constricting action similar to but milder than that produced by plain colder water. This constricting of the skin probably offers a mild but positive resistance to the flow of blood in the large peripheral surface, with the result of enhancing cardiac energy.

Judging from the susceptibility of the dartos, of the scrotum to cold air, as manifested by contraction of its cutaneous structures, I utilized this peculiarity of the scrotum for the purpose of ascertaining the effect of the CO₂ waters of these springs. There was noted a very decided formation of rugæ in the scrotum of patients emerging from a CO₂ bath. (Illustrated by lantern slide.)

There is no reason to doubt that the same constricting effect is produced upon the unstriated muscular fibers in the cutaneous surface of the entire body, though not so perceptible to the eye. It is not unreasonable to assume that this muscular contraction, to the effect of which I have already referred in connection with compressing the capillaries, furnishes added resistance at the periphery, which promotes reaction, despite capillary dilatation. You will find illustrations of this in the *N. Y. Medical Journal* of the 13th inst.

It is plain that through the combined effect of all the elements furnished by the CO₂ baths, as described above, there is a mild resistance at the periphery, which impels the ventricle, already stimulated by absorbed CO₂, to drive the blood with more energy to all the outlying districts. This mild training of the heart, once a day, though for only a short period, appears to be productive of salutary conditions in the entire vascular system.

This explanation of the rationale of the CO₂ baths is much more reasonable than that of a special, or an occult effect from the CO₂.

The action of the salines rests upon a scientific rationale. They are *not* absorbed, but as the Nauheim doctors correctly claim, an imperceptible layer

remains deposited on the skin even after drying. Being hygroscopic the skin remains somewhat moist. Added to this there is an irritating action of the salines upon the skin, producing a moderate hyperaemia; both furnish an enduring physiological rest to the failing heart.

But a more potent influence of the salines is evidenced by the discovery of H. Winternitz in von Mering's Erlangen Clinic, that the addition of chloride of sodium to the CO₂ bath promotes the penetration of the gas through the skin and its entrance into the blood. The importance of this fact has been overlooked. Believing that an essential effect of the CO₂ bath arises from the absorption of CO₂ gas, which acts primarily upon the unstriated muscular coats of the arteries and arterioles, increasing peripheral resistance and thus enhancing ventricular energy, in a mild but positive form, I lay great stress upon its presence in proper quantity, as found in the Nauheim water.

It is my gratifying privilege to-day to present another important and, as far as I am aware, hitherto unknown value of salines in connection with CO₂ baths. Under my direction the talented chemist of the Reservation Commission, Mr. Herbert Ant, made certain experiments. Under date of December 29, 1915, Mr. Ant reported: "I have completed the experiments on the artificial baths requested by you," and he concludes "this gives only 16.3 per cent. free gas that is actually available for the beneficial effect of the bath. Of this 16.3 per cent. only from 5 to 7 per cent. is supersaturation." In compliance with directions for another experiment, I sent to Mr. Ant, he reported on April 18, 1916: "You will note from some of my previous results on artificial baths that the addition of the salts seems to retain the gas better and therefore improves the supersaturation." In fact, the difference is marvelous, being 5 to 7 per cent. from the best artificial preparation, without the salines and 20 to 25 per cent. with the same preparation, when the proper quantity of salines is added. Mr. Ant has also, in accordance with my instructions, determined that when the salines are added there is a loss of only 1 to 2 per cent. of gas during a ten-minute bath, and 2 to 5 per cent. during fifteen minutes. Hathorn No. 1 loses 8 per cent. during the first few minutes of the bath which loss would be prevented by the salines.

These reliable data must set at rest all further disputes over the value of the salines in the Nauheim waters, for they show that absorption of CO₂ is furthered by them and escape of CO₂ is prevented by them.

Last October I advised the Chairman of the Reservation Commission to direct the Manager of the Kayoderosseros Bath, as a temporary measure, to add 6 lb. sodium chloride and 10 oz. calcium chloride to each bath, which though milder than the salines of the Nauheim water, was reported by Dr. A. S. Downs as a great improvement. The nurses also remarked upon the increased hyperemia.

In order, therefore, to have the closest approximation to the Nauheim water in Saratoga, it is necessary to add to the water of the Hathorn Spring No. 1, which contains, besides many of the minor mineral ingredients, about 21 ounces of chloride of sodium, but no chloride of calcium, in each 60 gallons definite quantities of salines calculated by Mr. Ant. The other mineral ingredients are so minute and practically the same in both waters (Nauheim and Saratoga) that it is not

worth while to calculate them. It would be easy to dissolve in the smallest quantity of Hathorn water 12 lb. sodium chloride and 1 lb. pure calcium chloride, in the tub; then permit a sufficient quantity of the Hathorn water to flow in to make 60 gallons, which would cover the average person. In this manner the average saline contents of the three Nauheim springs commonly used mixed would be approximated. Any physician may, if these salines be held in readiness at the bath house in packages of whole, half, and quarter quantities, prescribe the exact percentage desired, viz., full, half, or quarter salines, and by dilution prescribe full, half, or quarter quantities of CO₂ water as they do in Nauheim with success.

Physicians would do well to use the Kayoderosseros (now called Saratoga) bathhouse chiefly for Nauheim baths in order to avoid confusion, and to use the Lincoln and Empire Springs for other cases. My reasons are:

1. The Saratoga bath on Phila Street, being situated in the town near the lodgings of the patients, would diminish the exertion to reach their rooms, while the Lincoln bathhouse, especially, is some distance from town, an advantage for cases of neurasthenia and other functional diseases that require open air exercise after the bath, viz., when the system has been thoroughly aroused.

2. The attendants of the different bathhouses would in this manner become skillful in their respective lines.

3. Another important advantage of this specialization would be that by treating cardiac cases in the bathhouse on Phila Street the physicians would have more easy access to the bathhouse, enabling them to supervise the treatment occasionally as the Nauheim colleagues do. In the event of overcrowding, the High Rock or Lincoln bath could be used for all purposes by having the necessary saline packages on hand.

Therapeutic Application.—Formerly the Nauheim physicians began a series of baths with the thermal bath, containing the salines, with a minimum CO₂ left after exposure to the air, then increasing CO₂ content. Groedel, the highest authority, dilutes the spring water with Suesswasser to obtain percentages desired of the Nauheim spring waters.

Therapeutics.—Recognizing the rationale mentioned it is not difficult to devise a scheme of treatment by which the heart may be gently trained. I shall confine myself to a few illustrations.

In cases of positive insufficiency of the circulation, in which there is no great dyspnoea in the recumbent posture and only slight oedema, rest is the most important element of treatment, especially after arrival from a journey.

In Saratoga Springs such cases may receive with benefit the Hathorn No. 1 in the Saratoga bathhouse, diluted with 50 per cent. plain water (Groedel method), in which the salines are dissolved and poured into the tub, the bath being of about 93° F., duration 6 to 8 minutes, and repeated every other day. This should be followed by a rest of one or two hours in bed. Patient should return to his room in a wheel-chair or other easily-running vehicle. After three or more of these baths, the duration may be increased to 10 minutes, and the dilution diminished from time to time. If dyspnoea and other manifestations are relieved, the temperature of each bath may be reduced gradually as far as 91° F. and the full saline and CO₂ given. The number and frequency of the baths should be arranged entirely

in accordance with the effect of each partial series, ascertained by a report of the nurse or, better still, by the physician himself. *The prevailing mode of ordering a series of eighteen baths is unscientific and unjust to the patient.* An enduring sense of fatigue or loss of sleep are warning signals that the bath is too long, too cold or too warm.

If the cardiac insufficiency be more recent, or compensation appears to be initiated, the full strength of the saline and CO₂ bath may be administered for three baths at 93° F. and afterwards each bath reduced in temperature and the duration increased up to 12 minutes, omitting the third day.

In *uncomplicated mitral insufficiency*, if there is no cardiac muscular degeneration, the temperature of the bath may be reduced every other day until 86° F. or less is reached, according to the effect upon the pulse and general manifestations. In cases of aortic or mitral stenosis, or if there is much fibrillation, the temperature should never go below 90° F.

If there is no disturbance of compensation, namely, if palpitation or slight dyspnoea ensues only on decided or prolonged exertion, or during ascending stairs, one may begin at once, with the combined CO₂ and saline bath and proceed to the strongest baths at a temperature of 90° F. and duration of 10 minutes, but not exceeding 15 minutes. Only well-ascertained tolerance after each of these baths would warrant proceeding to lower temperatures, and this with great caution, but with a shorter duration, not exceeding 10 minutes.

Attention should be paid always to the general manifestations following these baths. A sense of prolonged fatigue and loss of sleep indicate that the bath is probably too intense.

In *so-called fatty heart* and so-called weak heart, manifesting themselves by a feeble compressible pulse of 80 or over, or increased considerably by ordinary exertion, one may readily proceed from the mildest to the strongest CO₂ bath, with intermissions, raising the duration up to 15 minutes, and lowering the temperature to 85° F. by degrees for each bath.

In *arteriosclerosis*, the therapeutic indications are conditioned upon the presence or absence of increased blood pressure and high pulse tension. In the latter cases, the bath temperature and duration may be gradually increased to a point at which results appear to be favorable, always being ready to recede on the appearance of unfavorable manifestations. When there is high blood pressure, however, great caution is necessary and it is well not to allow the temperature to go below 95° F. A full bath of Hathorn No. 1, with preceding saline addition at 93° to 95° F. is ideal in such cases, if the duration be gradually and cautiously increased as far as fifteen minutes.

In *true angina pectoris*, when the nitrite of amyl does not relieve the paroxysm, Groedel advises to refrain carefully from the carbonic acid bath. He gives the same warning for patients with arteriosclerosis, who have had an apoplectic attack, even of the mildest type. Babcock says "Nauheim baths must be ordered with extreme care. I now recall only one patient who appeared not to be benefited by these baths."

Angina pectoris of the so-called nervous or functional type, requires gradual neorovascular training, beginning with baths of five minutes at 93° F. and diminishing the latter in each bath, as far as 85° F. without salines. Groedel and Goldscheider

regard the carbonic acid baths as the most excellent means of exercising the vasomotors and of raising the tone of the cardiomuscular nervous system. This is entirely in accord with my own observation, these baths, without salines, having brought me very satisfactory results in cases of nervous or false Angina, which must be diagnosed cautiously.

In Basedow's disease and in neurasthenics suffering from nervous disturbances of the heart, manifested by easily produced palpitation, without exertion, cases should be carefully differentiated. The depressed type may be treated energetically, with brief and cold CO₂ baths, at the Lincoln Spring, which has the highest CO₂ content, starting with 90° F.

In the *erethetic type*, the carbonic acid baths are contraindicated unless 100° F. is used.

Purely anemic patients should be treated with a full gas content (Lincoln Spring), *without salines*, increasing duration and decreasing temperature, beginning with 90° F. and decreasing until the lowest temperature, which produces an agreeable reaction, is reached. On account of the value of open air exercise after the bath in non-cardiac cases, I recommend the Lincoln and Empire Springs, for the neurotic cases.

The Nauheim physicians have ascertained, by long experience, that patients arriving there should be kept at absolute rest, before the baths are begun, until a fairly normal condition of the pulse and respiration is established. They should also have physical and mental rest before each bath. The most favorable time for the bath is in the morning, about an hour after a light breakfast. Patients should endeavor to be quiet in the bath and avoid inhalation of carbonic acid gas. He should be dried gently, without friction, with warm linen sheets or towels, and he should rest in bed in a well-ventilated room, one or two hours after each bath. A fairly strong patient, whose pulse is not easily excited, may walk slowly to his lodgings, and there take a rest, but in the majority of cases, I regard it as advisable for the patient to ride in a chair to the hotel, and in a severe case he should not leave the bath house without resting at least an hour. The period of rest is the time for the physician to see him personally, if possible, in order to note the effect of the bath. The same rule applies to the artificial Nauheim bath.

A reliable guide to the beneficial or other effect of the bath is the condition of the pulse, which should be reduced in frequency and somewhat increased in tension, in uncompensated or imperfectly compensated patients. Groedel, Sr., holds that cases that do not respond to digitalis are, as a rule, not benefitted by baths. I am disposed to believe that this is too broad a statement, since we have in the bath (plain water or water containing CO₂ of varying temperatures and durations) means for adapting them to conditions that will not respond to digitalis.

An important auxiliary in the Nauheim Method is the mechanical treatment by passive and active movements.

Mechanical Treatment.—While rest is probably one of the most important elements in the management of cardiac ailments proper exercise is of great service. The latter must be adapted, just like the baths, to the responsive capacity of the heart, with due regard to physiological principles, viz.: that exercise of the voluntary muscles produce an

emptying of the veins, which in advanced cardiac cases always are too well filled. That the respiration may also be affected by certain mild forms of exercise, I have had abundant opportunity to prove. I have in mind a medical society meeting, in which an eminent internist stated as a result of a recent visit to Nauheim, that the resisting movements are a negligible fad. I called upon him to permit me to give him some resisting exercises of the arms, and on his declining I gave them to another colleague, who, in reply, to the question if he felt any effect said that he felt somewhat fatigued.

Active exertion, like tennis or bicycling, etc., or long walks, are absolutely forbidden, but the energy of the heart may be trained by mild methods of exercising; passive and resisting, following by the Oertl system of walking, all of which must be applied with due regard to the reserve power of the heart and the vascular system, always bearing in mind that the latter is vicarious of the former. The condition of the patient is here of great moment. He must be absolutely calm during the exercises. In the passive method the attendant grasps an extremity, with the right hand. Holding the adjoining portion of the limb, with the left hand, he flexes and extends it slowly several times, with a view to press the venous blood out of the muscles and of increasing the arterial supply of the latter. This is repeated with several extremities, after each of which the patient is advised to rest.

Resisting Movements.—I still adhere to Schott's *Widerstand Gymnastik*, consisting of slow movements executed by the patient, and resisted by the operator, short intervals allowed between each for rest; patient sitting in chair, rises for each movement. They may be alternated with the baths or used after the completion of the series.

Exertion should be small and cause no increased respiration, flushing or pallor. Patient should be loosely clothed and told to breathe quietly. Resistance should be of such kind that patient feels himself master. Operator must not grasp or constrict limb, but oppose by his hand held flatly.

1. Each movement is to be performed slowly and evenly, that is, at a uniform rate.

2. No movement is to be repeated twice in succession in the same limb or group muscles.

3. Each single or combined movement is to be followed by an interval of rest.

4. The movements are not allowed to accelerate the patient's breathing and the operator must watch the face for the slightest indication of (a) dilatation of the alae nasi; (b) drawing of the corners of the mouth; (c) duskiness or pallor of the cheeks and lips; (d) yawning; (e) sweating, and (f) palpitation.

5. The appearance of any of the above signs should be the signal for immediately interrupting the movements in process of execution, and for either supporting the limb, which is being moved; or allowing it to subside into a state of rest.

6. The patient must be directed to breath regularly and uninterruptedly and should be find any difficulty in doing so, or for some reason show a tendency to hold his breath, he must be instructed to continue counting in a whisper during the progress of each movement.

7. No limb or portion of the body of the patient is to be so constricted as to check the flow of blood.

Exercises.—1. Arms extended in front of body on a level with the shoulder, hands meeting; arms

carried out until in line and brought back to original position, operator resisting.

2. Arms hanging at sides, palms forward, arms flexed at elbow until tips of fingers touch shoulders, back to original position; one arm only moved at a time.

3. Arms down, palms forward, arms carried outwards and upwards until thumbs meet overhead; back to original position.

4. Hands in front of abdomen, fingers flexed so that second phalanges touch those of opposite hand; arms raised until hands rest on top of head; back to original position.

5. Arms down, palms against thighs, arms raised in parallel, planes as high as possible; back to original position.

6. Trunk flexed on hips; return to original position.

7. Trunk rotated to left, to right, return to original position.

8. Trunk flexed laterally.

9. As No. 1, but fists clenched.

10. As No. 2, but fists clenched.

11. Arms down, palms against thighs, each in turn raised forwards and upwards until arm is alongside of ear, then turned outward; arm descends backwards.

12. Arms, down, palms to thighs, both together moved backwards in parallel planes as far as possible without bending the trunk forwards.

13. Thighs in front flexed on trunk, opposite hand resting on chair.

14. Lower extremities in turn extended fully, and bent on trunk forwards and backwards to extreme limits of movements, opposite hand resting on chair.

15. Legs in turn flexed on thighs, both hands on chair.

16. Feet together, lower extremities in turn abducted as far as possible and brought back to original position, opposite hand on chair.

17. The arms extended horizontally outwards, are rotated from the shoulder joint to the extreme limits forwards and backwards.

18. The hands in turn are extended and flexed on the forearm to extreme limits and brought back in line with arm.

19. The feet in turn are flexed and extended to extreme limits and then brought back to their natural position.

These exercises are given on the Zander apparatus in Nauheim and other resorts.

The principal guide to a prescription of the Nauheim method, whether natural or artificial is *adaptation of the bath in duration, temperature, and gas and mineral contents, to each case and a careful watching of the response of the heart to the bath.* Omitting the salines is as unwise as omitting any element of asepsis in surgery.

Artificial Nauheim baths, when prescribed at home, demand greater precision in the use of the ingredients than is possible now. I would suggest a ready method as follows: When in the beginning a weaker CO₂ and stronger saline content is desired, for example, it is easy to pour the entire quantity of water required into the tub, dissolve the full quantity, 12 lb. sodium chloride and 1 lb. calcium chloride in the water; then add one-half of the acid and alkali supplied in the package to the water. If a full Nauheim bath is required, dissolve the full quantity of salines in the entire quantity of water, then add all the alkali and acid of the package. To imitate the

Nauheim bath, the water temperature should not be higher than 94° F. nor go below 86° F. unless patient has a fine reaction and is improving. The object of all treatment is to mildly raise the responsive capacity of the heart muscle by withdrawing obstacles to its free action at the periphery and enhancing the ventricular energy by slow degrees; in other words, to train the heart muscles as we train the muscles of the arm, with dumbbells, by gradual increase of labor. This is a coarse analogy; no harm can be done to the healthy voluntary muscles, by over-exercise, whereas the cardiac muscle acts involuntarily and is related intimately to the complicated machinery of the entire body, to which it furnishes pabulum, for the organic activities. Moreover, we have to deal with a pathological condition of a delicate organ, demanding cautious adjustment.

In Nauheim they find a series of eighteen baths and not exceeding twenty-four of average usefulness. From this brief data it may be inferred that the routine prescription of a series of eighteen or less number of baths, which many American physicians are in the habit of prescribing, is not to be commended. Positive individualization, which involves examination after every two or three baths, is necessary in every case, not alone on account of occasional idiosyncrasies that may bring about serious or fatal results, but owing to the uncertainties in the responsive capacity of patients, suffering from cardiac diseases, no two of whom are alike. One of my patients complained that a doctor in Nauheim, to whom I had sent him, was objectionable, because he seemed to pursue him, when he did not appear at his office, as directed. The patient regarded his motive as mercenary, but the fact was that this conscientious physician was intent upon protecting him against possible deleterious consequences from negligence of his prescriptions. It is safer to err on the right side, at the risk of being charged with mercenary motives, and see the patient frequently.

51 WEST SEVENTIETH STREET.

A SCHEME OF STATE CONTROL FOR DEPENDENT INFANTS.*

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

A VERY large number of dependent children are annually cared for in the State of New York by municipalities and various agencies under the official supervision of the State Board of Charities. The methods of operation and results of these different agencies vary according to the ages of the children. It seems wise in this connection to make a distinction between the infant and very young child and older children.

Let us first glance at the relative numbers that are cared for at different ages. The magnitude and growth of this work is shown by the chart on the following page, prepared by the State Board, which exhibits graphically the relative average rate of increase in the population of the State as compared with the fluctuations in the population of the institutions for children. The heavy line represents the fluctuations in the population of the institutions for children, as reported for September 30 of each of the years represented, and the dotted lines represent the rela-

tive average rate of increase in the population of the State.

The total number of children admitted to institutions reporting to the board was 18,801 during the year ending September 30, 1915. The ages of these children when admitted were as follows:

Less than one year of age	3,677
Between one and two years	1,421
Between two and five years	3,104
Over five years	10,999
	18,801

The ages of the children remaining in the care of institutions on September 30, 1915, were as follows:

Less than one year of age	1,486
Between one and two years	1,227
Between two and five years	4,807
Over five years	29,574
	37,094

A glance at these two tables will show a much smaller number of infants at the end of the year than were admitted during the course of the year. While some of these infants were discharged, or transferred elsewhere, a very large number died. The following two tables will show the number of deaths of infants and little children in institutions during the past two years. These figures do not include hospitals for the treatment of acutely sick infants.

1914. CASES DISCHARGED FROM INFANT ASYLUMS YEAR ENDING SEPT. 30, 1914

LENGTH OF TIME IN INSTITUTION	LESS THAN ONE YEAR					FROM ONE TO TWO YEARS
	Under 3 Months	3 to 6 Months	6 to 12 Months	1 to 2 Years	2 to 5 Years	1 to 2 Years
Age When Discharged						
Total	1306	540	582	504	614	318
Died	956	303	261	96	22	74

1915. CASES DISCHARGED FROM INFANT ASYLUMS (YEAR ENDING SEPT. 30, 1915)

LENGTH OF TIME IN INSTITUTION	LESS THAN ONE YEAR					FROM ONE TO TWO YEARS
	Under 3 Months	3 to 6 Months	6 to 12 Months	1 to 2 Years	2 to 5 Years	1 to 2 Years
Age When Discharged						
Total	1035	621	746	666	671	313
Died	674	380	350	122	22	74

As the whole number of infants in the institutions at one time is not included in these tables the mortality rate cannot be given, but a careful study of this question by a committee of the American Association for Study and Prevention of Infant Mortality has given information on this point as well. An examination of the statistics of eleven institutions operating in New York State showed that from 1909 to 1913, inclusive, 28,210 children under two years of age were cared for in these institutions, and that the death rate for babies under two years for this period, based upon the total number of children cared for, varied in the different institutions from 183 to 576 per thousand, with an average mortality rate for the eleven of 422.5 for the five years. During the years 1909 to 1912, inclusive, the death rate for children under two, based on the estimated population for the State at that age, was 87.4, practically one-fifth of that in institutions. These figures emphasize the fact well known to those working in this field that institu-

*Read before the Pediatric Section of the State Society at Saratoga Springs, May 18, 1916.

tional mortality among infants, especially in the first months, is very heavy.

We may here briefly inquire why the institution is not a favorable place to permanently house babies. Each age and period of life has its own special susceptibilities and reactions to various environments. The infant, in the first place, needs individual watching and care, and always suffers when this is lacking. It seems to crave the usual environment of family life, as this is the unit best fitted for its healthy development. In other words, it needs a home and mother. The farther we get away from these normal and natural conditions, the more the baby suffers. A poor mother and a poor home are better for the baby than an institution. But even in the best of institutions there are rarely enough good nurses for individual care during the day, and practically never at night. A baby can lose from a restless, untended night, the good that may have taken days of care to secure. The babies quickly show the lack of this individual nursing, generally by stationary or losing weight.

They rarely get sufficient fresh air, and oxygen is as necessary to their well-being as protein or fat. This may explain why improved methods of feeding have not had as favorable results inside institutions as outside of them. Lying in cots for long stretches of time, they miss the handling and fondling that even the poorest mother gives, and the muscular exercise that goes with it. When babies are removed from the natural conditions that usually go with even the poorest home, they droop in the presence of an artificial environment. The baby is the most susceptible member of the family to all external conditions.

There are other dangers in collecting and treating infants *en masse*. Reference may first be made to the spread of specific infections, such as pertussis, diphtheria and the exanthemata, to which little children are unusually susceptible. Young proto-plasm is receptive to germs of all kinds, which are passed from one to another unless the greatest care is exercised in preventing their transmission. When the general vitality is depressed, resistance is likewise lowered. Institutional infants seem to lose their immunizing power against bacteria after a certain length of time. Probably the greatest and most constant danger, however, comes from the

ordinary ward infections. It is almost impossible to prevent cross infections, especially from ordinary colds and influenzas, when many cases are collected in one ward. It is a constant experience in institutional management to have cases of pneumonia develop, as well as affections of the mucous membranes of the nose, ears, throat, bronchial tubes, gastrointestinal tract, and vagina. Unfortunately, if vaginitis occurs, it is nearly always specific and it is exceedingly difficult to prevent its general spread or even to treat the disease successfully in the individual.

Unfavorable conditions that cause a high death rate, and favor the spread of infections, are also usually reflected in a poor vitality in those who survive. This is one of the most serious aspects of this question. The first few years of life are, biologically considered, the most important ones we live. The rapidly growing organism has at this time stamped on it the possibilities of future vigorous life or of early degeneration or decay. Defective conditions at this period cannot be compensated for, as they sometimes can be in later life.

What then shall be done with the many foundlings and abandoned infants that drift from one institution to another in our large cities? It is a most difficult problem involving helpless, unmarried mothers, worthless, or hopelessly poor and ignorant parents, and social conditions that are hard to remedy. The institution has, at best, very poorly succeeded and usually failed in the solution of this problem, so that some other plan should be tried. The most promising endeavor consists in a proper amplification and systematizing of boarding out, accompanied by a careful follow-up system constantly at work. Relief must be aimed along the lines of family life with individual supervision instead of the collective life with institutional methods. Boarded-out babies, however, should be kept under constant oversight by some competent authority. There is nothing in common between a well-organized system of boarding-out and the old-fashioned baby farming which was subject to many abuses.

It is proposed to abolish the large city asylums and institutions for the care of homeless babies, and, instead board them out in the surrounding country. A method of operating this plan would

(Chart showing (dotted lines) the relative average rate of increase in the population of New York State as compared with (continuous line) the fluctuation in the population of the institutions for children.

first consist of having a few small collecting stations in the city. These stations will merely act as receiving homes to study the infant's physical condition and find the proper substitute food, after which it will be promptly boarded out in the country or even in the city, but under the constant oversight of a doctor and nurse who are never to lose sight of the case. This plan requires the work to be done in certain definite localities that will serve as units, each unit having its own staff. These babies must never be allowed to get away from constant and careful supervision if good results are to be obtained. Systematic, careful study of the field of operation is required if such a work is to succeed. Desultory, haphazard methods will not avail. The same care, routine, and system that are usually brought to bear in institutional work must be applied here. Its advantage lies in working largely through direct human agencies instead of depending overmuch upon a plant or a machine. A unit should consist of a definite locality, whose limits are not too widespread, which will thus allow of a complete understanding of the community by the visiting nurse. A survey should first be made to find out the general healthfulness and hygienic condition of the locality. Next, a census of homes, desirable and available for boarding babies may be made, with data as to the members and apparent intelligence of the family, and the hygienic condition of the household. The health and tone of the mother's own children will form a very good index as to her suitability for undertaking such a work.

The large infant asylums now board out quite extensively, but do not exercise sufficient oversight of their charges. The following plan of boarding out was inaugurated by the writer in 1902 and has been in successful operation ever since. As no institution was involved, a society was formed to oversee and carry out the work. The Speedwell Society emphasizes the following points: First, boarding out in a certain district of the country noted for its healthful conditions. Second, constant attention to diet and hygiene on the part of a physician and nurse who are thoroughly familiar with this class of cases and competent to deal with them. Third, the infants are kept as long as necessary, until feeding is regulated and digestion and assimilation are improved sufficiently to result in an increase of weight. Work is kept up during the whole year and not limited to certain seasons. Fourth, the training in a given neighborhood of a number of foster mothers, who, by constantly taking these infants into their homes, become fairly expert in handling them under conditions totally unlike those offered by the best institutions, and far superior to them.

The infants are kept until they are essentially improved—the average stay being about four months—when they are returned to their homes if such exist and are suitable for the infant. There is no reason why this principle should not be indefinitely extended. For the homeless or parentless infant, it would take the place of the institution. It is safer and more natural to house the child permanently in a home, however humble, than in the best equipped institution. In the long run the baby will do better in the home, but boarding out, according to this plan, should always be done in units which will allow intensive working in many small fields. Each village around a city could have its unit, with doctor and nurse working under the direction of a local committee. Money collected

for such a work would thus be largely expended in direct human service, rather than in keeping up bricks and mortar. The large sums of money now spent by the State in various communities to support children in institutions could gradually be deflected into real homes. Immense amounts are annually given by various municipalities for the institutional care of children. Thus the City of New York in the decade from 1904 to 1913 contributed \$4,481,251.28 to five institutions devoted to the care of infants. Instead of paying money to institutions, it would be better for the State to support a series of carefully regulated units for the intensive care of dependent infants boarded out in homes. Various centers for this work could be formed along the lines of densest population. These lines always follow those of transportation, and in this State the Central Railroad traverses the most populous sections of the community. Following this idea, the following centers suggest themselves for tentative trial: New York, Albany, Syracuse, Rochester, Buffalo. For the upper part of the State, Watertown might serve, while Binghamton could act as a center for the lower tier of counties. Each of these localities might serve as a unit, with a doctor and nurse on a salary, and homeless or abandoned infants from the surrounding area could be placed in homes under their oversight. The whole work should be under the control and inspection of a central body, such as the State Board of Charities, in cooperation with the State Department of Health. The difference would be not only in lowering mortality, but the money would go to trained human instruments, such as doctors and nurses, rather than be expended in overhead charges for operating large buildings.

The homes in which the children are placed will be helped financially by the board paid, and morally by the good advice and watching of the trained overseers. It will thus help the problem of poverty in every community and aid in keeping families together in line with the widowed mothers' pensions. The educational value should also be considered, as the constant oversight by a doctor and nurse will help instruct each foster mother in the care of her own children. It would be possible to raise the whole standard of living among many poor families in this way and I believe this has already been accomplished in the section of Morristown, N. J., in which the Speedwell work has been going on for the past fourteen years. We have been astonished at the labor and solicitude often given by our foster mothers in the care of sickly, atrophic infants and the marvels occasionally wrought thereby. A woman who bears a baby is a creator: a woman who takes a feeble, ailing baby and restores it to health and strength is a re-creator. In this work, even poor mothers often succeed where the most exemplary nurses fail. There is something in the mother instinct that makes for healing; love has a distinct therapeutic value to the little child.

The best solution is thus to place the well and normal child in a private home constantly supervised by the authority of the State; the defective, and sometimes the acutely sick infant, may best be treated in the institution. We would not imply that good intentions and kindly service are not found in institutions in spite of the lack of individual care, but the time has gone by when good motives can be accepted as a lasting excuse for bad methods.

Thus far we have only studied this problem from the standpoint of efficiency; there still remains the

question of economy to consider. This is reached by comparing the daily per capita cost to the individual in an institution with the cost for the same type of case as handled by boarding out according to the Speedwell method. The daily per capita cost is obtained by dividing the total number of days service into the total cost of operation. This is the standard by which the Hospital Saturday and Sunday Association of New York City estimates the amount of work done by institutions, with the cost, in apportioning its funds. The following is taken from their statement of the daily per capita cost of four hospitals in New York City dealing principally with infants and little children:—\$1.98, \$1.90, \$1.81, \$1.54. Three of the city institutions for infants, in which hospital care is not an important feature, do not receive aid from the Association and hence do not report according to its standards. In an accounting to the Department of Finance of the city they report a weekly per capita cost of \$4.75, \$3.48, \$3.34. No explanation is given as to how this amount is reached and what is included or excluded in arriving at these figures.

In estimating the real and actual cost of caring for children in institutions, several items should be considered to which attention is usually not directed. Thus no account is taken of the original cost of the plant. As this means locking up a large sum, several hundred thousand dollars—and in one case well over a million dollars, the interest of which might be expended in more fruitful methods of operation, this lost interest should be charged against the expense of the work. These buildings are also not taxed, which means that the community at large must make up this deficit by additional taxation, and thus indirectly contribute an added cost. It is thus seen that the institutional care of infants is really very costly when analyzed from all sides. Against this, the cost of the Speedwell method of carefully regulated boarding out amounts to \$1.15 per capita per day, which includes absolutely everything. Travelling expenses of nurse and child to and from the country, extra clothing, special milk, the price of board and the salary of a doctor and two nurses, with occasional unforeseen additional expenses, are all included in this item.

It is seen that this plan of management is economically sound as well as practically efficient. While efficiency should always come first in charitable work, economy of administration is a feature that is too often overlooked.

The time is ripe for new and concerted efforts along the line of conserving the life and vitality of motherless and abandoned infants. It is believed that the plan here proposed offers the best solution of a difficult problem if intelligently and perseveringly tried. The life of the infant is, economically, the most valuable asset of the State, as it should have the longest duration in years and the highest possibility of usefulness. The preservation and conservation of vigorous infant life should thus be one of the first concerns of the State.

Incipient Mental Disease.—Floyd M. Alpin states that in his early observation of suspected mental cases there are four major points he uses in much the same spirit as a woodsman would the four points of a compass. First, is the patient above normal in spirits, lowered in his religious habits, bold in manner, free with money and remiss in home relation? Second, is he below the average in spirits? Third, what about any peculiar ideas if any are present? Fourth, does there exist or likely to exist a decrease of mental capacity?—*Wisconsin Medical Journal*.

ANGIOMA OF THE LARYNX.*

By EMIL MAYER, M.D.,

NEW YORK.

LARYNGOLOGIST TO MOUNT SINAI HOSPITAL; FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, ETC.

ANGIOMA of the larynx is of rare occurrence. The importance of its recognition becomes at once apparent when we consider the danger that may follow upon an attempt at the removal of a portion of the angiomatous induration for diagnostic purposes. In the case here recorded, there was good reason to suspect the condition to be due to a malignant growth, and an attempt at removal of a specimen for confirmation of that diagnosis might have led to fatal consequences.

Mrs. S. R., aged 52, was first seen by myself in consultation with her physician at my office September 20, 1915. She had been hoarse for a year. This was her second attack. Six months previous to the beginning of this attack, she had been hoarse for a time, had a profuse hemorrhage from the mouth, and her hoarseness left her to return some months later. There was some cough, no pain, but attacks of dyspnea occurred on the slightest exertion. Patient was well nourished and there was no loss of weight. An examination showed a growth involving the left side of the larynx, extending from the lower surface of the left false cord downward, diminishing the lumen of the larynx appreciably. The left vocal cord was not visible.

The diagnosis of cancer of the larynx had been previously made, and the likelihood of this was not deemed impossible. The patient was advised to enter hospital for observation and operation if indicated.

On October 4, 1915, she entered Mount Sinai Hospital in the service of Dr. Charles A. Elsberg, and I was requested to examine her and report as to the diagnosis. On examination I found a dark, bluish-gray mass, yielding to the probe, generally rounded and extending downward on the left side from the under surface of the false vocal cord, and completely hiding the true cord without having the external appearance of a cancerous growth. My diagnosis was angioma of the larynx. In view of the history of a previous hemorrhage, and the danger of uncontrollable hemorrhage following, I declined to remove a portion of the growth, but advised laryngo-fissure and extirpation of the mass.

The operation of laryngotomy and excision of the angioma of the larynx was done by Dr. Elsberg. Local anesthesia. Under infiltration anesthesia incision 5 centimeters long over thyroid cartilage. Cartilage split in median line and edges retracted. Mucous membrane of larynx thoroughly cocaineized with 10 per cent. cocaine. The posterior half of the left true vocal cord is occupied by a bluish tumor which extends into the ventricle on that side and over the greater part of the false vocal cord. The tumor was 2 centimeters in its greatest length and 1 and one-half centimeters in its greatest width. After incision of the mucous membrane above the tumor down to the cartilage, the entire mass was peeled out of its bed, part of the thyroid cartilage, the entire false vocal cord, part of the wall of the ventricle and the posterior half of the true vocal cord being excised. The base was touched with the thermocautery. Bleeding was very slight. The mucous membrane was then raised up to the epiglottis and into the sacculus until it was possible to unite its edge with the mucous membrane below the vocal cord. The edges were united by interrupted sutures of fine catgut and the continuity of the mucous membrane thus restored. Edges of the thyroid cartilage were then approximated by sutures of catgut and the skin wound closed with drainage.

At the time of operation a frozen section of the tumor was made by Dr. F. S. Mandlebaum, pathologist to Mount Sinai Hospital, who reported it to be non-malignant. Subsequent sections showed that it was a hemangioma.

The patient made an uneventful recovery and was discharged cured from the hospital on November 6, with a reasonably good voice.

*Read before the 38th annual congress of the American Laryngological Association at Washington, D. C., May 9, 1916.

An examination made January 27, 1916, showed no evidence of the former growth; the left vocal cord was much thinner than normal, the voice was strong but husky and the patient had had no discomfort.

The greatest point of interest in this case lies in the diagnosis. She had been seen by a number of laryngologists, all of whom concurred in the diagnosis of tumor of the larynx, cancerous in nature. In fact at first it seemed so to me, but the color of the growth, its yielding to the probe, and finally the history of an unaccounted-for hemorrhage, made me confident that it was an angioma. I then promptly decided not to attempt the removal of the whole or a part endolaryngeally, and I am confident that had I done otherwise, there would have been a severe hemorrhage, requiring a hasty tracheotomy and perhaps a fatal ending. This opinion is held by others who have encountered this affection in this most unusual situation.

The number of cases found in the world's literature is very small. John Phillips and H. O. Ruh¹ have recorded an interesting case of this affection in a young child. It has been carefully studied and is very interesting.

A boy aged nine months was hoarse, had gradually increasing difficulty in breathing, cough and inspiratory stridor dating back to an attack of measles four months previous. The dyspnea was especially severe at night. The child was brought to the hospital with pneumonia and moribund. The larynx could not be examined. The child died the next day.

At the autopsy, stenosis of the larynx, chronic catarrhal laryngitis, hemangioma simplex of the larynx, early lobar pneumonia of the lower lobe of the left lung, were the main features found. Of special interest is the detailed description of the condition of the larynx and trachea. "On removing the larynx and on external inspection it appears quite normal. On looking down between the vocal cords, however, marked changes are found. Instead of the characteristically shaped chink between the true vocal cords, there is only a very small slit-like aperture with granular edges. On opening the larynx over the anterolateral portion of the wall and extending from the true vocal cord down to the third ring of the trachea, there is a reddish gray growth with quite an irregular and granular surface. Opposite the lower border of the thyroid cartilage there is a slightly larger growth of a deeper red color, with a more irregular surface. The lumen of the larynx and upper part of the trachea is greatly narrowed by this growth. The greatest narrowing is at the true vocal cords, where the opening measures 1.5 by 3 mm.; the point of the greatest thickening is at the lower border of the thyroid cartilage, where the mucous membrane measures 4 mm., while at the latter it is only 3 mm. at the widest point."

The pathological changes in the larynx was confined to the mucosa, and showed marked differences in the various regions. "Just below the vocal cords there is a great thickening of the mucosa. This depends on an increase of all the elements, but more especially in the fibrous connective tissues. Toward the lumen, the tissue is infiltrated with mononuclear leucocytes, and plasma cells. Thin-walled engorged vessels are quite numerous, and the mucous glands, which normally in this region are rather small, are quite large and show evidence of an active hyperplasia. In places they are considerably distorted by the overgrowth of the surrounding connective tissue. The lumina of the glands and their ducts are filled with a faintly basic-staining homogeneous material in which a few mononuclear cells are found. The gland cells stain deeply, and the nuclei are very large. The epithelium of the larynx is absent in not a few regions, and here the tissue is densely infiltrated with round cells and the surface is covered by a small amount of a cellular exudate. The tissue in this region is quite edematous. Near the lower border of the thyroid cartilage in the region which microscopically appeared of a deeper red than elsewhere, very interesting changes are found. Here, as in other portions of the laryngeal mucosa, the glandular elements are hyperplastic, but instead of being imbedded in an edematous, infiltrated, fibrous, connective tissue, they are compressed and distorted

by what appears to be a true hemangioma simplex. The main portions of the tissues are composed of numerous small tortuous vessels, with thin walls and quite prominent endothelium, which in places seems to be more than one layer in thickness. The vessels lie very near each other, the interstitial tissue being composed of numerous spindle-shaped cells. All the vessels are filled with blood."

The same writers found but twenty-six cases of this affection in a critical review of the literature, their own case being the twenty-seventh, and they present a brief reference to each of these twenty-six cases.

Their earliest recorded case is by Fauvel in 1876. Others were presented by Coupard, Heinze, Louis Elsberg, Kidd, Seiler, Wolfenden, Schwarz, Desvernine, Brown, Loomis, M. Mackenzie, Beau, Brady, Glasgow, Ferreri, Matzen, and Thurber.

These cases, however, are not all the recorded ones, for I have found twelve more cases omitted by them, and one more published since theirs. These with my own case bring the total number of cases found in the literature up to forty-one. They are here presented in brief:

Edmund Meyer,² at a meeting of the Berlin Laryngological Society, January 22, 1904, showed of specimen of cavernous angioma of the larynx removed from a thirteen-year-old boy by means of laryngofissure and galvanocautery snare. The growth was subglottic on the right vocal process, and so filled the larynx as to occasion great dyspnea. Microscopically, it was composed of cavernous tissue and newly formed vessels.

Biaggi³ (Eighth Congress of the Italian Society for Laryngology) records a case of cavernous angioma of the larynx in a hemophiliac forty-two years old. Hoarse for two years and occasional attacks of dyspnea. Tumor of the larynx, size and color of a raspberry. Spontaneous expectoration of the tumor with much hemorrhage checked by enemata of gelatine. Another growth remained in the larynx still larger than the first, which was removed by forceps eight days later and again the hemorrhage controlled by gelatine enemata.

Blevgad⁴ (Proceedings Danish Oto-Laryngological Society, 1908) reports a case of pedunculated angioma on the left processus vocalis. Male, hoarse a few months, slight improvement, later becoming worse. Fourteen days before examination sudden expectoration of blood, without any cause, after which the voice was better.

Examination showed a tumor of the size of a millet seed, white and irregular surface, between the anterior and middle third of the left processus vocalis. This tumor was removed with the cold wire snare. There was little bleeding. The microscope showed it to be angioma. The writer believed that there was an attempt at healing after the spontaneous bleeding.

D. von Navratil⁵ (Rhino-Laryngeal Section of the Royal Hungarian Medical Society of Budapest, January 30, 1908) presented a case of angioma laryngis. Woman of thirty-one, with a tumor of soft consistency, reaching beyond the left vocal cord. If there was any increase of stridor the speaker contemplated removal of the tumor by laryngofissure. In the discussion, von Lenart would proceed endolaryngeally, while Donogamy asked for histological examination. Von Navratil, in closing, said he had observed the case for nine months and noticed its increase. He would not consider endolaryngeal procedure or removal of a portion, because of his experience of a severe hemorrhage from an endo-

laryngeal interference in a similar case, which caused suffocation and required hasty tracheotomy.

J. Safranek⁸ (Tumors of bloodvessels in the upper air passages) reports two cases of angioma, one in a woman of twenty-seven. A small angioma with pedicle extending from the vocal process, and the other with a broad base on the right arytenoid.

E. Pistre⁹ (Contributions to the history of bloody tumors of the larynx; Cavernous angioma of the right vocal cord), records a case with histological report.

Loubert¹⁰ (French Congress of Oto-Rhino-Laryngology, Paris, May, 1912), reports a case of Subglottic Angioma.

F. Roux⁹ (on angioma of the larynx), reports three cases occurring on the vocal cords and a fourth one at the tip of the left arytenoid.

G. S. Ryerson¹⁰ Angioma of the Larynx

Female, aged fifty-five. Difficult and oppressive breathing without pain, hoarseness, or cough. Had lingual varix which was cauterized. "On the left side on the anterior surface of the arytenoid, on the ventricular band, and along the external margin of the vocal cord, is a bluish-purple mass, lobulated and presenting the appearance of a small raspberry. Another similar smaller body, on the anterior surface of right arytenoid, extended beyond it. Because of disastrous effect of operative interference, radium was preferred and tried successfully."

Martuscelli and Porfidia.¹¹ The writers lay especial stress on the size of the growth and upon the fact that the tumor had undergone hyaline and amyloid changes. They state that Massei (International Congress of Laryngology, Vienna, 1908) declared that of eight hundred cases he had seen, only ten were large enough to be called "giant tumors." Massei was the first to call attention to the association of hemo-angio-endothelioma of the larynx and general sarcomatosis cutis, and the similarity in the histological structure of the two kinds of tumors. Such growths may attain a large size in the larynx, and have been found not only in the isthmus and under the vocal cords, but also on the uvula, soft palate, and walls of the pharynx. The authors give only a short history of their patient.

A man, thirty-two years of age, addicted to excesses—tobacco and alcohol—was brought to them with the history that he had been having attacks of painful asthma for a long time. Breathing had been much interfered with at times, he had the feeling as if there was a foreign body in his throat. Occasionally he felt as if he was suffocating and one night had an attack in which he had great trouble in getting air. Examination: A large growth filling the aperture of the larynx almost completely, very soft and changing its shape and volume with respiration, so that it caused a varying amount of obstruction to breathing. After the thorough application of cocaine and adrenalin, the base of the growth below the vocal cords could be seen. The growth was the size of a chestnut and presented the appearance of an angioma. (The authors do not describe the appearance of the growth, they do not say what was its color, and fail to state exactly where the growth started from.) With a Mackenzie forceps, modified by Martuscelli, an attempt was made to get around the growth. This failed on account of the deep situation under the cords. At a second attempt the growth with its pedicle was removed. Lively bleeding followed, and though the hemorrhage was never an alarming one, it required all the skill and close attention of an experienced laryngologist to control it. Frequent applications of cocaine and adrenalin finally controlled the bleeding. The growth was the size of a chestnut, it consisted of a mass of dilated and new formed capillaries, lying in an amorphous and homogeneous stroma, which gave with rosin the typical staining reaction of hyalo-amyloid degeneration.

After remarks on amyloid degeneration of laryngeal tumors, the author's conclusions are:—

- (1) Report of a rare "giant" growth of larynx.
- (2) It was a rare form both as an angioma and because of the amyloid degeneration.

In a discussion on a case of angioma of the larynx presented by Thurber¹² before the laryngological section of the New York Academy of Medicine, Simpson advised evulsion, while I called attention to the dangers of this method and advised laryngofissure.

As a rule angiomata of the larynx lie at the entrance, and my own case is the only one, as far as I can ascertain, whose position was in the favorite site of malignant disease and was suspected of malignancy.

A study of this and of the recorded cases enables us to reach the following conclusions:—

1. Angioma of the larynx is a rare disease, occurring mostly in adults and the proportion of males to females is approximately four to one.
2. It may be mistaken for cancer.
3. Endolaryngeal removal of a portion of the growth for diagnosis, or its complete removal in this manner, is fraught with danger and may have serious results.
4. Laryngofissure, removal and suturing the mucosa are entirely safe and feasible procedures.

40 EAST FORTY-FIRST STREET

DUODENAL ULCER, MISTAKEN FOR CHRONIC APPENDICITIS.

REPORT OF FOUR CASES.*

BY RICHARD LEWISOHN, M.D.

NEW YORK.

ATTENDING SURGEON, BETH ISRAEL HOSPITAL AND MONTEFIORE HOME ASSOCIATE ATTENDING SURGEON, MOUNT SINAI HOSPITAL.

WHILE the differential diagnosis between acute appendicitis and perforated duodenal ulcer is extensively discussed in the medical literature, the differentiation between chronic ulcer of the pylorus or duodenum and chronic appendicitis is hardly ever dwelt upon. Moynihan, for instance, in his monograph on duodenal ulcer, discusses the differential diagnosis between cholelithiasis and duodenal ulcer. He does not, however, say a word about the differentiation between duodenal ulcer

*From the Surgical Department of Mount Sinai Hospital, service of Dr. A. A. Berg, New York City.

and chronic appendicitis. In his book he gives over 180 detailed histories of cases of duodenal ulcer. In not one of these histories is the possibility of an error of diagnosis considered.

And yet errors in differential diagnosis between duodenal ulcer and chronic appendicitis are not at all infrequent. The more carefully we study these cases with indefinite abdominal pains, the more we shall be impressed with the diagnostic difficulties.

We know that a chronically inflamed appendix may cause hyperacidity, with pylorospasm, pains in the right hypochondrium and vomiting, symptoms which, as a rule, point toward a duodenal ulcer. Even more or less profuse hemorrhages from the stomach may be caused by chronic appendicitis.

It is not the object of this short paper to discuss this subject from the standpoint of the appendix, *i.e.* those cases which have all the symptoms referable to the stomach and which are cured by appendectomy.

In this communication I wish to report four cases which, though suffering from a duodenal ulcer, were in other hospitals erroneously operated upon for appendicitis.

CASE I.—M. S., cutter, 34 years old. Admitted June 14, 1915; discharged July 4, 1915. Patient had suffered from abdominal pains for fifteen years. The pains came on three hours after meals; they continued to the next meal and were relieved by the taking of food. He had never vomited. An appendectomy was performed two years ago without relief of his symptoms. The physical examination was negative except for a rather marked tenderness in the epigastrium. The chemical analysis of the stomach showed no abnormality.

X-ray examination (Dr. Jaches): Peristalsis very active. An incisure was seen on the lesser curvature near the pyloric region throughout the entire observation. Slight residue was still present in the stomach after six hours. The very active peristalsis, the irregularity in the pyloric region, the residue after six hours, and the persistent incisure near the pyloric region suggested a pyloric ulcer. A second examination revealed a deformity in the duodenal cap. Diagnosis: Duodenal ulcer.

Operation, June 19 (Dr. Berg): In the anterior wall of the first part of the duodenum a marked induration was felt. No crater was palpable, no stenosis of the pylorus was present. Posterior gastrojejunostomy and pyloric exclusion was done.

Re-examination, January 10, 1916: All the pains have disappeared. The patient feels perfectly well except for some gaseous eructations. X-ray examination shows the stoma patent and the pylorus closed.

CASE II.—M. H., tailor, 38 years old. Admitted June 14, 1915; discharged July 13, 1915. The patient had complained about very severe abdominal pains for the last seventeen years. The pains were localized in the epigastrium. They usually started a few hours after eating. On admission to the hospital he complained of sour eructations, vomiting, loss of weight, and constipation. He was operated on April 1, 1915. The hospital reported that after the appendix had been removed an exploration of the stomach was made through the appendix incision; an induration was felt around the pylorus; the abdomen was then closed without any further surgical interference.

Physical examination: Distinct rigidity of the upper right rectus; no masses felt. Test meal normal. X-ray examination (Dr. Jaches): Violent peristalsis and segmentation of stomach. Retardation of food in first portion of the duodenum. The stomach was entirely empty four and one-half hours after the food ingestion. Diagnosis: Duodenal ulcer.

Operation, June 26 (Dr. Lewisohn): Exploration revealed an indurated crater-like ulcer about the size of a 25-cent piece in the second part of the duodenum. Gastrojejunostomy and pyloric exclusion were done. Postoperative course was uneventful.

Re-examination, January 16, 1916: Patient is feeling very well; has gained 26 pounds since the operation. X-ray examination shows a partial re-opening of the pylorus.

CASE III.—S. H., operator, 32 years old. Admitted June 14, 1915; discharged July 5, 1915. Patient had

been suffering from pains in the right upper quadrant for about eight years. His appendix was removed six years ago without relief of symptoms. He complained about pain in the epigastrium. The pains started about one hour after each meal, were burning in character, and continued to the next meal. His appetite was very poor. He never vomited. He had lost some weight in the last few years.

Physical examination negative. Test meal normal, except for the presence of some blood. X-ray examination (Dr. Jaches) showed marked hyperperistalsis, irregularity of the duodenal cap, retardation of food in passing through the duodenum, and a residue of the test meal in the stomach after six hours. Diagnosis: Duodenal ulcer.

Operation, June 19, 1915 (Dr. Lewisohn): An indurated ulcer (the size of a bean) was felt on the anterior surface of the duodenum about $\frac{1}{2}$ inch from the pylorus. Posterior gastrojejunostomy and pyloric exclusion were done. Postoperative course was uneventful.

Re-examination, January 25, 1916: The patient felt perfectly well for about four months. In the last two months he complained of heartburn and occasional vomiting of bile. X-ray examination shows that the stoma is patent. The pylorus is not completely excluded.

CASE IV.—L. K., singer, 32 years old. Admitted August 14, 1915; discharged August 26, 1915. The patient had suffered from stomach trouble for many years. An appendectomy was done fourteen months ago in Paris. Six months ago he was operated upon for perforated gastric ulcer (closure of the opening and gastrojejunostomy were done). His complaints on admission to the hospital were epigastric oppression one hour after ingestion of food, nausea, vomiting, and loss of weight.

Physical examination: Marked tenderness in the right upper quadrant. Test meal normal. Raisin test meal negative; no retention. X-ray examination (Dr. Jaches) showed hyperperistalsis, at times violent; incisures on both curvatures. Duodenum not clearly defined, except after massage, and then not completely filled. No evidence of patency of stoma. Slight residue after six hours. The hyperperistalsis and the irregular filling of the duodenum suggested the presence of a duodenal ulcer.

Operation, August 14, 1915 (Dr. Lewisohn): The abdomen was opened through an upper median incision. Division of numerous adhesions. The gastrojejunostomy was perfectly patent, easily admitting two fingers. The pylorus was markedly thickened. A punched-out ulcer was felt in the first part of the duodenum. A purse string suture was put around the pylorus. This stitch did not close the pylorus perfectly tight (application in the inflamed area). A second stitch was therefore applied proximally to the first stitch and an absolute occlusion was thus obtained.

Postoperative course: The patient never vomited after the operation. His pains disappeared immediately.

Re-examination, December, 1915: The patient re-entered the hospital on account of recurrence of symptoms. He had been relieved from pains for about two months. He now complained of frequent vomiting. The X-ray examination showed a marked residue. We were probably dealing with a gastrojejunal ulcer. The patient left the hospital after a few weeks' medical treatment and we have not been able to trace his whereabouts.

These four patients had been suffering from distinct and severe stomach symptoms for many years (two of them as long as fifteen and seventeen years, respectively). Previously to their admissions to Mount Sinai Hospital they all had been operated on for supposed appendicitis in other hospitals, without relief of their symptoms. The appendectomy had been performed six years, two years and one year previously in the first three cases, and four months previously in the fourth case. In one case the surgeon, after removing the appendix, which was evidently normal, felt the induration of the pylorus. He did not, however, follow up his observation with a gastroenterostomy and possibly pyloric exclusion, as his findings would have warranted.

The operation which we performed in these cases consisted in a posterior no-loop suture gastro-

jejunostomy and a pyloric exclusion according to Berg's method.

In our indications for operative interference in pyloric and duodenal ulcers, the service is guided by three factors: clinical history, chemical examination of the stomach contents, and x-ray examination. We demand that two of these factors point toward ulcer before we advise operative interference. Even when all three factors are positive, the diagnosis of ulcer of the stomach or duodenum is not absolutely certain. We have had a number of cases in the last year which had a typical history, positive chemical and x-ray findings, and in which a careful exploration of the abdomen did not reveal any surgical abnormality.

Three of the four cases reported above had positive histories, and x-ray findings and negative chemical analyses, and the fourth case had the whole triad pointing toward duodenal ulcer.

The first two patients (those that had been suffering for fifteen and seventeen years, respectively) are entirely cured. The x-ray examination of the first patient shows complete occlusion of the pylorus. In the second case the pylorus has partly reopened; the patient is, however, free from symptoms, and has gained twenty-six pounds since his operation. The third patient is not entirely cured, though very markedly improved. The fourth case was not permanently benefited by the operation, which consisted simply in occluding the pylorus with a Pagenstecher stitch. The patient probably is suffering now from a gastrojejunal ulcer, which may require surgical interference.

I shall not try to enumerate certain symptoms which point toward duodenal ulcer and others as pointing toward chronic appendicitis. The textbooks make it appear as if certain symptoms are pathognomonic for duodenal ulcer, whereas certain other symptoms can only be caused by chronic appendicitis. That may be true for the very typical cases of both these groups. All the text-book doctrines, however, will not help us in atypical cases. As stated above, a chronic appendicitis can cause typical symptoms of duodenal ulcer (pylorospasm, vomiting, hemorrhage, etc.). In duodenal ulcer, on the other hand, a superficial examination may suggest the presence of chronic appendicitis, and the disease will be correctly diagnosed only after a careful study of the case.

The object of this short presentation is to draw attention to the intimate relation of symptoms caused by duodenal ulcers and those caused by chronic appendicitis in atypical cases. The fact that three cases of this type were admitted to one hospital on the same day is sufficient proof that this diagnostic error (appendectomy in cases of duodenal ulcer) must occur frequently. For this reason this very interesting subject ought to have much more attention in the medical literature than it has heretofore received.

161 PEEK AVENUE

Mortality of Pneumonia in Children.—Pisek and Pease, from a study of a thousand cases have established a mortality-rate for pneumonia in children of 34.3 per cent. This is probably a higher rate than obtains in private practice, but is the average for city dwellers. Bronchopneumonia is preëminently a disease of the first two years of life, and after the third year is relatively uncommon. Lobar pneumonia is the type of the disease which is present after the third year in practically all cases, if those which are frankly secondary, or in which the pneumonia occurs as a terminal infection, are omitted.—*American Journal of the Medical Sciences*.

DYSPNEA: A BRIEF REVIEW OF ITS OCCURRENCE AND SIGNIFICANCE,

WITH REPORT OF A CASE DUE TO TUMOR IN THE SUPERIOR THORACIC APERTURE.*

By J. WHEELER SMITH, JR., M.D.,

BROOKLYN, N. Y.

Definitions.—The regulation of normal breathing is twofold. (a) chemical, by the concentration of carbon dioxide in the blood; and (b) nervous, through the vagi, of which there are two sets of fibers: (1) inhibit inspiration and incite expiration; are excited by expansion of the lungs; (2) incite inspiration and inhibit expiration; are excited in strong expiration, as in dyspnea, by collapse of the lungs, but are not active in ordinary respiration. Any condition which leads to excessive concentration of carbon dioxide in the blood or which otherwise excites directly the respiratory center of the medulla or which does so indirectly through the vagi, produces a departure from the normal respiration.

Dyspnea means difficult or labored breathing. It should be distinguished from hyperpnea, which is exaggeration of the respiratory movements, and tachypnea, which is excessive rapidity of respiration. However, very commonly hyperpnea is associated with dyspnea, as is also sometimes tachypnea. On the other hand, hyperpnea or tachypnea commonly occur when there exists no real difficulty in the ingress or egress of the respired air. Under such circumstances it is really incorrect to call the condition dyspnea.

Varieties.—In general dyspnea may be divided into two varieties: (1) physicochemical and (2) mechanical. The physicochemical variety is due to insufficient oxidation of the tissues, and is an expression of the air-hunger of the tissues, entirely independent of mechanical interference with respiration. This last characteristic is the quality of mechanical dyspnea.

Among the varieties of physicochemical dyspnea is that which is experienced in an ascent to a high level, as on a mountain-top or in a balloon. The atmospheric rarefaction predicates a diminished oxygen concentration of the inspired air with diminished oxidation of the erythrocytes in the pulmonary capillaries. A compensatory response is made, because of the lessened peripheral resistance, by a vasodilation of the periphery, including the lungs, and an acceleration of the action of the heart. After a variable period of time, as the organism accommodates itself to its new environment, the dyspnea passes off. The erythrocytes increase rapidly in number. The red blood cell count of mountaineers is ordinarily greater than that of dwellers in the lowlands—usually 6,000,000 rather than the average normal, 5,000,000 per cu. mm.

The dyspnea of anemia is a very similar phenomenon. Whereas in the case of altitude dyspnea the hemoglobin is relatively insufficient, in this case the hemoglobin is absolutely diminished. The "breathlessness" of chlorosis is a well-recognized feature.

One speaks commonly of cardiac dyspnea and of renal dyspnea. By cardiac dyspnea is meant that which is associated with the decompensatory stage of cardiac disease. The circulations, both general and pulmonary, are impaired and the rate of flow in the capillaries is reduced. As a result there occurs

*Read before the Brooklyn Society of Internal Medicine, December 30 1915.

a passive congestion, evidenced by cyanosis and edema. The same condition obtains in the lungs, over the bases of which the physical signs of edema may be readily elicited. The dyspnea which characterizes this condition is due to a number of factors. For one thing, the unusual volume of blood in the lungs encroaches upon the air-space, thus mechanically interfering with ventilation. This effect is enhanced by the edema of the dependent parts of the pulmonary tissue, which edema naturally ensues when the passive congestion becomes more or less chronic. For another thing, because of the stagnation of the blood current, aeration of the tissues is insufficient. Carbonic acid accumulates in the blood and stimulates the respiratory center. The respiratory rate increases in consequence and, depending upon the degree of pulmonary edema and its association with cardiac distress, is more or less difficult.

The dyspnea of chronic nephritis which is unaccompanied by myocardial insufficiency, is rather difficult of explanation. According to the recent researches of Francis W. Peabody of Boston, it is a manifestation of acidosis. He offers very illuminating evidence in tabular form which reveals the relations between renal insufficiency, acidosis, and hyperpnea. He has found that in cases of chronic nephritis a reduced phthalein excretion is associated with a high alkali tolerance and a low CO₂ alveolar tension. Myocardial insufficiency complicating chronic nephritis introduces a confusing element, which makes it almost impossible to decide just how much of the dyspnea is due to the acidosis of nephritis and how much to the tissue asphyxia of passive congestion.

The dyspnea of diabetic acidosis is explained in the same way as is that of chronic nephritis.

Pneumonia of the lobar type presents as a classical symptom an increase of the respiratory rate. This symptom is very prominent, and is independent of the degree of lung involvement. The consolidation of one lobe will be the occasion of just as rapid breathing as will the solidification of an entire lung. However, the air may pass very freely to and from the uninvolved areas. In other words, there may be simple tachypnea but no real dyspnea. It appears to be due to stimulation of the respiratory center by the toxins of the pneumococcus. At the crisis, when the body asserts its immunity and the toxins are neutralized, the temperature drops, the pulse-rate falls, and the respiratory rate falls *pari passu*. The degree of pulmonary involvement, nevertheless, remains practically the same. The exudate is many days in being absorbed, and those portions of the lungs which were affected do not function again until resolution has occurred. If the tachypnea were due to limitation of the lung area it would persist after the crisis. Of course, it is quite natural to imagine that a very extensive bilateral pneumonia might so seriously interfere with the breathing surface as to produce a mechanical dyspnea from that cause. Ordinarily this is not the case. During the course of pneumonia an associated pleuritis will produce dyspnea due to the pain incident to breathing. Myocardial failure will also give rise to a dyspnea of tissue asphyxia.

Acute toxemias regularly are associated with elevation of the temperature, pulse, and respiration. The hyperpnea here is due probably to direct stimulation of the respiratory center, either by the toxins of the infecting organism or to toxic bi-products of the interaction of host and parasite. The dys-

pnea of lobar pneumonia may be better explained on this hypothesis than on that of mechanical interference with aeration.

Dyspnea is not a common manifestation of pulmonary disease, with certain exceptions, notably bronchopneumonia and bronchial asthma. One may have extensive destruction of lung tissue, as commonly occurs in pulmonary tuberculosis, and still be able to breathe quietly and easily. Dyspnea occurs in phthisis when there is a rapid extension in both lungs of a bronchopneumonia, with the occurrence of miliary tuberculosis, with the formation of pneumothorax, accidental or intentional (if too great a volume of gas be introduced), with emphysema and with beginning cardiac decompensation in old cases.

We now come to the subject of mechanical dyspnea. This we may consider under two heads: (a) that due to insufficiently pervious air passages, and (b) that due to inadequate respiratory movements.

Dyspnea due to insufficiently pervious air passages is called obstructive dyspnea. It is caused by some obstruction of the respiratory tract, either in the larynx, the trachea, the bronchi, the bronchioles or the vesicles; by anything within which occupies the lumen (as foreign body, excessive secretion, new growth) or by anything without which presses upon the tract and thus narrows the lumen (as aneurysm or new growth). As to nature, obstructive dyspnea may be considered as inflammatory, neoplastic, or spasmodic. The etiological classification is almost too extensive to enter upon here. Its extent may be indicated in a consideration of edema of the glottis. This condition occurs as a rare sequence of ordinary acute laryngitis, in chronic luetic or tuberculous laryngitis, in severe inflammation (as diphtheria, cervical erysipelas, pharyngeal, laryngeal, and cervical cellulitides).

Spasm of the glottis (laryngismus stridulus or thymic asthma) is little understood so far as its etiology and pathology are concerned. Its nature is probably reflex from peripheral irritation. In the edema the dyspnea is progressive and is associated with hoarseness and finally loss of voice. The condition is very fatal. In the spasm the respiration is very suddenly arrested without premonitory symptoms. As the cyanosis develops, the spasm relaxes.

The dyspnea of acute bronchitis is seen particularly in children, and is due to accumulation of tenacious secretion which is difficult to raise. It is essentially a "foreign-body dyspnea," the secretion occupying the lumen to such an extent as to preclude the easy ingress and egress of air.

Fibrinous bronchitis falls into the same category. Bronchopneumonia, in especially the "suffocative catarrh" of children, is characterized by a particularly intense and distressing dyspnea.

Bronchial or spasmodic asthma is marked by paroxysms of the most intense dyspnea. The inspiratory efforts are herculean but very little air enters the lungs. Expiration is prolonged and wheezy. The respiratory rate remains about normal. The dyspnea in spasmodic asthma is thought to be due to spasm of the bronchial muscles and to turgescence of the bronchial mucous membrane.

Dyspnea is not a prominent symptom of hypertrophic emphysema. It is particularly aggravated by recurrent attacks of bronchitis.

Acute hydrothorax, such as not uncommonly occurs in kidney and heart disease, is usually the occasion of severe dyspnea. Hydropneumothorax

and pyopneumothorax are characterized by urgent dyspnea. The dyspnea of these conditions is due to compression of lung tissue to such a degree as to render it non-functioning.

The last mentioned conditions really fall also into the category of dyspnea due to inadequate respiratory movements. Under this heading we may consider also acute pleurisy, without exudate. In this condition the pain incident to respiration is the producing cause.

Paralysis of the respiratory muscles may be due to organic disease of the central nervous system or may be hysterical. The syndrome of Briquet, which is hysterical, consists in paralysis of the diaphragm, shortness of breath, and suppression of voice. Another remarkable hysterical manifestation consists of extremely rapid breathing, reaching 60 to 100 respirations a minute, the temperature and pulse rate remaining quite normal. I have seen this condition in a Chinese deck-hand, who was sent from his ship to the Long Island College Hospital for treatment for a genitourinary condition of minor importance. While there he was seized on two occasions by paroxysms of intense tachypnea, precipitated presumably by fear that his ship would sail without him.

Meteorism or abdominal tumor may so impede the movements of respiration as to cause very severe dyspnea. The respiratory relief experienced by a patient with ascites when the abdomen is tapped is a matter of common note.

Mediastinal tumor may be solid or fluid. Hydropericardium, hydropneumopericardium or hydropyopericardium act by displacing and compressing lung tissue. Aneurysm, commonly of the transverse portion of the arch, produces pressure on the left recurrent laryngeal nerve and directly on the trachea or the left bronchus. Thus are induced hoarseness, due to spasm or paralysis of the left vocal cord, and dyspnea.

Solid mediastinal tumor is a condition ordinarily in the nature of lymphosarcoma or metastatic carcinoma. In five hundred and twenty cases of mediastinal disease collated by Hare there were one hundred and thirty-four carcinomas and ninety-eight sarcomas, located, in order of frequency, in the thymus, lymph glands, pleuræ, and lungs. The symptoms are pressure symptoms, most important of which are cough, hoarseness, and dyspnea. The cough is usually severe, paroxysmal, and of a brazen quality. The hoarseness is progressive, and is due to pressure on the recurrent laryngeal with consequent spasm or paralysis of the corresponding vocal cord. The dyspnea is suggestive of pressure on the vagus or the bronchus or both. It is accompanied by cyanosis of the face and audible wheezing respiration. There is ordinarily engorgement of the jugulars, more marked in inspiration, at which time the radial pulse is almost imperceptible and the apex impulse is feeble. There is commonly a sense of weight, aching, even acute pain beneath the sternum, radiating to the back and sides of the chest and to the shoulders. There may or may not be dysphagia; esophageal constriction may be recognized by the use of bougies. There may or may not be signs of pressure on the return circulation of either or both upper extremities, or of the lower part of the body, with ascites and edema of the legs. There is usually a pupillary change of the nature of inequality, due to pressure on a sympathetic trunk.

Report of a Case of Dyspnea Due to Tumor in

the Superior Thoracic Aperture.—The superior aperture of the thorax, or inlet, is formed behind by the body of the first thoracic vertebra, at the sides by the arches of the first ribs, and in front by the upper border of the manubrium. It is contracted, reniform, and measures 10 to 12 cm. transversely and 5 cm. anteroposteriorly. Its plane is oblique from behind downward and forward. In expiration the superior border of the sternum lies on a level with the fibrocartilage between the second and third thoracic vertebrae. The inlet is small; it is bounded on all sides by absolutely rigid bony walls; it contains no waste space. Even the smallest increase in tissue in the inlet is marked by what would seem to be enormously disproportionate symptoms.

The case which I report is one with the management of which I had very little to do. I report it through the courtesy of Drs. Wightman, Robertson, and Larkin, City Hospital, New York.

A white man, 48 years old, presented himself, with hoarseness and dyspnea, both of three months' standing and both increasing in severity. He was put to bed and studied for six days. During this time his temperature ranged between 98.6° and 100°; his pulse rate, 60 and 30; his respiratory rate 16 and 20. His dyspnea was both inspiratory and expiratory in type and was very severe. During the inspiratory phase his abdominal muscles were held rigid. A very sudden, brief, vigorous contraction of the diaphragm marked the expiratory phase. He was markedly emphysematous and, due to this and to his moving very little air into and out of his lungs, breath sounds were absent except over the infraclavicular regions. He was very hoarse. At infrequent intervals he grew deeply cyanotic and his breathing became even more labored. At such times he obtained relief from oxygen inhalation. His respiratory rate was normal, but the rhythm and the time relation of inspiration and expiration were much disturbed, there being no pause after expiration. A stomach tube was passed to sound the gullet; it encountered no resistance. A woven catheter was passed into the trachea and seemed to enter the left bronchus. For a time breath sounds were feebly audible over the root of the left lung and the patient seemed to be easier. Bronchoscopy was not done, nor was esophagoscopy. His right pupil was about three times the size of the left and his right vocal cord was almost completely paralyzed. A small hard mass was felt at the level of the right sternoclavicular junction. It was not pulsatile but moved regularly with the cardiac systole, as though propelled by a pulsating vessel. Radiograph revealed an indefinite shadow in the region of the second right chondrosternal junction. A Wassermann reaction on the blood serum was negative. There were none of the evidences of aortic regurgitation. Except for an intense cyanosis during the paroxysms, circulatory disturbances were not evident.

A diagnosis was made of tumor of the anterior mediastinum, possibly either aneurysm of the ascending portion of the arch, possibly low thyroid, but probably neoplasm.

To relieve the man's dyspnea it was decided to perform a decompression operation. The right clavicle was sectioned and one inch of the first rib and of the second rib of the right side was resected. The pleural cavity of the right side was entered and a pneumothorax thereby induced. Exploration revealed an inoperable mass in relation to the trachea. The man died eight hours after the operation.

Autopsy showed a bilateral pneumothorax. Apparently the left pleural cavity had been punctured as well as the right. Why he should have lived so long under the circumstances and what was the mechanism of his dying I am unable to surmise.

There was great enlargement of the right group of tracheobronchial lymph glands, which were matted together and infiltrated by a hard neoplasm, thus forming a very firm mass. The mass pressed upon the trachea to such a degree as to deflect it from its course and had even invaded the trachea, appearing on its inner surface as an elevated tumor, about 2½ by 4 cm.

Scattered uniformly throughout both lungs were small metastatic nodules. There was no lesion of the tongue, submaxillary glands, thyroid gland, or para-

thyroids. The left group of tracheobronchial glands and the paratracheal glands showed no invasion macroscopically. Search for the primary process resulted in its discovery in the esophagus, as a very small, ulcerated epithelioma, about 3 cm. in diameter. Microscopical study confirmed the diagnosis.

What seem to me to be most interesting are the facts that (1) the primary tumor was without symptoms; it was quite overlooked; (2) both lungs were extensively involved; (3) the very severe symptoms were all due to the metastatic involvement of a small group of glands, so placed, however, in the rigid superior aperture as to be very important.

1249 ST. JOHN'S PLACE.

Medicolegal Notes.

Liability for Wrong Diagnosis.—In an action for malpractice for negligently and unskillfully diagnosing and treating the plaintiff's injury to his right leg as a sprain only when in fact both bones were fractured, the fibula and tibia, about three inches above their lower ends, there was considerable testimony of physicians on both sides as to the difficulty of diagnosing injuries to the lower leg or ankle, and as to the methods of examination for such injuries, and the relative utility of the different recognized tests. While not altogether in harmony, that testimony disclosed a consensus of opinion that there are certain recognized methods of examination or tests to be used when the nature of such injuries is not obvious, but hidden and difficult of diagnosis. And all agreed that an x-ray picture of the injured parts will disclose with almost absolute certainty whether any fracture exists, that the next most useful mode of examination is manipulation and moving of the injured part while the patient is etherized, and that manipulation without etherization is the least efficient, because it is necessarily more or less limited on account of the pain thereby caused to the patient. The defendant concluded that it was unnecessary in the plaintiff's case to have an x-ray picture taken of the leg, or to etherize the patient, and he relied upon his manipulation of the injured parts and his examination for deformity or other possible indication of fracture. He made a mistake, however, and his diagnosis was wrong. But that fact alone was not sufficient to render him liable. It must first be shown that the mistake was the result of a failure to use painstaking care and diligence, and to exercise the best of his admitted learning, skill, and judgment in his examination and treatment of the plaintiff's injuries. Whether this was so was a question for the jury.—*Nickerson v. Gerrish*, Maine Supreme Court, 96 Atl. 235.

Correctness of X-Ray Photographs.—The Iowa Supreme Court holds that the rule as to the identification of photographs, diagrams, maps, and other illustrative evidence, in case of personal injury, is properly extended to skiagraphs, or pictures obtained by the x-ray process; that is to say, they are sufficiently identified by the testimony of experts who took them and surgeons who saw them taken. In an action for damages for broken legs, an objection that there was no showing that such skiagraphs were correct representations of the plaintiff's legs at the time they were taken was overruled. In one sense of the word, the Court said, no such identification is possible. A skiagraph is a picture of a state or condition of things which is not visible to the naked eye, and its correctness is, at best, a conclusion. Owing to its novelty, the courts were for a time somewhat slow to admit a skiagraph in evidence, except upon quite minute preliminary proof of its scientific accuracy, but its use has become so common and the general correctness of its representations has been so fully proved by investigation, that the above rule has now been very generally adopted.—*Ingebreetsen v. Minneapolis, & St. Louis N. Co.*, (Iowa) 155 N. W. 327.

Liability of Third Persons for Physician's Fees.—A physician sued to recover the alleged reasonable value of professional services rendered to the husband of the defendant. The services were alleged to have been performed at the joint request of the defendant and her husband, now deceased.

It is well settled that the performance of services by a physician for a third person at the request of another gives rise to no implied promise to pay for the services

by the person making the request, unless the relationship of such person to the plaintiff be one which imports a legal obligation to provide them. *McGuire v. Hughes*, 207 N. Y. 516, 101 N. E. 460, 46 L. R. A. (N. S.) 577, Ann. Cas. 1914C, 585. In order to support such a liability of a person under no legal obligation to provide the services of a physician, there must be an express promise on the part of such person to pay for the services, made before the services are rendered.

The plaintiff recognized this rule, and that a wife is under no legal obligation to provide such services for her husband out of her own estate, but relied upon an alleged express promise of the defendant to pay for the services. The evidence of such express promise by the defendant was the testimony of the plaintiff that at the time when he commenced the services he had a joint conversation with the defendant and her husband, the patient, in which they said:

"Doctor, you are the one we have confidence in, and we want you to visit me, or the sick one, three times daily, and we will pay you for everything you do for us."

He was asked to state exactly what each party said, and replied:

"They all talked. They were both talking together. I cannot separate them."

The defendant denied that she made any statement in regard to payment for the plaintiff's services, and testified that there were several other doctors in the room, who were all talking in consultation, and she had nothing to say to any one.

Resolving this issue of fact most favorably to the plaintiff, the court was of the opinion that the testimony did not show an express promise by the defendant to be individually personally responsible for the debt. Assuming that the wife said, jointly with her husband, "We will pay you for everything you do for us," it was held that under the circumstances disclosed the "we" clearly referred to the family, and to the husband as the responsible head of the family. In the absence of a separate statement by the wife, saying "I will pay you," or words to that effect, no express promise on the part of the wife to be personally liable for the doctor's fees could be found. Judgment for the plaintiff was reversed, and a new trial granted.—*Bernaglia v. Cirota*, New York Appellate Division, 156 N. Y. Supp. 432.

Employment by Corporation.—The manager of a manufacturing company, who was accustomed to consult the directors individually about its affairs, no formal meetings being held, employed a physician to treat an injured employee, and thereafter consulted individually a majority of the directors in relation to the employment. No objections were interposed by any of the directors as to what the manager had done, and the latter again directed the physician to proceed with the treatment. It was held, in an action against the company for the physician's services, that there was a ratification by the company of the manager's original contract with the physician, since directors may bind their corporation by acting separately if that is their usual practice.—*Indiana Die-Casting Development Co.*, Indiana Supreme Court, 111 N. E. 16.

Malpractice—Burden of Proof on Plaintiff.—In an action against a physician and surgeon for negligence in the treatment of an injured finger, it was held that expert testimony as to what would be the ordinary, usual, and approved method for treating the finger under like circumstances, was properly admitted. In such an action the plaintiff must show that the defendant's treatment either did something that physicians and surgeons of ordinary care, skill and diligence would not have done under similar conditions, or that the defendant omitted to do some particular thing that they would have done under similar conditions, and must further show that the injury directly resulted from the neglect or omission shown.—*Hier v. Stites*, Ohio Supreme Court, 110 N. E. 252.

Practising Medicine—Clairvoyancy.—Under the Massachusetts statute, Rev. Laws, c. 76, § 9, providing that the provisions of Section 8, prescribing a penalty for one who, without lawful authorization practises medicine, shall not apply to a clairvoyant, provided he violates none of the provisions of Section 8, it is held that a person to whom the diagnosis of a disease and the kind of medicine prescribed for it were claimed to be revealed by clairvoyance cannot prescribe medicine for the cure of the disease.—*Commonwealth v. Lindsey*, Massachusetts Supreme Court, 111 N. E. 869.

QUANTITATIVE MICROESTIMATIONS OF BLOOD CONSTITUENTS.

THE pursuit of quantitative analysis of the blood has led logically to the use of larger and larger quantities of that fluid until a limit has been reached; hence attempts began to be made to determine what could be done with minimal quantities of blood. No one of course will deny that great advantage is inherent in working with large volumes of blood, for these alone can permit of a complete analysis of the fluid. But when a single constituent alone is concerned, be it sugar or urea, a very small quantity of blood may be made to yield the percentage presence of such bodies, which is all that can be expected in blood analyses. Before micromethods can be regarded as efficient, the results thereby obtained must be compared critically with those of ordinary quantitative analyses; and in so far as they agree closely with the latter they may be used to replace them, allowing for error. The clinical advantages of the newer method will be enormous in theory, for not only is the amount of blood necessary for a test trivial and the test amenable to repetition, but the results of analysis may be obtained in a relatively brief time.

During 1913 Ivar Bang of the University of Lund in Sweden published several preliminary papers on microestimations of blood and quite recently his first formal publication on the subject has been issued.¹ The subject matter comprises only the chemical technique and the clinical application of the finds is quite ignored. The subject is, however, ready for the clinical pathologist, and has probably been in use in certain clinics for some time. Professor von Noorden has already spoken of it as a welcome aid in renal diagnosis. In quantities of blood varying from 10 to 15 centigrams Bang has computed the percentage of the chlorides, residual nitrogen, urea, total albumin, blood-sugar, fat, water, and dry solids.

The principle of this procedure consists in the absorption of a few drops of blood by a small piece of filter paper. Such of the constituents as can be extracted by the proper solvents are now removed in succession, the total albumin being left in the paper, while sugar, urea, amino acids, salts, etc., are present in their individual solutions. The filter

paper is weighed before and after absorption of blood and the weight of the latter determined by subtraction. The filter paper must be specially suited for the purpose. Each sheet which must weigh at least 50 gm. is cut up into pieces and extracted first with acetic acid and then with water at 50 to 60 deg. C. The fragments are dried at room temperature and cut up again into bits of 16 x 26 mm. The process of weighing these pieces of paper before their use is a complicated one which need not be detailed; a special torsion balance is used. As soon as the weight has been recorded, the blood is at once absorbed and the paper reweighed before any evaporation can take place. Blood is taken from the ear or pulp of the finger, and no attempt is made to collect it in quantity. The finger is gently stroked and the blood at once caught on the paper. On no account should the bleeding parts be forcibly squeezed for this would mean admixture with tissue fluids. The paper should not be saturated with blood, for this would interfere with the extraction of the soluble constituents. It is better to err on the other side. If the paper has taken up too much blood it will avail nothing to dry it, for extraction will in such a case be greatly prolonged. Experience has shown that at least 8 centigrams of blood must have been absorbed for the success of the test and that 12 centigrams is the average amount taken up. There is absolutely no advantage in using more than 15 centigrams. After the absorption of the blood, for which 5 minutes should be allowed, the paper should be dropped into a test tube and one of the solutions added in sufficient quantity to cover it. Sugar comes out in half an hour, chlorides require twenty-four hours, etc. The solutions should remain clear.

In the microestimation of urea, residual nitrogen, and all bodies which contain nitrogen, the so-called micro-Kjeldahl method is employed, which is made up of a combination of gross methods now in use. To the solution must be added an acid mixture—the author uses purest sulphuric acid and potassium sulphate—and a catalysator (he prefers a few drops of a 5 per cent. solution of copper sulphate). Heat is then applied and the mixture is distilled. In the special determination of urea the solvent consists of alcohol and ether. The test tube is corked and allowed to stand five hours. It is then decanted into a Kjeldahl bulb and the reagents added with a little water, after which the bulb is placed on a water bath until the ether and most of the alcohol have evaporated. The bulb is then heated until its contents assume a pure green color after which they are distilled as in ordinary analyses. The urea is of course estimated as nitrogen.

The sugar solvent contains saturated solution of potassium chloride, uranyl acetate, and chlorhydric acid, and after it has extracted the sugar from the paper a copper stock solution comprising four more ingredients is added and the whole boiled for nearly two hours (half an hour had been allowed for extraction). The bulb is rapidly cooled, and the contents tested for sugar with iodine solution. This test is really for the entire reducing substances in the blood, and not for dextrose alone, hence, as in all such cases, there is room for error. Further

¹Methoden zur Mikrobestimung einiger Blutbestandteile, von Ivar Bang, Wiesbaden, J. F. Bergmann, 1916.

sources of error are also to be borne in mind. In all micromethods there must be comparison with gross method standards.

It is evident that the technique of these micro-methods places them well beyond the capacity of the ordinary office laboratory. Only a few of the larger hospitals contain laboratories and chemists who are equal to such analyses. From the two examples given it is seen that in experienced hands reports could be made in very short time and with little expense. In times more favorable for travel the chemist would much prefer to see Bang carry out his tests than to attempt them from the printed directions which constantly bristle with cautions and possibilities of error.

HEALTH INSURANCE.

A NEW edition of a tentative draft of an act on health insurance has been issued by the Committee on Social Insurance of the American Association for Labor Legislation. The draft as revised meets some of the objections raised against the original act when it was presented to the New York Legislature in the form of the Mills bill.

The section which interests us particularly is the one dealing with the medical aspects of the act. The revised edition contains several important additions. In the first place it provides that the insurance carriers shall make arrangements for medical, surgical, and nursing service through appropriate institutions or associations, and that the medical aid provided under this act shall be secured either through a panel of physicians from among whom the beneficiaries shall have a right to choose, subject to the physician's consent to serve, or through salaried physicians in the employ of the insurance carriers to whom shall be assigned certain areas or a certain number of insured persons. The act allows a large degree of latitude in arranging the medical service and in combining the two or three recognized methods of compensation to suit the various demands and conditions. This section of the act seems to very reasonable and well considered. The restriction placed on the physicians under the free choice plan, not to accept on their lists more than five hundred insured families nor more than one thousand insured individuals, is well advised. It has been demonstrated that an unlimited service makes it impossible for a popular practitioner to give more than a very cursory attention to his patients when his list exceeds a certain number. In England some of the practitioners have assistants in order to meet the heavy demands made upon them. This is a practice which defeats, in a measure, the provision of the law as to free choice.

The second new section of the act, which relates to medical officers, should be modified. To relieve the physician of the burden of issuing certificates of disability and to divest him entirely of responsibilities on which very often the success of health insurance depends, the act provides for special medical officers whose duty it will be to examine the patients who claim cash benefits and to issue certificates of disability. Incidentally, it will also be

the duty of the special medical officers to supervise the character of the medical service. One may agree or disagree with the principle of supervision of medical work, but when it is once decided upon it should be exercised in such a way as not to hurt the feelings of the conscientious men who must submit to it because of the failings of a few. The best form of supervision is from within, that is by the medical bodies or associations of physicians themselves. The provision of the act, which leaves it to the insurance carriers to appoint medical officers to perform this duty, should be changed in such a way as to give the appointing power either to the medical associations or to the State Insurance Commission or to both of them jointly.

The provision for an arbitration committee which shall sit in judgment over disputes between the insured and physicians or between funds and physicians concerning medical benefits, and shall be composed of representatives of the interests concerned, with an impartial chairman appointed by the State Insurance Commission, is a very important addition to the act. The new draft is much more definite in its provisions than was the Mills bill and it is an improvement over its predecessor.

AVIATORS' SICKNESS.

FLYING is so common in Europe nowadays that it is somewhat a matter for surprise that more has not been written concerning the effects of rapid flight on the human organism. Perhaps those engaged in the pursuit of flying are so occupied with their duties of observing or of fighting the enemy's aviators that they have no time to attempt to analyze their own sensations. Also they are for the most part unable to describe their feelings from a scientific standpoint.

In the *Medical Press*, May 3, 1916, Dr. M. G. Ferry, a French aviation instructor, gives an experimental study of the arterial tension during flight, and concludes as follows: An ascent in an aeroplane leaves after it a condition of arterial hypotension, and this is the more clearly marked as the ascent and especially the descent have been more rapid. On the other hand, being called upon to adapt its systolic effort rapidly to circumambient conditions, which are essentially and constantly changing the cardiovascular apparatus becomes quickly fatigued. The fatigue brings about at an early stage a degree of lassitude quite disproportionate to the amount of effort expended. Why should we not attribute to the development of a certain degree of cerebral anemia the causation of which is referable to two factors of clearly associated influence, cardiovascular fatigue and arterial hypotension, the onset of these sensations of somnolence, fainting, and vertigo, which are sometimes experienced by aviators and referred perhaps too hastily to modifications of auricular tension; unequal degrees of pressure on the two faces of the tympanic membrane, hypertension within the labyrinth, on modifications in the conditions of the semicircular canals? We might thus have also an explanation of certain grave accidents, such as have occurred after rapid descents from high altitudes.

From these considerations, the writer regards it as highly necessary to advise the aviator to fly at a tranquil pace, and not pass too rapidly from one altitude to another. Not only will he avoid the various forms of malaise to which the aviator is subject but he will also escape the fatigue of his cardiovascular system, which tends to recur more rapidly with the frequent succession of flights; and more especially when such ascents and descents in particular have been effected at a too swift pace.

BLOOD STAINS AND CRIME.

EIGHTY-FIVE cases a month would prevent even the indefatigable Sherlock Holmes from having recourse to the needle. This is the average of criminal cases which come under the notice of the Imperial serologist at Calcutta, India, who in thirty-one months examined 6,566 articles suspected to be blood-stained, representing 2,643 criminal cases. The officer in question, Lieut.-Col. W. D. Sutherland (*India Journal of Medical Research*, Calcutta, 1915) gives some Kiplingesque side-lights on crime in the land of mystery, India, especially showing how the natives manufacture evidence and cheerfully perjure themselves to convict their enemies of crime. Sutherland found Vibert's solution (one-half part of mercury perchloride, two part salt, and distilled water to make a hundred parts) the best for the microscopical examination of blood. He does not find the difficulty in distinguishing human blood from ape's blood that German investigators have affirmed, and moreover the ape does not appear to be readily available in India. In thirty-six of the cases examined by Lieutenant-Colonel Sutherland the stains were found due to nonmammalian blood, in ninety cases they were due to mammalian, but not human blood, and in the remainder, about 5,000 cases, the blood was human. Certainly, with 212 blood-stained articles to examine a month, besides the other routine duties of his office, the Imperial serologist at Calcutta cannot find time hang heavily on his hands.

TRUE NARCOLEPSY.

So many conditions have been brought under the rubric of narcolepsy that it has become necessary to discriminate between the original or essential and the symptomatic types. As described by the French epileptologist, narcolepsy consists of a series of attacks of deep somnolence which are secondary to a sudden and profound fatigue. The patient slumbers for a quarter hour or thereabouts and awakens depressed. The attacks may be ushered in by mirthless, spasmodic laughter, the head is flexed and the lower jaw drops. The patients have a taint, but are quite free from epilepsy or hysteria. At a military medical evening held at Zehendorf last October Henneberg described a case which he characterized as of the strict Gelineau type. The patient was a soldier, aged 35, whose father died of tabes dorsalis, and who lost a brother from multiple sclerosis. He himself was free from epilepsy and hysteria. A member of the Landstrum, he was equal to campaign work save that he slept on march and on foot. He wakened readily, but sleeping on sentinel duty led to an investigation. The man was prematurely gray, had the degenerative facies, and was "nervous." Nevertheless he was powerfully built and did not tire readily. He had had up to five attacks daily for two years.

News of the Week.

Medical Schools Graduate.—Seventy-three graduates of the College of Physicians and Surgeons, New York, received the degree of doctor of medicine at the commencement exercises of Columbia University on June 7. The degrees were conferred by President Butler of the University, and the Hippocratic oath was administered by Dean Lambert of the Medical School.

On the same day New York University conferred the degree of doctor of medicine on forty-six graduates of the University and Bellevue Hospital Medical School. Announcement was then made of the award of the Glover C. Arnold prize in surgery to Daniel B. Lynch, and of the Valentine Mott medals to Bertram Krugman and Emerson Noll.

The graduating exercises of the Cornell University Medical College were held in the Dispensary Hall of the college building in New York on June 8, degrees being given to four women and twenty-six men graduates. Dr. W. Gilman Thompson, acting dean, presided at the exercises; the degrees were awarded by President Schurman of the University, and Dr. Lewis A. Stimson, who has recently returned from the war zone, addressed the class. Several prizes were awarded, the John Metcalfe Polk Memorial prizes for general efficiency to Monroe A. Meyer, first prize; Arthur S. McQuillan, second prize; Anna Kleegman, third prize; for efficiency in otology, Charles T. Olcott, first prize; Robert S. Cleaver, second prize.

Twenty graduates of the College of Physicians and Surgeons, Boston, were given diplomas and the degree of doctor of medicine at the commencement exercises held on June 5. The degrees were conferred by Dr. Charles C. Farnham, president of the college.

Dr. William H. Welch, professor of pathology at Johns Hopkins University, received the honorary degree of doctor of laws from the University of Chicago at the commencement exercises on June 6.

P. & S. Appoints Women.—For the first time in its history, the College of Physicians and Surgeons, Columbia University, New York, has appointed women to its staff. Dr. Rosalie S. Morton has been made attending surgeon to the Vanderbilt Clinic, Dr. May G. Wilson, clinical assistant in medicine at the clinic, and Dr. Vera Dantschakoff instructor in anatomy.

New Floating Hospital.—The new floating hospital of St. John's Guild, the Helen C. Juilliard, a gift of the late Mrs. Juilliard, was opened for inspection on June 7 and will make its first trip with New York's sick babies on July 5. The boat was built at a cost of \$125,000, and is the third floating hospital to be used by the guild. Since 1875, when the work was first started, 1,601,933 persons have been carried in the hospitals, and last summer alone the number reached 31,764.

To Inspect Restaurants.—Having ascertained that at least one million persons dine daily in the 5,163 hotels, restaurants, cafés, or other eating houses of New York City, the Department of Health, operating through the Food and Drug Inspection Bureau, has begun a study of the conditions under which the food therein served is prepared, of what quality it is, how it is treated, and how cooked. The restaurants will then be graded as "good," "fair," or "bad."

Hospital Units.—The Massachusetts General Hospital and the Boston City Hospital, Boston,

have each organized a base hospital unit, similar to those recently organized in New York, for service during war time.

Red Cross Membership Grows.—As a result of the campaign now going on throughout the country, the membership of the American Red Cross in and about New York has been increased by over 23,000 members, making the membership of the metropolitan district, embracing the territory within twenty-one miles of Manhattan, over 50,000. It has been decided to continue the movement through June, and it is hoped that the total membership in the United States may be raised to the one million mark.

Bar Wood Alcohol.—In response to the request of the Commissioner of Health of New York City, the members of the Brewers' Board of Trade of New York and vicinity, controlling thirty-seven breweries in New York City and nine in New Jersey, recently adopted a resolution prohibiting the use of methyl alcohol in connection with the varnishing of vats in their plants. It had been shown previously that the use of wood alcohol in this way was a serious menace to the health of the men employed in the work of varnishing, and that several cases of death or of complete or partial loss of vision could be traced to this cause. The Department of Health is particularly gratified with the action of the brewers in this instance, as showing the superiority of the newer method of public health administration which makes effective use of persuasion rather than of legal compulsion.

P. & S. Alumni Prize.—The prize offered biennially by the Association of the Alumni of the College of Physicians and Surgeons, New York, has been awarded this year to Dr. Harold Neuhoof, '05, New York, for his essay on "Fascia Transplantations into Visceral Defects."

College Raises Requirements.—The University and Bellevue Hospital Medical College, New York, beginning with the class entering September, 1918, will require two years of college work before admission. This increase in entrance requirements is made necessary because the facilities of the college are greatly overtaxed by the present classes, the previous requirements having included only one year of preparatory college work. By arrangement with the academic department of New York University it will now be possible for students after six years and a half to obtain the combined degree of bachelor of science and doctor of medicine. Dr. Samuel A. Brown, assistant professor of medicine, has recently been made dean of the medical school.

Teaching the Deaf.—The American Association to Promote the Teaching of Speech to the Deaf has offered a prize of \$300 for the best essay on the subject of teaching and training deaf children in the home, the essay to be submitted before November 1, 1916. Details of the competition may be obtained on application to the judges of the Alexander Graham Bell Grosvenor Memorial Fund, Volta Bureau, 1601 Thirty-fifth street, Washington, D. C. The successful essay becomes the property of the association and will be published in the *Volta Review* and later in book form for wider distribution.

City Death Rate.—The death rate in New York during the week ending June 3 was slightly higher than that of the corresponding week of last year, the increase being due principally to the increase in the mortality from heart disease, nephritis, and

cancer, with a smaller increase in the number of deaths due to bronchitis and diarrhea. The mortality of practically all the other diseases was decreased, thus offsetting to a considerable degree the increased mortality of the first group. The total deaths reported during the week were 1,473, as compared with 1,430 reported during the corresponding week of 1915, the respective rates being 13.75 and 13.68 per 1,000. The death rate for the first twenty-three weeks of 1916 is 15.13 as compared with 15.34 for the corresponding period of last year.

Opportunity for Volunteer Service.—There are several vacancies for volunteer clinic physicians at the Occupational Clinic of the Division of Industrial Hygiene, Department of Health, New York, the service requiring attendance three mornings a week for two hours, and physicians who are willing to co-operate in this work are requested to apply in writing to the Director of the Bureau of Preventable Diseases. Those who have in the past associated themselves with the Occupational Clinic as volunteer clinic physicians have, with few exceptions, acquired knowledge and experience which has fitted them for service in the newer phase of medical practice, industrial corporation service.

Corrective Exercises for Children.—The class for corrective exercises for the children of the Harlem Italian Clinic maintained by the Department of Health, New York, held its annual exhibition recently, eighty children participating. As a means of increasing bodily resistance and so acting as an effective preventive measure against tuberculosis and other diseases, these exercises have been deemed of very great value by those who have given the subject careful study, and their wider adoption is to be hoped for. Much credit is due to the Society for the Prevention and Relief of Tuberculosis, whose generosity has made it possible to maintain this class as an important branch of tuberculosis preventive work.

Health Insurance.—In response to public interest in health insurance the Massachusetts Legislature has created a commission to study social insurance with special reference to sickness. The State Department of Health and the Bureau of Statistics are directed to co-operate with the commission of nine members which will prepare a report and recommend the form of legislation to be introduced in January, 1917. California has a similar state commission already at work on this problem, which is attracting wide attention since the introduction this year of bills for health insurance in the legislatures of Massachusetts, New York, and New Jersey. Proponents of this legislation believe it will bring about a movement for "health first" comparable to the "safety first" campaign which followed the passage of laws covering workmen's compensation for accidents.

Street Accidents.—The Police Department of New York reports that during the month of May, 1916, forty-two persons were killed by vehicles in the city streets, of this number twenty-six were children under sixteen years of age. Of the total number two were killed by surface cars, thirteen by passenger automobiles, twelve by automobile trucks, ten by horse-drawn vehicles, one by an unidentified vehicle, one by collision between a motor cycle and an automobile truck, one by an accident to a truck, and two by being thrown from wagons drawn by runaway horses.

A School of Hygiene for Johns Hopkins.—It is announced that the Rockefeller Foundation has decided to establish in Johns Hopkins University a school of hygiene and public health which will be devoted to training students in preventive medicine and public health work. It is expected the school will be opened in October, 1917. It will take a year to construct and equip the necessary building and organize a staff of teachers. The work of organization will be undertaken by Dr. William H. Welch, professor of pathology, and Dr. William H. Howell, professor of physiology, of Johns Hopkins. Dr. Welch has been selected as director of the new school. The immediate need of such an institution has been emphasized by the difficulty experienced by cities and States in finding men equipped for promoting public health, sanitation, and preventive measures generally.

Fight Sanatorium.—A petition signed by more than 100 of the residents of Verona, N. J., protesting against the location of a tuberculosis sanatorium in the residential section of the town, has been presented to the New Jersey State Board of Health.

Medical Society Elections.—NEBRASKA STATE MEDICAL ASSOCIATION: Annual meeting at Omaha on May 24 and 25. Officers elected: *President*, Dr. William F. Milroy, Omaha; *Vice-Presidents*, Dr. Miles S. Moore, Gothenburg, and Dr. Porter F. Dodson, Wilbur; *Secretary*, Dr. Joseph M. Aikin, Omaha; *Treasurer*, Dr. A. S. Von Mansfelde, Ashland.

MASSACHUSETTS MEDICAL SOCIETY: 135th annual meeting at Boston on June 6. Officers elected: *President*, Dr. Samuel B. Woodward, Worcester; *Vice-President*, Dr. Fred W. Taylor, Cambridge; *Secretary*, Dr. Walter W. Burrage, Boston; *Treasurer*, Dr. Edward W. Buckingham, Boston.

DES MOINES VALLEY MEDICAL ASSOCIATION: Annual meeting at Ottumwa, Ia. Officers elected: *President*, Dr. Charles B. Taylor, What Cheer, Ia.; *Vice-Presidents*, Dr. Charles H. Magee, Burlington, Ia., and Dr. Burt O. Jerrel, Oskaloosa, Ia.; *Secretary-Treasurer*, Dr. E. B. Howell, Ottumwa.

Obituary Notes.—Dr. SARAH HOWE MORRIS, formerly of Buffalo, N. Y., a graduate of the Boston University School of Medicine in 1869, and a member of the Erie County Homeopathic Medical Society, died at Santa Monica, Cal., on May 25, aged 83 years.

Dr. BENJAMIN U. JACOB of Waukesha, Wis., a graduate of Northwestern University Medical School, Chicago, in 1881, and a member of the American Medical Association, the State Medical Society of Wisconsin, and the Waukesha County Medical Society, died on May 28, aged 66 years.

Dr. ALLEN A. GREENE of Anniston, Ala., a graduate of Vanderbilt University Medical Department, Nashville, Tenn., in 1891, and a member of the Medical Association of the State of Alabama and the Calhoun County Medical Society, died at St. Luke's Hospital, Anniston, on May 27, aged 46 years.

Dr. JAMES STENHOUSE of Denver, Col., a graduate of the Denver College of Medicine in 1886, died at St. Joseph's Hospital, after a short illness, on May 24, aged 57 years.

Dr. CHARLES J. STOVALL of Bowling Green, Ky., a graduate of the Kentucky School of Medicine, Louisville, in 1891, died at his home on May 26, aged 62 years.

Dr. JAMES J. GIBSON of Lexington, Ky., a graduate of the Hospital College of Medicine, Louisville, Ky., in 1889, and a member of the Kentucky State Medical Association and the Fayette County Medical Society, died suddenly at his home, on May 28, aged 48 years.

Dr. WILLARD PARKER WORSTER of New York, a graduate of the College of Physicians and Surgeons, New York, in 1867, formerly physician to the Post-Graduate Dispensary, and a member of the Medical Society of the State of New York and the New York County Medical Society, died at his home on June 7, aged 74 years.

Dr. ALFRED KING of Portland, Me., a graduate of the Medical School of Maine, Portland, in 1886, and a member of the American Medical Association, the American Therapeutic Society, the Maine Medical Association, and the Cumberland County Medical Society, and a fellow of the American Surgical Association, died at his hospital on June 4, aged 55 years. Dr. King was professor of surgery in the Bowdoin Medical School and consulting surgeon at the Webber Hospital.

Dr. NATHAN JENKS of Detroit, Mich., a graduate of Cornell University Medical College, New York, in 1899, and a member of the American Medical Association, the Michigan State Medical Society, the Wayne County Medical Society, and the American Association of Obstetricians and Gynecologists, died at his home on May 30, aged 44 years. Dr. Jenks was associate professor of obstetrics and clinical midwifery in the Detroit College of Medicine and fellow of the American College of Surgeons.

Dr. ELIZABETH CORBETT, formerly of San Francisco and more recently of New York, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1879, an honorary member of the American Medical Association, and sister of Dr. Harvey W. Wiley of Washington, died in the Washington Sanitarium, Takoma Park, Md., on June 4, aged 83 years.

Dr. THOMAS FRANKLIN SMITH of New York, a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1860, and a member of the American Institute of Homeopathy and the New York State Homeopathic Society, died at his home on June 6, aged 83 years. Dr. Smith was a charter member of the International Homeopathic Medical Association, was physician to the Metropolitan Hospital on Blackwell's Island, and during the Civil War was a surgeon in the United States Army.

Dr. ALFRED P. KEAM of St. Paul, Minn., a graduate of the Detroit Medical College in 1880, died at his home after a short illness, on June 1.

Dr. JAMES T. SHERMAN of Boston, Mass., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1869, died at his home in Dorchester on June 6, aged 67 years.

Dr. AMBROSE TALBOT of Kansas City, Mo., a graduate of Harvard University Medical School in 1885, and a member of the American Medical Association, the Missouri State Medical Association, and the Jackson County Medical Society, died suddenly in his office on June 1, aged 56 years.

Dr. FREDERICK H. SAGE of Middletown, Conn., a graduate of the New York Homeopathic Medical College and Hospital, New York, in 1884, and a member of the American Institute of Homeopathy and the Connecticut State Homeopathic Society, died in the Middlesex Hospital, on June 7, aged 55 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CENTRAL MEDICAL WAR COMMITTEE ENROLLMENT
SCHEME — COMPULSION — DISTRICT NURSING —
PANEL SYSTEM—SETTLING ACCOUNTS.

LONDON, MAY 27, 1916.

THERE is a demand for a considerable addition to the medical officers serving in the Royal Army Medical Corps and a number of those in the Home Service have gone abroad. The Central Medical War Committee scheme of enrollment has not been quite completed so that volunteers from both the enrolled and the unenrolled are being taken on. This seems to offer attractions above conscription which has never been favored by the English people. The War Office scheme was entrusted to the Central Medical Committee, which represents the schools and corporations as well as the profession at large. It is also connected with the Insurance Commission and chief government departments, or all which officially consult medical men. The advantages of voluntary enlistment over compulsion require no argument. It is preferred by all concerned and approved by the general public. Of course, the success of the scheme depends on the number of enrollments, but at present the response has been satisfactory though no little anxiety is felt as to the early future. If the response should fail a resort to conscription would be required, and this would be the case with the profession as well as the general public.

The extent to which medical practice is being taken out of the hands of general practitioners calls for consideration by the profession. The Central Council for District Nursing in London has had referred to it the notification and nursing of measles and whooping cough, and some have even proposed to take these maladies away from medical practitioners and entrust them altogether to the care of nurses. That this scheme should have been considered reasonable is the consequence of the way in which the intrusion of nurses into the work of the doctors has been encouraged. Too often left to carry out the treatment under the slightest supervision, they have come to consider themselves the chief agents, and the doctor is needed only to bear the responsibility of serious cases.

The panel system is by no means approved by all, and many who are working under it express disappointment with it. Even from a monetary point of view, complaints are rife though some might well have been anticipated; a committee has resolved that they be invited to communicate their views as to the desirability of pressing for settlement of the accounts more promptly. The London Panel Committee resolved to bring about, if possible at once, a settlement of the accounts for 1914. Considering this resolution was not put forward until last March its terms are by no means forcible. It was however further agreed to represent strongly to the commissioners the growing indignation of those on the panel at the delay in settling those accounts. Their resolution said the delay was "most regrettable, and that the Insurance Commissioners and the committee should be so informed." In pursuance of this intention, the panel committee has been invited to forward their views as to the desirability of pressing for emergency settlement of their accounts for 1915.

NAUHEIM AT SARATOGA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—After reading your editorial in the issue of June 3 on Nauheim treatment at Saratoga, in reference to the position taken by Commissioner George B. Pratt, I venture to express my views on the situation. Saratoga has, within a radius of three miles, all the varieties of spring water that Nauheim and many other European spas have in a radius of many hundred miles. Consequently there is no occasion for her to attempt to increase her prestige by adopting the name or reputation of any other spa, either in our own country or in Europe. It is well known that the Drs. Schott, with their great skill in developing the resistant exercises, made Nauheim's wonderful reputation; and, further, that the same procedures, when followed out in connection with the use of our natural Saratoga waters, will have identical results. This has been repeatedly demonstrated by our physicians at Saratoga.

I am sure no one claims more for the bath (regardless of the name) than the effect on the economy through peripheral irritation and the congestion of the capillaries. Consequently, if the benefits derived from a course of treatment at any spa depend, as they do, upon a change of atmosphere, scene, and mode of living, diet, exercise, and rest, in combination with the use of natural mineral waters externally and internally—then when we have all this here at Saratoga, why should Saratoga promulgate the artificial? She certainly should *not*; if Saratoga cannot stand on her own wonderful resources as a health resort, she should not pose at all. We have had too long and too hard a fight to obtain the seal of our great State upon the genuineness of our waters, to accept modifications of these waters regularly.

However, if in the judgment of a physician, his patients require baths of a different character from that of the water as it flows naturally from the spring, they should have it, of course, without criticism. But the physician should write a prescription for such modification as he desires, and not simply use the word "Nauheim" and leave it for the bath attendant to interpret. I would suggest that if it is desired to increase the specific gravity of the Saratoga waters for a particular reason, instead of adding a mixture of salts for this purpose, our natural mineral water be evaporated to a definite constituency and that the brine thus formed be used to produce the effect desired. This brine would then have the same relative proportion of salts as the natural water.

D. C. MORIARTA, M.D.

SARATOGA SPRINGS.

Progress of Medical Science.

Boston Medical and Surgical Journal.

June 1, 1916.

1. Five Years' Progress in the Diagnosis and Treatment of Consumption by Massachusetts Physicians. John B. Hawes, 2d.
 2. Disinfection of Septic Joints. F. J. Cotton.
 3. A Classification of Renal Infection, with Particular Reference to Treatment. Hugh Cabot and E. Granville Crabtree.
 4. B. Dysentery as a Cause of Infectious Diarrhea in Infants. Carl Ten Broeck and Frank Garm Norbury.
 5. Intraspinal Injections of Bichloride of Mercury. Edward Livingston Hunt.
1. Five Years' Progress in the Diagnosis and Treatment of Consumption by Massachusetts Physicians.—John B. Hawes, 2d, bases this study on figures obtained

at the Massachusetts General Hospital and the Boston Consumptives' Hospital. From these figures he finds that there has been a distinct improvement in the early diagnosis of tuberculosis during the past five years, as shown by the increased number of diagnoses of incipient tuberculosis without the presence of positive sputum. There has been a vast increase in the number of patients who have gone to a doctor before they suspected that they had tuberculosis, as shown by the figures 77 out of 500 in 1911, and 408 out of 500 in 1915. In cases consulting a physician because of hemorrhage fewer have been told that they did not have consumption in 1915 than in 1911. This was, likewise, the case in regard to the patients who were told that they did not have consumption on first consulting their doctor. The improvement in these two respects was not as great as was to be hoped. It is not encouraging that at the present time out of 500 consumptives over 50 per cent. were not given to understand by their physicians that they had consumption. There has been an encouraging increase in the number of applicants for State Sanatoria which were made at the time of the examination of the patient or immediately after. Of the 1915 patients, 163 consulted only one physician, while 336 went to two or more physicians. Of the patients who consulted two or more physicians, 41 per cent. went to another physician to be sure the first was right, 23 per cent. because they did not improve, and 17 per cent. because the first physician advised them to do so. According to the statements given out by these 500 patients, it cost approximately \$10 per patient for them to obtain diagnosis and treatment for their condition.

3. A Classification of Renal Infection, with Particular Reference to Treatment.—Hugh Cabot and E. Granville Crabtree review the various sources of confusion that surround the subject of renal infection and thinks this is justification for presenting the following classification of renal infections: 1. Infection in kidneys having no previous gross lesion and not part of a general and in itself lethal septicemia. 2. Infection in kidneys having an antecedent gross lesion, such as stone in the kidney or ureter or damage dependent upon obstruction of ureter or bladder. In the first group, to which the writers confine their attention in this paper, there are three quite distinct types of infection: 1. Those due to infection with the coccus group. 2. Those due to infection with the colon bacillus group. 3. Those due to infection with the tubercle bacillus. After discussing each of these types they summarize by stating that lesions produced by the coccus are far more likely to require surgical treatment because of their location and the tendency of the organism to pus formation. Such surgery, if required, will come during the comparatively early stages of the infection. As opposed to this, the colon bacillus infection produces a lesion which rarely requires surgery in its early stages, which is comparatively amenable to medical treatment, but which has a remarkable tendency to become chronic, and which may in time produce a lesion of the kidney which so completely destroys that organ that nephrectomy becomes necessary. The treatment of renal tuberculosis consists wholly in the removal of the kidney when the diagnosis has been made.

4. B. Dysenteriae as a Cause of Infectious Diarrhea in Infants.—Carl Ten Broeck and Frank Garm Norbury during the summer of 1914 examined the stools of infants suffering from diarrheas in the Boston Floating Hospital and show that in the severe cases the dysentery bacillus was more constant in its presence than the other assumed etiological organisms and that the evidence in favor of its being the cause of the trouble was

better than for other bacteria. During the summer of 1915 they decided to make a more thorough search for it and in those cases in which it could not be isolated to test for agglutinin for it in the blood. In 75 cases studied the dysentery bacillus was isolated from 74.6 per cent. Only 14 of 19 bacteriologically negative cases were studied for agglutinins, and 64.3 per cent. of these or 12 per cent. of the total number, gave a positive reaction, thus making a total of 86.6 per cent. of the 75 cases in which there was good evidence that the dysentery bacillus was present. The authors were unable to obtain any evidence that the *B. welchii* is ever the cause of infectious dysentery and all the results point to the dysentery bacillus as the etiological agent. In their cases all these bacilli belonged to the mannit-fermenting group. In spite of the apparent scarcity of the dysentery bacilli in the feces they believe that they are the cause of infectious diarrhea of infancy because of their universal association with the condition, the great numbers of these organisms in the mucosa of the cecum and the fact that the sick individual produces immune bodies against them, while such bodies specific for the other assumed etiological agents have not been demonstrated, and finally because experimentally they are known to produce a diarrhea.

5. Intraspinal Injections of Bichloride of Mercury.—Edward Livingston Hunt recalls that at a recent meeting of the Section on Medicine of the New York Academy of Medicine he reported forty cases of spinal syphilis treated by the intraspinal administration of mercurialized serum, and five cases treated by the direct intraspinal infection of bichloride of mercury. Since that time he has treated twelve additional cases by the direct administration of bichloride of mercury into the spinal fluid. These twelve cases consisted of cases of general paresis, tabes, tabo-paresis, hemiplegia, optic nerve atrophy, and one case of brain syphilis with complicating hemiplegia. They were given either 1/64 or 1/50 of a grain of bichloride of mercury at each intraspinal injection. The injections were approximately at intervals of two weeks. The patients were at the same time being given mixed antisyphilitic treatment. In a few of these patients it was not possible to obtain definite results, but in the large majority improvement was manifest. The writer concludes that the administration of bichloride of mercury directly into the spinal fluid gives practically the same results as the administration of mercurialized serum. It has the advantage over the latter of simpler technique, shorter method, and easier administration, with less opportunity of infection. Both the administration of mercurialized serum and bichloride injected directly into the spinal fluid can be considered as valuable substitutes for the administration of salvarsan. Whether the results will be as permanent as the latter remains to be seen. In no instance was any change manifest in the reflexes, but change was evident in the tremors, in the pains, in the spinal fluid content, and especially in the general condition of the patient.

6. Presenile Gangrene—Thromboangiitis Obliterans.—Charles Goodman and Eugene P. Bernstein present this serological study which has reference to the possibility of typhus fever as an etiological factor in thromboangiitis obliterans. They call attention to the fact that a study of the literature reveals that a number of authors have suspected the infectious origin of this condition. A study of the epidemiology of typhus fever shows distinctly that in countries where this disease is quite common thromboangiitis obliterans is also abundantly found; on the other hand, in countries where typhus fever is lacking the condition is usually found less frequently. Since the specific microorganism of typhus fever has been isolated it has seemed advisable to make serological studies in thromboangiitis obliterans. Dr. Bernstein has done this, the cases having been sent him from the wards of Mount Sinai Hospital by Dr. Goodman. There were twenty-one cases diagnosed as typical cases of thromboangiitis obliterans, most of them having no recent lesions. In eighteen of the cases the serological reactions were negative. The three other cases gave quite marked reactions. In one case there was an almost complete agglutination up to a dilution of one in 200, and in two almost complete agglutination up to a dilution of one in 400. In three cases in which a previous typhus fever could not be excluded, a positive agglutination in a dilution up to one in 200 was found. Recent serological studies have made it evident that people in contact with typhus fever acquire a positive serological reaction because they have been infected by a number of bacilli too small to give the typical picture of the disease, but enough to set up immunological reactions. The view might be entertained that, because only three patients with thromboangiitis obliterans out of a total of twenty-one presented positive serological reactions, the thromboangiitis developed independently of the previous infection by the typhus bacillus. It was important, however, to remember that patients with typhus fever might lose their serological reactions within even as short a period as five months from the termination of the disease, and therefore some of the cases studied might have given a positive reaction at some previous time.

8. Unusual Complications in a Case of Glaucoma from Atropine.—T. Y. Sutphen reports this case in which, during treatment for glaucoma, a spontaneous sclerocorneal rupture and prolapse of the iris occurred. After treatment by repeated paracentesis vision was still 20/15 in the one eye. The delay in relieving the iris entanglement in the other eye resulted in an enormous corneal astigmatism. This, the writer thinks, emphasizes the great importance of relieving iris entanglements, especially in glaucoma. The immediate improvement in tension, when the pillars of the entangled iris were cut across was conclusive evidence that this should have been done earlier. This case also exemplified the danger of using atropine in some patients under forty years of age, though there was no other drug that gave such complete paralysis of accommodation.

9. Pellagra.—James MacFarlane Winfield submits the histories of eight indigenous cases of pellagra that have been seen in various parts of New York State since 1911. Five of these patients were inmates of State hospitals, two were in the dermatological service of the Kings County Hospital, and one was a private patient in Hornell, N. Y. All of these patients except one were females. Two of these patients had enlarged thyroids, three had evidence of pulmonary disease; in one the process was active, and in two others the disease had been arrested. It was not possible to learn what the diet of all the patients had been, but from what infor-

mation could be ascertained it seemed that none of them had indulged to any great extent in meat. One gave a history of having eaten for years only beans, oleomargarine, and tea biscuits. Two had subsisted for a long time on bread and tea. The writer states that this experience leads him to agree with MacKee in assuming that there have been cases of pellagra in New York and the vicinity that have either been overlooked or incorrectly diagnosed.

10. The Curatelle and Modern Psychiatry.—George W. Jacoby concludes a series of articles on this subject in which he discusses very exhaustively both the medical and legal phases of this subject, and in conclusion directs attention to certain main points in which our curatelle laws require reform, and in which, as is shown by the German law of curatelle, they are capable of being improved. These are: 1. Agreement in regard to the fundamental views about the psychic states which necessitate the institution of a curatelle, namely, insanity, feeble-mindedness, improvidence, and inebriety. 2. An extension of the interpretation of the term, inebriety, so as to apply to the habitual use of narcotics or other habit-forming drugs, so that it might be possible to place under guardianship, not only alcoholic inebriates, but also inveterate users of morphine, cocaine, or other drugs, and thereby permit all such unfortunates to be forcibly subjected to treatment. 3. Adoption of the concept, hitherto not accepted by Anglo-Saxon law, of restricted responsibility, through which it would be possible to place a person under guardianship without stigmatizing him as insane, or to refrain from placing a psychically defective individual under curatelle, if his capability to transact business properly is not affected by his psychic deficiency. 4. Appointment of the medical expert by the court in order to guarantee an absolutely impartial opinion.

1. The Nonspecific Factors in the Treatment of Disease.—James W. Jobling and William Petersen call attention to the fact that one finds a not inconsiderable accumulation of evidence, both from the laboratory and the clinic, definitely indicating a much larger share of certain nonspecific and as yet ill-defined factors in recovery from disease. Early in the development of tuberculin therapy Matthes demonstrated conclusively that to all intents and purposes the reaction considered specific for tuberculin could be produced when deuterio-albuminose was used, and showed that whatever difference occurred could be explained by the fact that the tuberculin fraction contained certain toxic peptones in addition. The history of the treatment of typhoid fever with vaccines is quite similar and similar phenomena have been observed in other diseases. After discussing certain phenomena in vaccine and serum therapy in relation to leucocytosis, to hyperexia in certain conditions, to the mobilization of ferments, and to

the increase in antiferment, the writer concludes that it seems probable that the fundamental change on which the majority of the biological reactions which he describes are based is one of colloidal dispersion, in that the injections bring about a less dispersed state affecting not only the serum proteins but also the serum lipoids. Such an alteration is sufficient to account for the fluctuations in the ferment-antiferment balance, and in the coagulation mechanism, as well as in the opsonic and complement powers of the serum, although it does not at present explain the increased antibody titer. With this as a basis we can understand that so many and diverse substances can bring about a reaction almost identical clinically and therapeutically. But here, as in so many biological problems which have to do with the most complex of tissues, the blood, it seems probable that no single factor can be identified as responsible for all the changes that occur, but that a whole train of events is inaugurated when the equilibrium in some of the delicate serum balances is disturbed, all of which tend toward a condition favorable for recovery from infection.

2. The Treatment of Arthritis by the Intravenous Injection of Foreign Protein.—Joseph L. Miller and Frank B. Lusk cite evidence confirmatory of that already recorded, making it quite apparent that the sudden termination of certain diseases is not due to the specific character of the vaccine used but probably to the action of a foreign protein. With this fact in mind it was decided to apply this method of treatment to acute, subacute, and chronic arthritis. Only those cases were selected for study in which the disease was of a persistent type. They gave a 4 per cent. proteose solution in doses of 2 c.c. The patient reacted by a chill, rise in temperature, and moderate leucocytosis. The day following the injection there was a moderate but definite improvement in the joint symptoms. As the supply of protein was limited a typhoid vaccine was substituted for the proteose. The reaction was the same as when the vaccine was given to a typhoid patient, except that the leucocytosis was much more marked. In three of ten cases of acute articular rheumatism, immediately following a single intravenous injection of 150,000,000 the fever terminated by crisis, the joint tenderness began to disappear, and within twelve to twenty-four hours the joints were apparently normal. The seven remaining patients were much benefited following a single injection, but the results were either not permanent, or soreness still remained in some of the affected joints. Three or four injections, however, sufficed to relieve all symptoms. Results quite as satisfactory were obtained in six cases of subacute arthritis of from three to nine months' duration. Results were even more striking in cases of chronic gonorrheal arthritis of from two months to three years' duration. The authors state that they believe the same process is active here that is responsible for the termination by crisis in typhoid, following the intravenous injection of vaccine. That the febrile reaction following injection is not solely due to the foreign protein injected is suggested by the much milder reactions in patients with low degrees of infection. Whether or not this method of treatment is of value as a therapeutic agent it will at least give further evidence of the non-specificity of vaccines. It does not, however, involve the specificity of vaccines for preventive purposes.

4. A Study on Food.—Robert J. Wilson and Walter L. Ratbun present an exhaustive study of the fuel value of the dietary at the New York City Municipal Hospital and of the various problems involved in providing a suitable dietary in such an institution from which they draw the following conclusions: 1. In all insti-

tutions for the care of the tuberculous, food studies, including the caloric content of the dietary and food waste, should be carried on at regular intervals, preferably for one week or more during the various seasons of the year, and these records should be made available for comparative purposes. 2. Special training, though advisable, is not a necessary requisite for the carrying out of a successful dietary study in an institution. It is, of course, essential that the doctor who directs the work should be thoroughly familiar with the problem. It is only necessary that the person or persons who are doing the work should be intelligent, careful, and willing to follow conscientiously the "rules of the game." 3. The elimination of meats and eggs from the morning meal and the substitution of milk is a sound and justifiable economy. 4. The dietary of the tuberculous should be high in caloric value, but confined to three daily meals in all but exceptional cases. 5. Males consume more food than females, both in total amount and in number of calories per pound of body weight, but in spite of this fact, females make much larger gains than males, enough so as to indicate that rapid accumulation of weight is a characteristic of the female sex. 6. The avoidance of frequent repetition of foodstuffs is very important. 7. A four weeks' menu, when used as suggested, is of great aid to those controlling the dietary, and tends to do away with repetition. 8. The treatment of small children, in separate units, in institutions with adults, is both feasible and advantageous in that it results in economy of foodstuffs. 9. Small initial servings with as many "seconds" as may be desired is satisfactory to the patients and prevents much plate waste. 10. The plate waste in institutions for the tuberculous is of necessity higher than in hospitals for the insane or in general hospitals.

5. Variations in Renal Function Dependent on Surgical Procedures.—Donald F. Cameron reports his observations of the changes in renal function produced by operations performed under general anesthesia and of the variations in renal activity dependent on relief from the back-pressure of urine. For this work the rate of excretion of phenolsulphonaphthalein and the concentration of urea in the blood have been taken as the indices of renal activity. The writer believes these tests are of great importance in selecting the most opportune time for operation so far as renal function is concerned. Following an operation under a general anesthetic there is, as a rule, an increase in blood urea concentration. This increase is most marked after operations on the urinary tract, and especially on patients who already have diminished renal function. In a small series of cases this increase was slightly more marked following operations under gas-oxygen-ether anesthesia than following similar operations under ether. Blood urea determinations are of great value in the diagnosis and prognosis of uremic states. Not infrequently blood urea concentration can be determined when other renal function tests are very difficult or impossible. In this investigation definite symptoms of uremia in uncomplicated cases appeared when the blood urea concentration reached 180 to 200. There is a definite group of patients who have a low phenolsulphonaphthalein excretion, but a normal or approximately normal blood urea concentration. Many members of this group withstand a general anesthetic without any complication due to renal insufficiency.

6. Paralysis During Pasteur Antirabic Treatment.—Frank S. Fielder reports seven cases, one terminating fatally, and six others previously unreported. He states that the administration of antirabic treatment is not entirely devoid of risk, since paralysis complicating the Pasteur antirabic treatment, though very rare, doubt-

less occurs. It affects adults chiefly, young children almost never. The prognosis is good in cases of mild or moderate degree, but the mortality among the severe cases is high. The possibility of the occurrence of paralysis in any particular case, however, is so slight that it should not deter those who evidently need antirabic treatment. The slight risk of paralysis should always be explained to those who are inclined to insist on antirabic treatment in the absence of clinical or laboratory evidence that the biting animal was rabid. In most instances this paralysis is caused by the antirabic treatment itself, fixed virus infection or toxin, or both. It is not often due to street virus infection modified by treatment. Its incubation is shorter than that of most cases of street virus rabies. Variations in the strength of the fixed virus used are probably a factor in the etiology. Personal idiosyncrasy is an important predisposing condition.

4. On the Presence of Lead in the Urine in Four Cases of Trench Nephritis. Charles Powell White.

1. Links in a Chain of Research on Syphilis.—J. E. R. McDonagh says the recognized fact that twenty-four hours after the first injection of salvarsan no spirocheta pallida could be found in syphilitic lesions, yet it was necessary to repeat the injection of salvarsan several times, and to prescribe mercury afterwards, led him to doubt whether the statements made about the German discoveries were correct. Three questions confronted him: 1. If the spirocheta was the cause of syphilis why did one never see it divide? 2. If all the spirochetæ were killed within twenty-four hours after the first injection of "606" why was it necessary to continue the treatment? 3. If the spirochetæ cannot pass through the placenta, how can an apparently healthy woman bear a syphilitic child, since it is impossible to imagine that an organism as long as the spirocheta pallida should enter the ovum with a spermatozoon? It then occurred to the writer that the spirocheta pallida was not the absolute cause of syphilis, but possibly only a phase in the life history of a protozoon. It seemed that the organism might perhaps be the adult male, or, at any rate, an end phase of a complicated protozoal life history. As a result of investigation with both live and fixed tissue he was able to work out the life-cycle of what was evidently a coccidial protozoon which he felt justified in assigning to the order *Sporozoa*, and to the sub-class *Telosporidia*. The species which most befitted it is the leucocytozoon, hence a good name for the syphilitic parasite would be *Leucocytozoon syphilidis*. As a result of some chemical investigations, he found that the phases of the protozoon consisted of a protein which had special properties. This then gave him a clue which enabled him to explain the rationale of the Wassermann reaction. The Wassermann reaction turned out to be a physical reaction dependent upon certain properties which the protein particles of syphilitic sera naturally possessed. Having found out these properties it then became clear how salvarsan worked. Further investigation into this subject soon unraveled the rationale of chemotherapy and opened the way along which future research might be expected to be most productive. The author presents an outline of all these investigations.

2. Malignant Disease of the Nose or Accessory Sinuses.—St. Clair Thomson describes the details of the operation of lateral rhinotomy or Moure's operation, which he finds precisely adapted for the removal of malignant tumors originating in the ethmoidal and antro-nasal wall, as well as for those starting in the roof of the nose, in the antrum, or in the sphenoid. He reports two cases that show that both an endothelioma and a carcinoma in the nasal area are susceptible of satisfactory treatment by this method. A comparison of this operation with the dangerous, difficult, and disfiguring operations formerly used demonstrates its advantages. In all cases there is no mutilation or disfigurement. Patients will readily consent to the operation. They are left with an intact roof of the mouth and require no troublesome obturator, as in the old operation of excision of the upper jaw. It is much easier after a Moure operation to keep a direct lookout in the nose and its accessory cavities for any suspicion of recurrence. Recurrences are more easily dealt with, either through the nasal orifice or by repeating the lateral rhinotomy, and patients are less likely to object to this than to a further facial disfigurement. Loss of smell is never complained of if the septum has been respected. The writer has met with no neuralgia or similar trouble, following operation even when the bone with the infraorbital canal in it has been removed.

4. On the Presence of Lead in the Urine in Four Cases of Trench Nephritis.—Charles Powell White says that on reading the accounts of trench nephritis it seemed to him that the incidence of the disease pointed to the possibility of its being attributable to the use of tinned foods in the diet. With this idea in mind he has examined five specimens of urine from trench nephritis for the heavy metals, two of them from the same case at different times; two specimens from ordinary nephritis, and a normal urine to serve as a blank experiment. Lead was present in all the specimens from trench nephritis, and in one of the mixed urines of ordinary nephritis. Iron was present in all the nephritis specimens and copper in most of them. Tin was also present in one specimen, a recent case that contained more lead than the others. This suggested the possibility of the lead being derived from tinned foods, though it was obviously impossible to draw conclusions from four cases only. The writer invites the attention of those who see these cases early to this subject, since it is probable that the lead may be present in larger quantities in the early cases.

6. An Easy and Rapid Method of Doing Widal's Reaction for Typhoid. Alfred C. Coles.
7. The Treatment of Wound Infections. W. Parry Morgan.

1. Gerontal Constipation and Its Treatment.—W. Ainslie Hollis calls attention to prostatic enlargement as a factor in gerontal constipation. He says that some, perhaps a majority of cases of enlarged prostate, begin with venous congestion. A serious change in the blood supply of the gland, which such a circulatory failure implies, would alone suggest the probability of some

central cardiac causation, either organic or functional, and this conjecture was strongly confirmed, if, as is often the case, we find the venules of the face, the nose in particular, affected. When this is so the elderly person, as a rule, suffers from symptoms suggesting "irritable heart." Another anomalous symptom was a feeling of distention in the upper rectum, probably due to the direct influence of the rectal tumor. In discussing the treatment of this condition, the writer says that drugs at best can be only palliative. With this limitation he suggests doses of aromatic syrup of cascara, which he thinks probably contains some constituent which acts specially on the mesenteric neuro-muscular plexus in the colon. As treatment for the senile heart he suggests tincture of strophanthus in a little water to which a few grains of sodium bicarbonate have been added. This mixture may be taken three times daily about one-half hour after a meal. As regards diet he calls attention to the value of fruits and the modified requirements of the aged man for meats. Cleanliness is the most important manipulative procedure. Pressure on the perineum just behind the symphysis will relieve the abnormal pressure of an enlarged prostate upon the rectum.

3. On Suture of the Nerves, and Alternative Methods of Treatment by Transplantation of Tendon.—Robert Jones concludes his article on this subject in which he has considered some general principles which should guide the surgeon in the treatment of limbs disabled by injuries involving nerves. He points out the importance of giving the muscles ample time and opportunity to recover by keeping them in a relaxed position for a sufficiently long period and discusses tendon transplantation as an alternative method of treatment where nerve suture is not possible. He considers in detail the transplantation operations which his experience leads him to recommend in various injuries to nerves of the upper and lower extremities. He says the chief lesson to be learned from what he has written is that there are many ways in which the disabilities following nerve destruction can be met, and that hardly any case is bad enough to justify a counsel of despair. Our knowledge of what can be done in poliomyelitis will invite us to take a cheerful outlook in traumatic paralysis. Not only does the author point out the value of keeping a paralyzed muscle relaxed by opposing the force of gravitation, but he indicates the great and ever-increasing field of usefulness that is opened up by utilizing tendon, whether that of an active or a hopelessly paralyzed muscle for the restoration of movement or the correction of deformity.

4. The Importance of Method in the Isolation of Pathogenic Organisms of the Typhoid Group from Feces.—C. H. Browning and L. H. D. Thornton state that in the examination of feces for typhoid and paratyphoid bacilli, the value of a simple fluid medium containing brilliant green, in addition to direct plating, as a means of increasing the number of positive results has been confirmed by a number of workers. A single fixed concentration of brilliant green (0.5 c.c. 1 to 10,000 per 10 c.c. of peptone water) seems to leave little to be desired as a medium for the isolation of *B. paratyphosus* B; but this fixed medium does not yield such good results with *B. typhosus*, for which a series of doses of green are required in order to secure the optimum concentration, which depends on a number of variables. In the examination of feces for *B. typhosus* a series of varying amounts of brilliant green along with telluric acid may be essential in order to isolate this organism in cases in which both direct plating and brilliant green alone fail. The importance of detecting carriers for the prophylaxis of epidemic should, in the

opinion of the writers, justify the time spent in this extension of the "one tube" method.

5. Examination of Fifty Dysentery Convalescents for Carriers.—J. A. Arkwright, W. Yorke, O. H. Priestley, and W. Gilmore examined fifty men who had suffered from dysentery contracted in the service. These convalescents were not selected but were the first fifty examinations completed in the course of a search for carriers. They all, with one exception, gave a history of having passed blood and slime for periods varying from three days to nine weeks. The examinations were made from three to six months after the onset of illness. Of these 50 men 9 were still excreting *E. histolytica* and 2 were still excreting *B. dysenteriae* (Shiga). These eleven men were therefore potential sources for the outbreak of fresh epidemics.

6. An Easy and Rapid Method of Doing Widal's Reaction for Typhoid.—Alfred C. Coles finds the following a rapid and simple method of determining, or, at least suspecting, the presence or absence of typhoid in non-inoculated persons: 1. With a color grease glass writing pencil, or a piece of wax, draw a line across the middle of two slides at right angles to their long axes. 2. Spread a film of the blood to be examined on one-half of each slide, and, when dry, spread a film of one's own blood, or that of a person who has not had typhoid or who has not been protectively inoculated against it, as a control, on the other half of each slide. The film may be as thin as that ordinarily used for stained films, or a little thicker. Dry. 3. By means of a platinum loop or pipette place a small drop of an emulsion of killed typhoid bacilli on the center of each half of both slides, and with the platinum loop, or with a needle, rub the drop well over the film of blood, taking care not to pass from one-half of the film to the other without sterilizing the needle. 4. On one slide carefully place a cover glass on each half, taking care that the two cover glasses are well separated in the middle by the mark of the grease pencil. 5. Place the other slide on a piece of wet blotting paper, and cover with a Petri dish to prevent evaporation for a period of 15 to 20 minutes. At the end of that time dry carefully over the flame, and then stain. At the end of 15 minutes distinct clumps of agglutinated bacilli will be seen on the first slide provided the case be one of typhoid or the blood of one who has been prophylactically inoculated. The film, stained with Leishman or Glemsa's stain, will show on one-half patches of agglutinated bacilli, while on the control half the typhoid bacilli are more or less uniformly spread over the film.

The Alcoholic as Seen in Court.—Victor V. Anderson has made a study of 100 cases of chronic alcoholics, those who are repeatedly arrested for drunkenness and seem more or less unmodified by any form of treatment. He gives statistics with reference to the number of arrests, the economic efficiency, the mentality, and the diagnosis in this series and finds that not more than one-half were capable of supporting themselves out in society. Fifty-six per cent. had the mental level of children below the age of twelve years. They were all suffering from conditions in general regarded as medical problems. For purposes of treatment they, in general, fall into two classes, namely, the steady drinker and the periodic drinker. The mentality of the former is either defective to begin with, or is so deteriorated from the insidious effects of alcohol as to require that he be confined or have prolonged care and hospital treatment. The periodic drinker, though in many instances he may require short periods of detention, as well as hospital treatment, is in general to be handled on probation and incorporation into society's scheme of living by means of well-directed medical, psychological and social service methods of treatment, methods that take full account of his peculiar mental make-up, his character defects, and temperamental difficulties.—*Boston Medical and Surgical Journal*.

Insurance Medicine.

Death Rates and Expectation of Life.—There are soon to be issued by Director Samuel L. Rogers, of the Bureau of the Census, a set of tables, which were compiled in the Division of Vital Statistics under the supervision of Prof. James W. Glover, of the University of Michigan. These tables will show death rates and expectation of life at all ages for the population of the six New England States, New York, New Jersey, Indiana, Michigan, and the District of Columbia on the basis of the population in 1910 and the mortality for the three years 1909, 1910, and 1911.

According to these tables, the average expectation of life, at birth, for males is 49.9 years; for females, 53.2 years; for white males, 50.2 years; for white females, 53.6 years; for native white males, 50.6 years; for native white females, 54.2 years; for negro males, 34.1 years, and for negro females, 37.7 years. Females are thus longer-lived than males to the extent of more than three years, and in the case of the native whites and negroes, more than three and one-half years.

The expectation of life at the age of one is considerably greater than at birth, being 56.8 years for native white males and 59.5 for native white females, and reaches the maximum at the age of two, when it is 57.5 for the former class and 60.1 for the latter. At the age of 12 the average native white male's expectation of life is 50.2 years; at 25 it is 39.4 years; at 40, 28.3 years; at 50, 21.2 years; at 60, 14.6 years; at 70, 9.1 years, and at 80, 5.2 years. Similarly, at the age of 12 the average native white female's expectation of life is 52.6 years; at 25 it is 41.8 years; at 40, 30.3 years; at 50, 22.8 years; at 60, 15.8 years; at 70, 9.5 years; and at 80, 5.5 years. A part of the difference between expectation of life for men and women is due to the greater number of violent deaths among men. Nearly four-fifths of these violent deaths—suicides, homicides, and accidental deaths—are of males, and such deaths form about 7 or 8 per cent. of the total number occurring each year. This fact, however, does not account fully, or even in major part, for the greater longevity of women. An examination of the table discloses a lower death rate for females than for males during each of the first 12 months of life, and in the case of the native whites, during each year of life up to the age of 94. During the first month of life the death rate among native whites is nearly 28 per cent. higher for boys than girls, and during the first year it is more than 20 per cent. higher.

To say that a person's expectation of life is a certain number of years is not the same as saying that he has an even chance of living that number of years. This is because expectation of life represents the averaging remaining length of life, at any given age, in a stationary population, whereas an average person in a given group has an even chance of living to what is called the median age at death, that is, the age below which half of the members of that group will die. The median age at death for all native white males in the assumed stationary population would be 60; that is to say, of a given number of such males born alive, half would die before reaching 60 and the other half at 60 or beyond. A native white male child at birth, then, has one chance in two of reaching this age. At the end of the first year, however, he has a trifle better than an even

chance of reaching 64; and at 42 he has one chance in two of attaining three score and ten. Similarly, a native white child at birth has an even chance of living a few months past the age of 64; at the age of one she has one chance in two of living until she is nearly 68 years old; and at 22 her chance of reaching 70 is an even one. Thus a native white man at 42 and a native white woman at 22 have about the same chances of celebrating their seventieth birthday.

The relative healthfulness of city and country is strikingly shown by the tables, according to which the death rate among white males under one year of age in cities having 8000 inhabitants and over in 1909, and in cities of 10,000 and over in 1910 and 1911, is 13,380 per 100,000 born alive, whereas in smaller places the corresponding rate is only 10,326 per 100,000, or 23 per cent. less than the rate for cities. A similar difference prevails with respect to white females under one year of age, for whom the death rate in cities is 11,123 per 100,000 born alive, while in rural localities it is only 8497 per 100,000, or 24 per cent. less than the urban rate.

For white males the expectation of life, at birth, in rural localities is 7.7 years greater than in cities; at the age of 10, 5.4 years greater; and until the age of 39 is reached there is a margin of more than five years in favor of the country. Thereafter the difference becomes gradually less, but is always in favor of the country until the age of 88 is reached, at and after which the cities show a slightly greater longevity than the rural localities. For white females the difference between urban and rural longevity, while pronounced, is somewhat less than in the case of males. At birth the white female's expectation of life is 6 years greater in rural than in urban localities; at 1, 3.3 years greater, and until the age of 46 is attained the difference continues to be more than 3 years. Thereafter it declines until the age of 83 is reached, after which the cities have a slight advantage over the country.

Women as Examiners.—Dr. Harriet Doane of Fulton, N. Y., wrote to nine insurance companies to ascertain their attitude toward woman examiners. To each she sent the following questions: Do you insure women? Do you insure women at the same rates as men? When available, do you employ women examiners for women applicants? To the first two questions all replied in the affirmative; to the third, three companies reported that they did employ women examiners; one said it was perfectly willing to do so when request was made; another answered that it had, in isolated cases, employed women physicians as examiners; two said it was not their practice to employ women physicians as examiners. The replies of the remaining two companies are not given in Dr. Doane's letter.—*The Woman's Medical Journal*.

The Confidential Report.—Dr. J. M. Ballew says that we are all aware of the importance of the confidential report, yet it is often the case that this report is given more credence by the medical director than the physician's report. He knows of such injustice having been done recently, but the misrepresentation was learned of and further investigation made in time to prevent rejection of an excellent risk. Such reports placed a conscientious examiner at a disadvantage unless full inquiry was made and opportunity had to verify such reports.—*Texas State Journal of Medicine*.

Book Reviews.

THE AFTERMATH OF BATTLE WITH THE RED CROSS IN FRANCE. By EDWARD D. POLAND; with a preface by OWEN WISTER. New York: The Macmillan Company.

The Aftermath of Battle is a story, told in the form of a diary, by a young American who served as a jack of all trades in some of the war hospitals of France. Many awful and pathetic happenings are faithfully recorded and the book is interesting from the very fact that it is, like Pepys' diary, faithfully and painfully true. The little book is well worth reading on account of both its human and its medical interest.

ROADSIDE GLIMPSES OF THE GREAT WAR. By ARTHUR SWEETSER. Illustrated. New York: The Macmillan Company, 1916.

THIS is a tale of an American cyclist who visited the war zone and went through many weird and extraordinary experiences. He procured a German military pass to Paris, said to be the only one issued since 1870. Mr. Sweetser had some remarkable adventures, was a prisoner two or three times and escaped death more than once by the skin of his teeth. The book is well worth reading.

A LABORATORY COURSE IN SERUM STUDY. Bacteriology 208. Being a Series of Experiments and Diagnostic Tests in Immunology Carried out in an Optional Course Given to Medical and Graduate Students in the Department of Bacteriology, College of Physicians and Surgeons, Columbia University, New York, by the Writers, HANS ZINSSER, M.D., J. G. HOPKINS, M.D., REUBEN OTTENBERG, M.D. New York: The Macmillan Company, 1916.

THIS book provides the outline and directions for a very complete course comprising thirty-two exercises. The subjects are well chosen and logically arranged and the directions are clear and sufficiently detailed. It contains no theorizing and but little discussion and is in no way a manual of immunity and therefore must be accompanied by lectures and reading. It is natural that the authors should desire to see this course a required one, rather than an optional study, but the wisdom of such a change is debatable. While no doubt any medical man would be better off for knowing how to do Wassermann reactions and how to standardize diphtheria antitoxin, still such a course takes up a great deal of valuable time. The medical curriculum is already overburdened and the next step will probably be to split it up and lighten it rather than to add to it such highly specialized courses. As an optional course it is admirable and any one desiring to give such a course may profitably consult this outline.

PULMONARY TUBERCULOSIS. By MAURICE FISHBERG, M.D., Clinical Professor of Tuberculosis, University and Bellevue Hospital Medical College; Attending Physician, Montefiore Home and Hospital for Chronic Diseases, New York. Octavo, 639 pages, with 91 engravings and 18 plates. Cloth, \$5.00, net. Philadelphia and New York: Lea & Febiger, 1916.

IN this new book on Tuberculosis, the first two chapters are concerned with the bacteriology of the disease; their correction by Dr. Park, Director of the New York Health Department's Laboratories, is a guarantee that they are up to date. Dr. Frederick L. Hoffman and his associate have helped in the compilation of the statistical data, which is likewise proof of accuracy. The chapters on the epidemiology, predisposition, and pathology reiterate what is known to-day of these important phases of the tuberculosis problem. The conservative phthisiotherapist would, however, take exception to the statement that "Facts have been quoted to disprove the transmissibility of tuberculosis, but in the light of our present knowledge they must prove that reinfection is impossible." The reader need hardly be reminded that new lesions have frequently been found alongside of evidences of healed early invasions which, according to clinical history, antedated the new tuberculous infection by many years. The denial of a predisposition, that is to say, the possibility that the fetal system could be influenced by the toxins of a tuberculous mother, is an equally hazardous statement.

The chapters on the symptomatology are excellent, but strong objections should be taken against the statements that "Many tuberculous patients show a remarkable change in their mental traits and character, a dis-

turbance in their emotional life, a striking divergence from their previous customs, habits, affections, and tastes," and that "A psychic trait of the consumptive which has been noted by most writers is selfishness. He becomes egotistical and egocentric . . . he will eat costly food while his children starve." Had Dr. Fishberg said *some* tuberculous patients show remarkable change in their mental traits, character, etc., instead of *many*, the paragraph on psychic traits might have had some justification. We have but to think of the master minds in tuberculosis science, all seriously afflicted with the disease, such as Laennec, Grancher, and Darenberg of France, Brehmer and Dettweiler of Germany, and in our own country our beloved Trudeau, all of whom showed traits exactly contrary to those mentioned by Fishberg, namely, unselfishness, devotion to others, and lives consecrated to the highest ideals of science and humanity. It would be difficult to give the long list of American tuberculous physicians, still living and active, who represent a veritable galaxy of scientists and humanitarians of the highest order.

The chapter on diagnosis, which includes excellent skiagraphic reproductions, is admirable on the whole. It is unfortunate, however, that the author merely speaks of auscultation with the aid of the stethoscope. All teachers of physical diagnosis insist, and justly so, upon both immediate and mediate auscultation. At least the character of the respiratory movements should always be determined by putting the ear directly to the patient's chest. Our only criticism of the chapter on institutional treatment is that it is inaccurate so far as historical data are concerned. It was not, as Fishberg says, a German, Dr. Dettweiler, in 1859, but an Englishman, Dr. Bodington, who established the first sanatorium as far back as 1840. Dr. George Bodington, of Sutton Coldfield, Warwickshire, England, was not only, as Fishberg admits in another chapter, an early advocate of the open air treatment, but he really gave us the first conception of sanatorium methods by treating tuberculous patients hygienically and dietetically under his personal supervision in a separate house located near his home. The first German sanatorium was established in the Silesian village Goerbersdorf, in 1859, and not by Dettweiler, as Fishberg says, but by Dr. Hermann Brehmer. Dr. Peter Dettweiler came to the Goerbersdorf sanatorium in 1872, first as patient and later on he became Brehmer's assistant. The sanatorium at Falkenstein was established in 1878 and Dr. Dettweiler became its first medical director. Aside from the few points here criticized, which the author may think worth while to consider in a future edition, the work is not only a good textbook for the general practitioner, but a tuberculosis specialist can also learn much from it.

THE PRACTICAL MEDICINE SERIES, comprising ten volumes on the year's progress in medicine and surgery, under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Chicago: The Year Book Publishers.

VOLUME IX. SKIN AND VENEREAL DISEASES, edited by OLIVER S. ORMSBY, M.D., Professor and Head of the Department of Skin and Venereal Diseases, Rush Medical College, with the collaboration of JAMES HERBERT MITCHELL, M.D., Research Fellow in Pathology, Rush Medical College. Miscellaneous Topics edited by HAROLD N. MOYER, M.D. Price, \$1.35.

THE many interesting cases which the book reports render the volume profitable reading for the general practitioner as well as the specialist.

THE MEDICAL CLINICS OF CHICAGO. Volume I. Number IV. (January, 1916). Price, \$8.00 per year. Philadelphia and London: W. B. Saunders Company.

THIS number contains seventeen reports from eight clinics and a brief article on the Schick reaction by G. H. Weaver. There is a good discussion of primary carcinoma of the liver and two interesting cases of meningitis are reported. The adherence to the stenographic style of reporting these clinics continues to lead to a good deal of loose usage of language as evidenced on page 671 where the Doctor is made to say, "There is a great deal of *pathology* in the lung." Surely if the material is worth printing at all, especially since it is printed so expensively, the proof should be more carefully revised. There is possibly room for some such publication as this but when one compares it with the information obtainable from a first class medical journal it seems as though it were hardly worth while.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

*Sixty-Seventh Annual Session—Held in Detroit, Mich.,
June 13, 14, 15 and 16, 1916.*

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

Monday, June 11—First Day.

THE PRESIDENT, DR. ALBERT VANDER VEER OF ALBANY,
IN THE CHAIR.

President's Address.—Dr. ALBERT VANDER VEER delivered this address in which he first referred to the loss the Association had sustained in the death of Dr. Rodman. It was his earnest desire to perpetuate Dr. Rodman's memory by faithfully prosecuting his work. He also referred to further losses which the Association had experienced which were not easily repaired in the death of Dr. Frank J. Lutz of St. Louis, Dr. Wisner R. Townsend of New York, Dr. Henry L. Elsner of Syracuse, N. Y., Dr. Henry B. Favill of Chicago, and others, all of whom had left them a heritage of work well done and an incentive to continue with the same diligence which they had always shown. He urged upon the members their duty in respect to medical legislation, and especially the importance of preventing evil laws, and advancing good ones. They had had the experience in New York State of having legislators from time to time who would not pass a law unless it had the approval of the medical profession. They had recently secured an amendment to the medical practice law, giving the Board of Regents power to exercise its judgment in increasing the requirements of those applying for a license to practice medicine. In regard to the medical inspection of schools it was indeed gratifying to note material progress; more than one-half the States recognized the value of school inspection and were conducting campaigns of child welfare. This was a practical work of preparedness, for without healthy children there was little to be hoped for in the direction of military preparedness. The laws of workmen's compensation should have more attention from the medical profession, but of this they would hear later. Dr. Vander Veer said he wished to bring more prominently to their attention the Trudeau School of Tuberculosis at Saranac Lake, which had been opened on May 17, where a great deal of information on the subject of tuberculosis could be acquired under teachers who were numbered among the most eminent men in America. He had just learned that the entire fund of \$500,000 which had been asked as an endowment fund for the school had been obtained. He then spoke at some length on the subject of preparedness, recalling what unpreparedness had meant at the outbreak of the Civil War and also during the Spanish-American war. The American Medical Association was a strong organization in connection with the Red Cross work and thoroughly alive to the situation and to the requirements that would be made of the medical profession and was prepared to lend its support. During the fall of 1915 the Clinical Club of Albany discussed a plan of preparedness, and by December had it so perfected that it was presented to the Surgeon General, who gave them a great deal of encouragement. It had also been commented on editorially in the *Journal of Military Surgery* as the "Albany Idea." This was a very practical method of preparation, the first preliminary of which was a course of reading, lectures, and discussion on the organization and duties of medical officers. It took as a definite basis the conditions that might arise if both New York and Boston were held by the enemy and the American forces were retiring toward Albany together with 100,000 men, women, and children. At the same time a spy had contaminated their drinking water. They had also assumed that there would be 10,000 wounded to be cared for. The club took account of all the local resources for caring for, nursing, and feeding this large number of people. Every detail was gone into thoroughly. For instance, just the milk supply was provided for under fourteen different subheads. This plan had been well received, and they had been asked to cooperate with the American College of Surgeons, the Clinical Surgeons of North America, and the Physicians of the American Red Cross. Such a plan as had been worked out by the Clinical Club of Albany might be worked out to

advantage in other localities. Dr. Vander Veer described the hospital units which had been established in New York City. The organization of such units, at a cost of \$24,000 each, had been completed, and funds for a fourth had been given by two public-spirited citizens. Each of these units provided for a base hospital, complete in every respect; medical staff, nursing staff, and supplies.

Report of the Secretary.—Dr. ALEXANDER R. CRAIG of Chicago presented this report. He said that the Fellowship of the Association on May 1, 1915, was 42,366. During the past year 441 Fellows had died, 1,540 had resigned, 713 had been dropped as not eligible, 658 had been dropped for non-payment of dues, and 17 had been removed from the rolls on account of being reported "not found," making a total of 3,369 names to be deducted from the Fellowship roll. The Fellowship of the Association on May 1, 1916, was 43,181, a net increase for the year of 815. This gain in the number of Fellows was largely due to circularizing subscribers who were eligible, urging them to become members. It was suggested that the status of the Wyoming State Medical Society be referred to the Judicial Council with power, at the discretion of this Council, to revive the present organization or to arrange for a new organization of the profession in Wyoming to become the constituent association of the American Medical Association from that State.

Report of the Board of Trustees.—Dr. W. T. COUNCILMAN of Boston presented this report. He said that considering the work of the Association as a whole, what it had accomplished in the past and the promise of the future, one was filled with a sense of pride in being a member of the body. This work, while of benefit to the medical profession, extended much wider than this and benefited the nation. In considering the work of the Association, he asked if they might not say that it had accomplished a still higher task, that of uniting the medical profession. There had never been a time when it had been so free from faction. And the great idea on which this unity was based was that of service. No ignoble aim could have accomplished it, and the ideal of service was evident in all the activities of the medical profession as represented by this Association. The weekly average of the issue of the *Journal* during 1915 was 67,390, and the percentage of physicians in the United States who were receiving the *Journal* was 45.3. The Association had continued its endeavors to increase the membership of the organization and this work was undertaken only after the assistance of the constituent State Association had been secured. With the cooperation of the officers of the State organizations and the officers and members of the component societies, men in the employ of the Association had been sent into certain of the States to solicit subscriptions to the *Journal* and fellowship in the Association, as well as to present the advantages of membership in the organization of physicians of the localities visited. The Propaganda Department continued its work with regard to medical frauds. The layman's interest in the work was shown by the increasing number of inquiries concerning advertised substance which were received. People who advertise were recognizing the fact that for their own protection the advertisements could not be fraudulent. There was a growing interest in the subject among educational institutions. State and municipal boards of health, civic organizations, women's clubs, etc., continued to call on the department for information. The report of the Council on Pharmacy and Chemistry showed that it had continued its work and had published reports on practically all the widely advertised proprietary mixtures. It was confronted with many difficulties, not the least of which were the questions of radium and the mixed vaccines. Only time could establish the true place of these substances as remedial agents. The work of the Council had reached a stage when little more could be done by the efforts of the Association as a whole; the continuance of the work and the final accomplishment depended upon the individual members. There was much evidence that the individual members of the profession were prescribing and using the very substances which as a combined body they condemned, and many of the journals which they supported advertised and recommended these substances. No great progress would be made until the medical profession awakened to the fact that the remedy against fraudulent proprietary medicines lay in its own hands—until the profession resolved to believe rather the evidence which was presented by the scientific investigations of the substances than the

biased statements of the agents, whether presented by word of mouth or by advertisements. With regard to the memorial to Congress regarding proprietary medicines, there was a prospect that the request for a government investigation would be granted. Such an investigation would lead to a wider knowledge of the matter and possibly to some remedial legislation. But even this would not avail unless the individual members of the profession would act on the information obtained. Great assistance in procuring such a commission could be rendered if the members of the House would bring the matter to the attention of their Congressmen and urge the measure.

Report of the Judicial Council.—Dr. ALEXANDER LAMBERT of New York presented this report. He said that as the volume of business coming before the House of Delegates had grown, there had been a growing realization from year to year that the mass of business was having an undesirable effect in that it crowded, often into hurried discussion, many important matters. There had been a growing feeling among the delegates that this situation should be remedied and that it would be best remedied by pushing forward the meeting of the House of Delegates, bringing the first day on the Saturday before the general meeting of the Association. In considering the matter it seemed to the Judicial Council that it were wiser to push on to a later day the general meeting of the Association and the first meeting of the Scientific Assembly; that was, that the House of Delegates should continue to meet on Monday and Tuesday and the Scientific Assembly should begin on Wednesday, breaking up Friday evening instead of Thursday evening, as was now done. To bring this change about, the following amendment to the by-laws was necessary and was recommended by the Council: "The House of Delegates shall meet annually on the two days preceding the opening of, and at the same place, the Scientific Assembly of the Association." There has been a growing conviction among many delegates that a great deal of time was unconsciously and unavoidably wasted in the House of Delegates in the transaction of its business. The Judicial Council, therefore, recommended to the House of Delegates that it take up the question of the election of a speaker of the House. This required a change of the constitution, and section 1, article 9, of the constitution should read: "The general officers of the Association shall be a president, four vice-presidents, a secretary, a treasurer, and a chairman of the House of Delegates." The Judicial Council further recommended that the constitution be amended to read: "No trustee shall be eligible to any other elective office the term of which runs concurrently with the term for which said trustee has been elected."

Report of Committee on Social Insurance.—Dr. ALEXANDER LAMBERT presented this report to the Council on Health and Public Instruction. He said the importance of this work had recently grown more and more evident, and it seemed that in all probability this subject would be in the next few years one of the most important that would occupy the attention of the profession both from an economic and a purely medical and surgical point of view. This committee was appointed with the understanding that its purpose and duties were to be the careful compilation of information in reference to social or health insurance and the relations of the physician thereto. They were to do everything in their power to secure such constructions of the proposed laws as would work the most harmonious adjustment of the new sociological relations between physicians and laymen which would necessarily result therefrom, and they had been authorized to carry on this work wherever it seemed most desirable. The services of I. M. Rubinow, M.D., Ph.D., chief statistician of the Ocean Accident and Guarantee Corporation and president of the Actuarial Society, were secured as executive secretary, and a bureau had been opened at 131 East Twenty-third Street, New York City. The Committee on Social Insurance presented to the House of Delegates a statistical study of the medical profession of the United States in its various relations, both in the ratio of physicians to population, their geographic distribution, and various other statistical facts that were of importance and interest to the profession. In the near future it was the intention of the committee to undertake to educate the American medical profession in the general principles of social insurance, particularly health insurance, the economic and social significance of the movement to obtain such insurance throughout the United States, and the absolutely essential part which

the medical profession must play in a successful adaptation of this new legislation to American conditions. The bureau would consider it a part of its work to answer all questions which any physician might desire to write to it, asking for information facts, or figures bearing on social insurance in any of its phases, and to be in reality a bureau of information to the medical profession in regard to the details of organization and of medical aid in various forms of insurance, both in European countries and in the United States. The committee considered it among its duties to appear before legislative bodies in this country with a view to bringing about friendly understanding between all parties concerned and to protect the legitimate economic interests of the profession in the laws coming up for discussion concerning social insurance. The work of the committee should be directed in such channels as to avoid the conflict which had arisen in England at the beginning of a similar movement and which had resulted in a very large amount of bitterness between the profession and the public. It was the intention of the committee to undertake the following lines of work: (1) To collect a bibliography on social insurance with special reference to medical questions involved; (2) to undertake, by correspondence, to get in touch with the various sickness insurance organizations in Europe so as to obtain first-hand information as to their experience; (3) to undertake a statistical study of hospital and dispensary facilities in this country in view of the possibility of these institutions assuming a broader function under health insurance; (4) to study the conditions of lodge practice both from the point of view of the physician and the patient; (5) to gather all available information regarding the status, earnings, etc., of the medical profession in regard to which problem the wildest statements were current without any basis of fact underlying them. The report then gave a very thorough review of the entire situation with reference to compulsory and voluntary social insurance in the various countries of Europe. The status of insurance in the United States was presented and shown to be in general that which had prevailed in Europe before the passage of their comprehensive health insurance laws. The report of the Commission on Industrial Relations showed in general the mass of systematic and yet incoordinated attempts that had gradually been developing to bring about health insurance in the United States. In the final report of the Commission on Industrial Relations the following conclusions were found: Each of the thirty odd million wage-earners in the United States lost an average of nine days a year through sickness. At an average of \$2 per day, the wage lost from this source was \$500,000,000. At the average cost of medical attendance of \$6 per head per year there was added to this, at the very least, \$180,000,000. Accidents caused one-seventh as much destitution as sickness and one-fifteenth as much as did unemployment. Sickness among wage-earners was primarily the direct result of poverty, which manifested itself in insufficient diet, bad housing, inadequate clothing, and generally insufferable surroundings in the home. This emphasized the well-known vicious circle of sickness, unemployment, and poverty. The responsibility for the disease causing conditions rested on the employer, the public, and the employee. A system of sickness insurance was the most feasible single remedial measure. A system of federal insurance, as drawn up by the Commission on Industrial Relations, was outlined, and health insurance standards and a tentative draft of a health insurance act were presented. The report also considered the relation of the physician to health insurance laws, the remuneration of physicians, the specialist in health insurance practice, the place of the hospitals and dispensaries under health insurance. Finally, in commenting on this voluminous report, Dr. Lambert stated that no pretense had been made of arguing either for or against health insurance, or of bringing together the advantages and disadvantages to be gained by the community, or its desirability as a measure of health or social necessity. They had simply offered a compilation of what had been done abroad, and in the United States, and had presented facts that might be of interest to the medical profession in preparing a study of the situation in any given state where health insurance was likely to be brought up and placed on the statute books.

Report of Council on Health and Public Instruction.—Dr. HENRY M. BRACKEN of Minneapolis presented this report. He said that the death of the chairman, Dr. Henry B. Favill, not only deprived this council of its chairman and its chief inspiration, but the American

Medical Association of one of its strongest, most effective and valuable members, and the medical profession of the country of one of its finest representatives. He urged that a committee be appointed to draft suitable resolutions for adoption by the House of Delegates. The work of the council during the past year had differed from that of previous years in that many of the plans that had been under consideration and development in the last five years had this year produced definite results, while the formation of new plans and activities had been somewhat checked by the necessarily limited appropriation made for the council's work this year. The council was endeavoring to develop the program outlined in 1914 and reaffirmed in 1915. This program included: (1) A thorough investigation of present public health conditions in the United States with a view to securing more accurate information on all phases of the public health program than was then available. (2) Education of the public by every possible means in order that the people might understand the enormous advances in scientific medical knowledge during the last generation and the possibility of utilizing such knowledge in the prevention of disease, the reduction of the death rate and the prolongation of human life. (3) The crystallizing of such educated public sentiment in necessary public health laws, regulations and ordinances which would render possible a conservation of human life, commensurate with our advancing knowledge, and which would render such laws more effective through an educated and enlightened public opinion. A tentative plan had been formulated for a study of the public health activities of the Federal government which it was hoped would be developed during the next year. The survey of State public health activities had been summarized in a comprehensive report by Dr. Charles V. Chapin, commissioner of health of Providence, R. I., including a rating sheet of forty-eight State health organizations and exhaustive tabulations of their various activities, appropriations, expenditures, etc. This report was ordered published and distributed to members of State boards of health and officers of the association. This survey and the publication of this report it was hoped would mark the beginning of as distinct a movement in the public health field as the first report and classification of medical colleges by the Council on Medical Education inaugurated in the educational field. Prior to the publication of Dr. Chapin's report there was no way in which the public health work being done in different States could be compared and estimated. It was to-day impossible to determine, except in terms of individual opinion, what was the ideal or desirable form of state public health organization, what such an organization should include, how many men were required to conduct it, or what should be its cost. It was impossible to determine whether, for the amount that was being expended, the people of any State were getting value received for their money or how near they were coming to such a realization. The council had been desirous of inaugurating a survey of municipal public health work similar to that made by Dr. Chapin in State public health work, but so far had been unable to devise any feasible plan for this purpose. Practically all our leading cities and many of the smaller ones had during the past twenty-five years established some kind of municipal health organization; the form which this organization had taken has been largely accidental or determined by the views of those responsible for its organization or administration. During the past year a number of requests had been received for information and advice as to what kind of a health department should be organized in a town of a given size, how many men would be required, etc. During the coming year the council hoped to make a study of this problem and to present a report showing what was actually being done in municipal health work. In the fourth field of investigation, that of voluntary public health organization, the report of the Central Committee on Public Health Organization was published in pamphlet form. This pamphlet contained the tabulated reports of forty-six voluntary public health organizations, was immediately accepted as authoritative, and had been in great demand. The most marked development of the past year in the educational work of the council has been the number and variety of the pamphlets on different subjects printed and distributed by the council. These numbered altogether 1,133,500. The pamphlet entitled "Minimum Health Requirements for Rural Schools" had the largest edition, 750,000. The entire edition had been printed, bound, addressed and mailed to every rural school teacher and rural school board member through-

out the country, as well as to every state and county superintendent of education and every state normal school. This work was a striking example of the value of intelligent cooperation between various organizations interested in the same line of work. The pamphlet was prepared by the joint committee of the American Medical Association and the National Educational Association; the funds were supplied by the Elizabeth Macormick Memorial Fund, and the addressing and distributing was done through the Federal Bureau of Education. A second instance of cooperation was found in the printing and distribution of 281,000 copies of "Save the Babies" pamphlet. In connection with child welfare work in twenty-nine cities cooperation was established between the drygoods stores and the local medical organizations; the medical societies furnished speakers and the dry goods stores furnished a place of meeting and advertised the meetings to the public.

The Medical Legal Bureau had been at work on three digests mentioned in the report of 1915. These were the digest of the Supreme Court decisions on the medico-legal relation of physicians, the digest of Supreme Court decisions with reference to malpractice, and the digest of Supreme Court decisions on the powers and duties of State boards of health. The first of these digests was about one-half completed, 874 cases out of a total of 1,697 having been abstracted and cited. Each of the other digests would also include a large number of cases. During the past year 89 inquiries had been received on medico-legal subjects.

Legislation.—Quite a number of laws had been introduced into Congress during the past winter touching on public health matters and of interest to physicians. To date none of these had passed excepting a bill providing for the national control of leprosy.

A *Standard Study Program for Women's Clubs* was presented by Dr. S. J. Crumline at the annual meeting of the Conference of State and Provincial Boards of Health of Kansas. This program proved so popular that in a short time many requests from all parts of the State were received for it. The demand for this program had continued and 3,000 copies were recently distributed at the New York biennial of the General Federation.

Special Activities.—Following the custom of the past five years, the secretary of the Council, with the cooperation of a local committee, arranged to furnish speakers on public health topics for every church in Detroit desiring such an address. It was recognized that one of the serious defects in the annual program of the Association was that there was no marked event which brought the annual session to a close. This fact and the growing interest of the public in health topics had led to the arrangement of a program for Friday, June 16, as Public Health Day. A public health parade under the auspices of the State Board of Health would be held just before the meeting. An invitation had been issued to the people of Detroit to attend this meeting as the guests of the Association. It was hoped that the success of this first meeting would justify the Council in making it a permanent feature of the annual sessions of the Association.

Reports of Sub-Committees of Council on Health and Public Instruction.—The *Committee on Women's and Children's Welfare* reported that they had adopted the policy of developing one line of action. At the present time the baby health movement was the one of most immediate interest and seemed to offer the greatest possibilities among the various phases of public health work, and attention had therefore been centered on this work. Their first year's work had resulted in the giving of the official score card to the public. In November, 1915, Miss Julia Lathrop issued the bulletin "Baby Week Campaign," which described the three acceptable types of conferences, namely: baby health conference without score card, baby health conference with score card, and baby health improvement contests. The baby health conference without score card was the ideal conference and the one the Federal bureau carried out. From the beginning State and county fair associations had been among their strongest cooperative influences. During the second year of their work an anthropometric table had been compiled based on data secured from score cards. During the third year 10,000 score cards had been secured and a new anthropometric table had been published by Mr. F. S. Crum. It was also their intention to tabulate all remedial defects from these cards. Seven States were planning to issue bulletins in which would be tabulated all facts of statistical value connected with this investigation of remediable

defects. It was urged that other States furnish the names of physicians who would be responsible for collecting and sending them duplicates of score cards secured from baby contests in their vicinity.

The *Committee on Cancer* submitted a report stating that as a committee they had done very little during the past year, but that each individual had done his share in disseminating knowledge as to what could be done when cancer was recognized early. After mature deliberation it was deemed best to allow the American Society for the Control of Cancer to take the more active part, as it in a large measure came into being through the efforts of the laity and they had contributed mainly to its support. It had been the desire of this committee to avoid duplication of work, and this accounted for their apparent inactivity. This committee, however, was doing excellent work in an advisory capacity and stood ready at any time to supplement the endeavors of the American Society for the Control of Cancer when it might be necessary.

The *Committee on Conservation of Vision* reported that this committee and their State managers had had much to do with the enactment of eye legislation in several States. It had also much to do with the prosecution of a number of individuals, physicians, midwives, and others who had disobeyed the State laws concerning the welfare of eyesight. They were endeavoring to teach the cheapness of health. It was cheaper to keep people well than to allow them to be sick. It cost \$100,000,000 a year to educate 3,000,000 "repeating" American school children; that is, the unprogressive school children. This was mostly unnecessary, since only about 3 per cent. of these children were mentally defective. Preventive eye work was very cheap, but its results were big. The wearing of goggles in shops and the use of protectives for dangerous machinery would cost but little, and would almost entirely prevent injury to eyes in shops. Control over the manufacture and sale of wood alcohol, in its various seductive forms, would save many eyes and many lives, and would cost practically nothing. This committee was endeavoring to inspire the different States with the necessity for State activity along the lines of visual conservation. The most efficient manner of doing this was by means of lectures in the different towns and cities. These were arranged by the several State managers, whose duty it was to bring competent lecturers and receptive audiences together. During the year 384 lectures had been given to a total audience of 84,900. The committee had undertaken the compilation of all the eye laws in the United States. In concluding they emphasized their need of funds for stereopticon pictures and more pamphlets, and pointed out that their work should include conservation of hearing as well as conservation of vision.

Report of the Council on Medical Education.—Dr. ARTHUR DEAN BEVAN of Chicago presented this report. He stated that each year since 1905 the report to this body had shown a continued progress in medical education. The large oversupply of medical colleges had given away to a more normal supply of greatly improved institutions. In 1905 conditions were ripe for the campaign which the Council on Medical Education had since been conducting. As a result of this eleven years' work the oversupply of medical schools had been reduced about 40 per cent.; the number of higher standard colleges had been increased by over 80 per cent. In 1904 the number of medical colleges was 162; in 1915, 95. In 1904 only 2.5 per cent. had the higher requirements; in 1915, 87.4 had higher requirements. In 1904 the number of medical students was 28,142; in 1915, 14,891. In 1904 only 6.3 per cent. of these were in high standard colleges; in 1915, 80 per cent. were in high standard colleges. In 1904 the medical graduates numbered 5,761; in 1915, 3,536. In 1904 only 369 were from high standard colleges; in 1915, 2,652 were from high standard colleges. Notable improvement had been brought about through the Medical Students' Register, which was established in accordance with the action of the House of Delegates in 1910. Through the facts known through this register and the information obtained by inspections, the conditions in all medical schools regarding the administration of entrance requirements, methods of teaching, facilities, etc., were now well known. Although the number of medical colleges had been greatly reduced, there was still no dearth in the supply of colleges. Statistics showed that fifty or sixty medical colleges could have cared for all the students enrolled in the ninety-five which held sessions last year, without the expenditure of another dollar for

teachers or equipment. The number of medical colleges would doubtless be further reduced, but statistics showed that the lowest ebb in the attendance of medical students had perhaps already been reached. During the last twelve years the Council had endeavored to secure the general adoption of the standard referred to as the "ideal" standard. This had been secured in so far as the year of physics, chemistry, and biology, and the four-year medical course were concerned. It had been adopted by 85 of the 95 medical schools in the country. As to the hospital interne year, a large majority of the medical school graduates voluntarily secured such work before beginning independent practice. As a result of the influence of colleges and universities, the ideal standard urged by the Council had been somewhat modified. Educators generally advocated two years of pre-medical college preparation instead of one, and the medical colleges gradually accepted the standard, so that at present 54 of the 95 medical colleges now required for admission two years of college work. It was evident that the twenty schools which would survive out of the remaining forty would likewise adopt this requirement. It was evident that the American standard of medical education that was to-day most widely accepted and which in the near future would be legally required in every State was as follows: A four years' high school course; two years of collegiate work, including courses in physics, chemistry, biology, and a modern language; a four-year medical course, and a year as interne in a hospital. It could be confidently predicted that such a standard would be the legal requirement in this country in 1920. When these requirements were adopted by all States, American medical education would be on as high a basis as that of any other country in the world. From the standpoint of providing proper training for the interne many hospitals were weak, but one could not expect the ideal condition at once. The inspecting and classifying of hospitals of the country was an important matter, and the Council had this work in hand. It had not had sufficient funds to prosecute the work more rapidly. In the meantime the Carnegie Foundation had given the American College of Surgeons \$10,000 a year for three years to be devoted to hospital inspection. The developing of satisfactory medical education in this country had been hindered in some of our important centers by the fact that instead of one strong medical school there were several which had different standards and conflicting interests. In this connection Dr. Bevan said he had just heard of the affiliation of three medical colleges in Philadelphia, the Medico-Chirurgical, Jefferson Medical College, and the Medical College of the University of Pennsylvania. In most of the centers of medical education in Europe there was but one medical school, which received the undivided support of the people, the profession, and as a rule, of the government. Such a system possessed many advantages. It would insure uniform requirements and advantages which could be obtained without interference with established university organizations, and much confusion and expense might be saved by a common administration. They could with proper conditions exchange credits, municipal hospitals could be better utilized, endowments could be more easily secured, and post-graduate work could be better organized. It should be no more difficult to get several medical schools to cooperate in this way than to get a number of railroads to cooperate in a great union depot plan or to get a number of steel plants to form a steel trust. It would require breadth of view, hard work, and organizing ability, but the end sought was worth all the hard work necessary to accomplish it, and some such plan was necessary to bring about the best result in American medical education.

Remarkable progress had been made in State board requirements since 1908, prior to which no State was requiring more than a four-year high school education as the minimum standard of preliminary education. There were now thirty-three States which had adopted the higher standard, fifteen of which required as a minimum two years of premedical college work. As a result of special investigation, it was found that only ten States had provided any control over the chartering of educational institutions, and in two of these the restrictions did not apply to irregular professional schools or corresponding colleges. In thirty-eight States it therefore appeared that any coterie of men could open an institution with the avowed purpose of granting degrees, no question being asked as to whether the institution was properly equipped or had sufficiently qual-

ified teachers to furnish the education usually demanded before such degrees were granted. The largest number of these institutions was found at present in Illinois, and California and Missouri were close seconds. In the interests of the public there should be provided in every State some competent board or authority to have in charge not only the chartering of all educational institutions, but also the right to revoke the charter and close the doors of every institution which was not being conducted in an honorable manner and for a proper purpose. New York appeared at present to have the most complete control of educational institutions. The professional relations between Canada and the United States had always been most cordial. Consequently, it was with surprise and regret that it was learned that discrimination against even the best medical colleges in the United States had been established in two provinces of Canada, Quebec and Ontario. Graduates from the highest grade medical schools in this country in order to secure licenses in the two provinces named were required to have taken an additional year's work in one of the medical schools of those provinces. No objection could be raised if only graduates of some of the lower grade medical schools in the United States were thus debarred, but it was clear that no exceptions were made, even for graduates of Johns Hopkins University, Leland Stanford, Jr., N. Y. University, Cornell, Columbia, Western Reserve, and others which required two, three, or four years of college work for admission. A survey of the situation showed that the conditions in education in the two countries were quite parallel, except that the entrance standards were now higher here than in Canada. There were now in the United States thirty or forty medical schools which would compare favorably with the medical schools of any other country. Considering these things it was to be hoped that our good medical friends of Quebec and Ontario would have their license laws so amended as to correct this unfair discrimination against the high grade medical colleges of the United States. This called attention to the fact that the time had arrived when a more careful discrimination should be used by the licensing boards of this country in the acceptance of credentials from foreign medical schools and in licensing the graduates from such institutions. There was also the question of providing reciprocal relations with other countries in the recognition of the graduates of high grade medical schools. As was well known, there had for the past fourteen years been talk of a national board of medical examiners. It was seen that no national body with legal powers could be established without first securing an amendment to the national constitution. It was, therefore, quite evident that the board to have this matter in charge would need to be a voluntary organization and its certificate to be of value would need to be based on unquestionable qualifications. This matter was brought into prominence a year ago by Dr. Rodman with the result that the Council on Medical Education held a business meeting in Washington Nov. 27, 1915, the object of which was to examine into the organization, the personnel, and the methods of the National Board of Medical Examiners. The executive committee of the national board as then organized, on invitation, was present. The Council was favorably impressed with the personnel of the membership of this board. However, they felt that further investigation was necessary, and a symposium on the subject was arranged at the twelfth annual conference of the Council in Chicago, in February, 1915. A detailed report of these conferences was presented and, although no examinations had yet been held, the Council felt confident that the certificates granted by this board would be worthy of acceptance by every State licensing board. The Council believed, further, that through the examinations given by this board the number of physicians in the Medical Reserve Corps who could be called on to aid the government in any national emergency would be greatly increased. It was believed also that through the examinations conducted by this board an avenue would be provided by which reciprocal relations in medical licensure might be established with other countries, offers of which had already been made by some of the countries of South America. The Council heartily recommended to the House the endorsement of this national board as it now stood.

Report of Council on Scientific Assembly.—Dr. J. SHELTON HORSLEY of Richmond, Va., presented this report. He stated that this was the first report of this Council. They had carefully considered the report of the Committee on Sections and Section Work and

agreed with the report that there was no doubt that too many meetings were held at the same time to the disadvantage of the fellows who attended the annual sessions. They further agreed that the duplication of subjects presented at the different sections at the same time could and should be avoided. Owing to its small membership and the fact that no program had been provided for this year, they recommended that the Section on Hospitals be discontinued. As to reducing the number of papers they believed this could be done without in any way curtailing the value of the sections. They suggested that the term "unit" be applied to one meeting of a section held either in the forenoon or afternoon and recommended that the average number of papers assigned to a unit be six, and that the maximum number of units assigned to any section be five.

Report of Committee on Red Cross Medical Work.—Dr. GEORGE M. KOBER of Washington, D. C. presented this report. He stated that the object of this committee was to stimulate in every county medical society the creation of a committee on Red Cross medical work so as to provide a body of representative physicians of approved qualifications to direct or participate in medical work carried on by the Red Cross in different localities in time of war or emergencies, and to advise with the representatives of that society in handling medical and sanitary problems incident to such an occurrence. It was desired to have in every county a committee of five physicians, two of whom should be president and secretary of the county medical society *ex-officio*. In case of disaster these county committees would be called upon to nominate qualified medical men in their respective counties for Red Cross service and also to serve in an advisory medical capacity to the Red Cross in time of disaster and in other lines of Red Cross activity. During the present European war many of these committees had been called upon to report on the qualifications of physicians and surgeons offering to serve the Red Cross in Europe. The endorsements had been invaluable in the selection of men, as it was highly important that reputable men only be chosen in order to protect the American Red Cross and the reputation of the medical profession whom they represented abroad. The reference committee on reports of officers at the session of the House of Delegates, held June 21-24, 1915, deemed it advisable that the activities of these committees be directed through the State committee rather than with the county committees. As an appendix to this report the regulations of the National Committee on Red Cross Medical Service were given in detail as well as the duties of the committee. In addition the duties of State and county committees were described, and the rules and conditions of enrolment.

All of these reports were referred to the respective reference committees for consideration.

OPENING MEETING.

Tuesday, June 13, 1916.

THE PRESIDENT, DR. ALBERT VANDER VEER OF ALBANY,
IN THE CHAIR.

AFTER a call to order by the president the meeting was opened by a brief invocation by Bishop Charles D. Williams of Detroit.

Address of Welcome to Michigan.—The Hon. WOODBRIDGE N. FERRIS, Governor of Michigan, delivered this address. He said, in part, that he would not consume much time in telling the audience about the great State of Michigan or the beautiful city of Detroit, but would simply bid them welcome this morning. Long years ago he had had a dream that he wanted to be a physician, but his father had discouraged him. Four years later, however, he entered the medical department of the University of Michigan and pursued a course of lectures. At this time it did not require much preparation to enter the medical school; there were only two classes, freshmen and seniors. Some of the freshmen went out and taught school or followed other remunerative pursuits, and then came back and got a senior note book and soon went out as full-fledged physicians and surgeons. They were required to know but little, and little was expected of them. He had concluded before taking that course that it would be of value to him, and he had since found that it was invaluable, and if he had his way he would have educational authorities require such a foundation as a part of any educational scheme, because without a knowledge of how to preserve health education availed little. When he com-

pared the requirements of the University of Michigan in those days and thought of the changes that had been wrought in and of the great university as it was to-day, he marveled; this was but indicative of the progress of the medical profession, the greatest profession in the world. He said that he supposed that some of the great physicians and surgeons who were with them to-day had pursued the same limited medical course, but they had gone on learning. He then proceeded to relate some of the achievements of medicine during the last seventy-five years. At that time some of the greatest gifts which medicine had given to the world were still unknown. When one recalled the work of Darwin, Huxley, Spencer, Haeckel, Gray, Dana, Yoemans, and others who had created a new era in scientific research, it would be recognized that it was modern science that had given to medicine the high place it now occupied. A few things that they all knew were worth while recalling. A new Prometheus had appeared in the amphitheater of a Boston hospital when anesthesia was given to the world. Prior to that time the world was a literal hell, in the description of which even a Jonathan Edwards could not have done justice. More widespread was the relief of disease through the growth of sanitary science and the knowledge of asepsis. They had been enabled to abolish smallpox and typhus fever, and typhoid fever was now driven to the last ditch. Cholera could now be controlled, and coming closer to our own time was the work done on the Isthmus of Panama. For four centuries the Isthmus of Panama had been the white man's grave. It was said that before Dr. Gorgas went there the mortality was 170 per 1,000 population. The health reports from the Canal Zone were the most interesting sanitary reading of the present day; they showed on an average a mortality rate of 8.91 per 1,000 population, a lower percentage than any city in the United States. After referring to the sanitary control of yellow fever as one of the finest achievements of modern science, Governor Ferris said he would like to tell what they were doing in Michigan along the lines of preventive medicine, and he hoped that before they left Detroit they would get some definite idea of their work. It was important to care for and to cure the sick, but it was quite as important to awaken people to what God had offered in the way of healthy living. As Governor of Michigan he had placed special emphasis on matters relating to health and sanitation. He stated that he belonged to that class of men who believed in preparedness, but he believed that there were other factors of preparedness just as important as carrying a gun. He did not disapprove of carrying the gun, but he did not want it used unless it was necessary; but what he did want was something under the gun; he wanted a high standard of citizenship. He did not believe in any of the "pathies," and scientific medicine had little to fear from them. Science would prevail in education, in medicine, in religion, and even, perhaps after a long time, in politics. Much had been done to eradicate the white plague, and he hoped that physicians might soon be able to eradicate the black plague, not by the attempt to cure it but by education so that there would be no occasion for treatment. In closing he said that aside from the more practical work of practicing medicine, the men of the medical profession should get in touch with the people, many of whom still lived in ignorance and superstition, and should endeavor to shed the light of their knowledge not only throughout their own country but throughout the world.

Address of Welcome to Detroit.—HON. ALLEN FRAZIER representing the Hon. Oscar B. Marx, Mayor of Detroit, made this address. He presented the regrets of the Mayor that he had been unable to be present and extend the welcome his heart had desired. It was his function to tell them how to enjoy life while in Detroit, and this he would do. Detroit was a place not without traditions. A study of its history showed that it had grown up under three flags, the Fleur de Lis of France, the flag of King George III, and, greatest and best, the Stars and Stripes. It had grown to be one of the greatest cities of the United States, famed not only for its automobiles but for its stoves, pharmaceutical preparations, and many other manufactures. Its great industries were controlled by men of high integrity who were more than gasoline kings. The character of these men was shown by the way in which they treated those who labored for them. They were treated not as machines or serfs but as civilized men, and were paid a living and honest wage so that they could live like American citizens. They had sanitary homes and their children went to school. They had medical and surgical

attention not only for the purpose of curing any trouble, but were also told how to avoid the source of that trouble. The children were educated to love and honor the law, the government, and the flag under which they lived. This was the kind of preparedness their government was taking up; they were making their men happy, self-respecting, and moral people. The city had also provided liberally for the recreation and amusement of her people. He hoped they would go about and see all these things for themselves.

Address of Welcome by the Medical Profession.—Dr. A. W. HORNBOGEN, president of the Michigan State Medical Society, made this brief address. He recalled the occasions on which the American Medical Association had honored Detroit by making it a meeting place. The association had first met here in 1856, then in 1874, again in 1892 under the presidency of Dr. Henry Marcy of Boston. He recalled the service that Michigan had rendered the profession through Dr. Beverly D. Harrison, who had done more for the medical profession than any one present. He had been instrumental in 1901 in urging a national medical licensing board. He was responsible for the present reciprocity in the United States. There were now about three-fourths of the States in the Union which participated in this reciprocity. In closing Dr. Hornbogen extended the welcome of the medical profession of the State to the members of the American Medical Association.

Inauguration of the President.—Dr. ALBERT VANDER VEER said he felt that he had successfully fulfilled his mission and took pleasure in introducing the Surgeon-General of the Public Health Service of the United States, who would now be inaugurated president of the American Medical Association, Dr. Rupert Blue of Washington.

President's Address.—Dr. RUPERT BLUE then delivered the presidential address (see page 1071).

SECTION ON MEDICINE.

Tuesday, June 13—First Day.

DR. ROGER S. MORRIS OF CINCINNATI IN THE CHAIR.

Blood Transfusions, with Special Reference to Blood Grouping.—Dr. WAITER V. BREM of Los Angeles, Cal., presented this study which was based on two hundred transfusions of defibrinated, citrated and whole blood. The diagnosis of the cases, the reactions and the results were discussed. A rapid method of blood grouping was described, and this was illustrated by lantern slides.

Dr. RICHARD LEWISOHN of New York said he wished to make a few remarks regarding the citrated reactions and the dose. Fourteen months ago he suggested the use of the citrated blood for transfusion, and the delicacy of this method was based on the small dose required which overcame the dangers that had been pointed out. At that time he said that sodium citrate was only an additional toxin, but the transfusion of but small quantities, such as one-fifth of 1 per cent. was not so dangerous. He had used this in about 75 cases, and he had never seen any severe reactions follow. It was certainly, at least in his hands, a very simple method and one that used to be left entirely in the hands of the surgeon, but which now could be placed with entire safety in the hands of the general practitioner. What he should be taught was just where to insert the needle. With regard to reactions, he believed that although they had seen some reactions, they had been less than when other methods had been employed. Out of these 75 cases, in 15 there was a rise in the temperature to 101° or 103° F., but this soon fell to the normal. He believed that they knew about what was going on in the blood from a biological standpoint. This method, simple as it seemed and sounded, needed a great deal of care, especially in regard to estimating the clinical results. He emphasized the fact that after the use of the method he advocated he had never noted any bad reactions.

Dr. GEORGE R. MINOT of Boston said that at the Massachusetts Hospital the results obtained accorded with those of the reader of the paper—the citrated suspension of the cells without washing was an advantage.

Dr. F. G. NOVY of Ann Arbor, Mich., said he wished to emphasize the fact that serum was always a poison. This agent had been used extensively for transfusion purposes, and the fact that it was a poison should always be kept in mind. The use of whole blood was even more dangerous.

Dr. A. JACOBI of New York asked Dr. Novy if the serum when injected into the spinal canal was as dangerous as when given in the usual way.

Dr. NOVY replied that he could not answer Dr. Jacobi's question, because he had had no experience in that line. His experience had been purely with the giving of the serum intravenously.

Preliminary Observations on the Apparently Immunizing Behavior of the Mixed Serums of Immune and Hypersensitive Guinea-Pigs.—DRS. HENRY SEWALL, WILLIAM C. MITCHELL and CUTHBERT POWELL of Denver presented this communication, which was reported by Dr. Sewall. Having found that guinea-pigs might be made either hypersensitive or insensitive to the action of horse serum following a few instillations of it into the nose, according to the amount of serum absorbed, it was sought to determine whether or not the blood of the two groups of pigs contained specific bodies capable of reproducing the respective production and anaphylactic effects. For this purpose the serum from treated animals was injected into normal guinea-pigs, which later received series of intravenous injections of horse serum. In general the serum of the "protected" pig enabled the recipient animal to withstand two intravenous injections of horse serum. The mixed serums from protected and hypersensitive pigs occasionally enabled the recipient animals to withstand an indefinite number of horse serum injections.

Dr. F. G. NOVY of Ann Arbor, Mich., said that he was exceedingly glad to hear Dr. Sewall present his conclusions regarding the treatment of anaphylactic shock; he had described a protective action. It seemed to him that immunity began with the presence of shock itself. He thought that they had made a mistake in the past in looking upon the chemical changes in the body as the most important things concerned. He was glad they were so satisfied with the results of the intensive work that had been carried on. This had been carried on for some time, and the results showed that in all probabilities this was a purely physical one from start to finish and that there was no chemistry connected with it.

Dr. SAMUEL J. MELTZER of New York said that possibly Dr. Sewall was the first one to test the effect of serum, not by its action on anaphylactic shock, but by its action when it did not kill and later when it protected. Subimmunity was protective. But all this must be confirmed before it can be accepted as fact. Anaphylactic shock had not been well studied. What the gentlemen had presented in their paper must be confirmed by other workers before their results could be accepted. The speaker was quite convinced that Novy's method was a very good one. However, after all had been stated, it should be remembered that personal experience at the bedside gave them facts which were as good as any statement that might come from the laboratory. The physicians who worked at the bedside should not become frightened by any laboratory statement that the patient was not doing well. Observations made at the bedside were as good, in his opinion, as any made in the laboratory.

Dr. SEWALL in closing said that taking the serum by mouth in his experience had resulted in negative results. The foreign proteins there were slowly absorbed.

Comparative Results in Antirabic Treatment with the Pasteur Method and with Desiccated Virus.—DR. DOWNEY L. HARRIS of St. Louis said that observations had been made during the past five years on the use of desiccated rabies virus in antirabic treatment. Animal experiments had been made to test the relative value of this material with the classic method of Pasteur. Desiccated virus conferred immunity in animals earlier than Pasteur's virus and the immunity was greater. The average length of treatment was from seven to nine days, compared to eighteen to twenty days with the Pasteur treatment. Its use in the treatment of persons bitten proved it to be as efficient as the old method. The cost of administering desiccated virus was much less than the cost of the Pasteur virus. The modification of the Pasteur method which he wished to describe was founded on Shackwell's investigations on the effect of desiccation *in vacuo* at a low temperature. This method had for its object the preservation of "fixed virus" in order that it might be prepared in quantity and be always available for treatment at any time. If the value of this material in the treatment of rabies could be judged by a record of 1159 cases treated with but two failures, the results obtained would compare favorably with those obtained by other modifications of the original method. Assuming from these data that the

material had an efficient immunizing power, it possessed another advantage; the time required for the complete administration of the treatment was less than one-half the time required by the Pasteur method. The 936 cases treated by Couret and by him averaged less than ten days per patient, a saving of over 9,000 days of treatment had they followed the Pasteur scheme.

Dr. MELTZER said that from the point of view of the virus he would perhaps look upon the facts presented as sort of confirming what Dr. Novy had stated, that the virus was an enemy in the tissues.

Dr. ROBERT A. PEERS of Colfax, Cal., said he was particularly interested in the paper because of the experience they had had in California during the past few years, an epidemic of rabies spreading from the southern to the northern part of the State. Many of these cases had been treated at the State Laboratory at Berkeley. If a patient had been bitten by a dog during the epidemic it was not advisable to kill the animal at once because the animal might be killed before there were any evidences or signs of rabies in the brain tissue.

SECTION ON SURGERY, GENERAL AND ABDOMINAL.

Tuesday, June 13—First Day.

DR. E. WYLLYS ANDREWS OF CHICAGO IN THE CHAIR.

Chairman's Address.—Dr. E. WYLLYS ANDREWS of Chicago read this paper. He spoke of the relation of the practical surgeon to the pure scientist. If there were an antagonism between the two he would despair of surgery. It was well to say that surgery rested upon the fundamental sciences, but was it doing its share of creative work? The great surgeons were the men who did their own investigating. When surgery let slip the surgical pathology of the biliary tract or of the gastrointestinal tract, it would give up its birthright. One obstacle to surgical progress was some antagonism between the routine surgeon and the pure scientist, but this did not exist between the real leaders. There was, also, some separation in some medical schools between the clinical and preclinical studies, some of which was due to accidental and in other instances to deliberate causes. He believed that the bigoted practitioner was more hopeless than the narrow-minded academician. The Pasteurs, Welches, Chittendens, and Rosenows were not of the latter class but medicine itself. Sometimes, it appeared, the pure specialist was the most fallible in other fields than his own. There was hope in the young idealists who were joining the ranks of the pure scientists and who were in the hospitals. It was a profit for the older men to teach them. They carried the poor efforts of their teachers into discovery. Men of broad scientific training should guide our scientific courses and make the laboratory and the clinic one, not adjuncts of each other.

Practical Results of Newer Methods in Surgery of the Stomach and Intestines.—DR. GEORGE W. CRILE of Cleveland read this paper. He based this paper upon the operations performed by himself and his associates. These included 468, of which 128 were by Dr. Sauer and himself. In these they had only three deaths, when the rule was three times that many. He attributed these results to anoci association. Ulcer, cancer and other lesions of the stomach interfered with the digestion of the food, as did the operation itself. Acidosis and death might follow. It was necessary to introduce water, sodium bicarbonate, and glucose, and to eliminate the acids as far as possible. The fate of the ulcer-bearing area was important. The development of ulcer into cancer was shown by the Mayo clinic. Rodman favored excision of the ulcerous site. The after care of stomach ulcer was as important as that of exophthalmic goiter. Avoidance of traumatization, a large incision, and in bad cases urea hydrochloride gave good results. Slides and moving pictures. It made little difference, in his opinion, whether the pylorus was excluded or not. If it was, the Brewer or Bartlett methods might be used. He used gut with the Bartlett needles for the buried sutures and silk, interrupted, for the outer ones. It was a good plan, too, to place three or four anchor sutures at each end of the suture line in gastro-enterostomy. It was important, as Cannon and Blake had shown, to locate the stoma near the pylorus, but its direction, whether oblique or horizontal, made no difference. The direction of the efferent jejunal loop was regarded of importance. He used novocaine 1/400. He emphasized the value of the "cobblers' stitch," which was an effective safeguard against bleeding.

Dr. A. J. OCHSNER of Chicago said that Crile had used good surgical judgment in recognizing the small margin of safety in his stomach cases. That margin was reduced if traumatization and nervous shocks were avoided.

Dr. R. C. COFFEY of Portland said the results of Crile's work were encouraging. He, like Crile, was getting better results with the two-stage operation for his excision cases. This mortality was reduced four times. He believed these ulcers due to silk or linen sutures, although he had two ulcers develop subsequently in one person and two recurrences in another. It was difficult not to enter the stomach or intestine at some point in the anastomosis, and it was this suture that caused the trouble.

Dr. MARCY of Boston said that he had showed thirty years ago the necessity of chromicizing catgut sutures for intestinal work. He used the cobbler's stitch, but with one needle.

Dr. J. B. DEEVER of Philadelphia said that he knew nothing about anoci-association. Pyloric occlusion was of no value. He favored excision of the duodenal as well as of the gastric ulcers. He had performed forty without a single fatality. Excision was easy in the first part of the duodenal and was facilitated in the second part by dissection of the pancreatic head or by passing a probe down the common duct into the papilla. He emphasized the importance of gastric lavage.

Dr. ALFRED A. STRAUSS of Chicago said that the temporary closure of the pylorus was not sufficient for chronic ulcer. He had had three cases in which the bismuth passed through the occluded area in twenty-one days. Rest of ulcer site was desirable. If occlusion was necessary, should use Von Eiselsberg's method or the fascial-band device of his own.

Dr. CRILE concluded the discussion. He said he had seen three lesions diagnosed cancerous, clinically; present at the first operation, but absent two weeks later at the second operation. From this it appeared a prolonged technique was unnecessary. Patterson's alkalinity theory might explain the good results in these cases.

Suggestions as to the Method of Teaching Surgery.—Dr. JOHN A. WYETH of New York said that it was recognized that effective teaching rested upon the aptness of the student. Dexterity with both hands added to technical perfection. Surgeons, properly qualified, were sent to the laboratory to acquaint themselves with abnormal and morbid anatomy and experimental surgery. Internes should follow their cases to autopsy if the opportunity offered itself. He had instituted group study at the Polyclinic Hospital. This gave the student practical instruction as an assistant at the operation. Moving pictures. He reported eighteen amputations at the hip joint. He urged the application of tourniquets above and below the tumor and the placing of rubber tubing above the uppermost tourniquet. He illustrated amputation, injection of hot water for thyroidectomy, removal of external carotid artery, and Bodine's herniotomy under local anesthesia.

Dr. A. D. BEVAN of Chicago said the moving pictures could not replace the operations for teaching purposes. He said one should differentiate the teaching of men for general practice and for special practice of surgery. For general practice one year's internship was necessary. For a skilled specialist one should spend three years in the hospital and medical school. It was desirable to improvise a method of paying such house surgeons.

Dr. STODDARD of Philadelphia said Dr. Wyeth's paper was far-reaching in its importance. Teaching, in a sense, was intuitive. One should know when to operate and when not.

Dr. WYETH ended the discussion by recommending the group method of teaching surgery.

Nitrous-Oxide-Oxygen Anesthesia in Major Surgery.—Dr. A. BENNETT COOKE of Los Angeles said that he had performed 300 operations under gas-oxygen in the past three years. Local anesthesia was an important adjunct. He had had no fatality chargeable to the anesthetic. The difficulties were: (1) Obtaining a competent anesthetist; (2) cumbersome apparatus; (3) the high cost of gas, and (4) the necessity for using pure gas. There were no limitations excepting for operations on the nose, mouth and air passages. The advantages were the safety and comfort for the patient. Nausea, vomiting, and postoperative pneumonia were rare. Patient was returned to his room conscious and quiet.

Dr. W. I. TERRY of San Francisco said he had used

gas for the past four years. He was convinced that it was best for the patient when supplemented with local anesthesia. The absence of postoperative heart, lung, and kidney conditions was a factor of safety. The lack of trained anesthetists and the high cost of gas kept gas from general use. Relaxation was secured by local anesthesia or by adding ether to the gas-oxygen.

Dr. CHARLES K. TEETER of Cleveland said gas plants were installed at Cleveland in St. Luke's and the Lakeside hospitals about ten years ago. It was sufficient for all minor surgery. The gas should be 75 to 80 per cent. pure. It was necessary to give morphine and atropine before operation. Even though some ether were given the patient, some would be saved and that would be beneficial to the patient.

Tuberculosis of the Cervical Lymphatics.—Dr. CHARLES N. DOWD of New York said tuberculosis of the neck occurred most often in childhood. He had studied 687 cases of neck tuberculosis covering a period of twenty years. The first group included those in whom the glands appeared in the upper parts of the neck and followed infections through the pharynx. There were 452 of these, 354 of whom he had traced. The results were good. The second group followed involvement of the greater part of the neck glands. These occurred in older people. He had 185 of them, of whom 68 per cent. were cured and 23 per cent. recurred. There was a mortality of 2.4 per cent. The third group were cases of general tuberculosis. There were forty-four of these, and most of them recurred. He emphasized the importance of safeguarding the eleventh nerve.

Dr. JOHN F. GOLDEN of Chicago said neck tuberculosis occurred in childhood and in adult age. In childhood the tendency was toward cure. There was another type incidental to tuberculosis elsewhere. Tuberculin was serviceable in separating these types and in curing the patients. He administered 1/20 drop tuberculin and took the temperature twenty-four hours later to determine the presence of another focus of tuberculosis.

Dr. ROBERT T. MORRIS of New York said the majority of cases of tuberculosis of the neck did not require operation at all. He recommended tuberculin, hyperemia, x-rays, and alternate heat and cold.

Dr. W. O. LADD of Boston said he had followed Dowd's methods for the past four to five years. He had cured 93 out of 130 cases. In 70 to 80 per cent. the portal of entry was the tonsil. He believed it as illogical to remove glands without tonsils as tonsils without glands. If cases were treated palliatively they became more involved and more difficult to treat operatively. His statistics seemed to show 50 per cent. of bovine origin.

Dr. WILLY MEYER of New York said the section of the sternocleidomastoid facilitated neck dissection in the males especially. In girls, Dr. Dowd's incision was admirable; it left little scar. He had placed an elastic band about the neck for eleven hours at a time, and aspirated and injected iodoform and glycerin after softening had occurred.

Dr. DOWD said many of the large glands were hyperplastic and should not be removed. He never saw any cures from tuberculin. Bovine tuberculosis occurred in forty-six cases.

Incorrect Technique as a Cause of Failure in the Application of Bismuth Paste in Chronic Suppurative Sinuses and Empyema.—Dr. EMIL G. BECK of Chicago said it was necessary to know the formation of sinuses. He regarded them as shriveled abscesses. Of 136 cases of hip-joint disease, six had rectal fistulæ; 25 per cent. rectal fistulæ come from disease higher up. Errors included insufficient incorporation of bismuth with vaseline, unsuitable instruments, too frequent injection, and insufficient patience. Bacteriological examinations should be made before injection. Sequestra, if present, should be removed. Radiograms should be taken. The speaker had not seen one case of bismuth poisoning in 1,800 cases.

Dr. A. J. OCHSNER of Chicago said one case operated upon seven times, and reoperated upon by him, was successfully treated by Dr. Beck. Bismuth presents a smooth surface for the discharge and is antiseptic. Failures followed from other pastes and too rapid injection. Immobilization and general hygiene were important in addition to the paste.

Dr. BECK added that he used bismuth subnitrate 30 per cent. and vaseline 70 per cent. Said he never operated upon glands of the neck, but had cured fifteen cases by bismuth injection.

SECTION ON OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY

Tuesday, June 13—First Day.

DR. EDWARD REYNOLDS OF BOSTON, CHAIRMAN.

The Uterine Secretions, Spermatozoa and Ovaries in Fertility and Sterility; from Microscopic Studies.—Dr. EDWARD REYNOLDS of Boston delivered the chairman's address, taking this as his subject. He stated that sterility must be considered biologically as a failure in mating, the fault being sometimes due to the male side, sometimes to the female. In a little over 50 per cent. of cases it was due to the male. The fertility of the male was to be determined by a study of the spermatozoa, and the ordinary microscopic examination was of little value. Experimental studies on guinea-pigs divided the semen into two classes, according to the number and motility of the spermatozoa. Unless this was first class in both respects, it was found that the animal was sterile. It was calculated that in ejaculation there were as many as 200 million spermatozoa, but an examination of post coital secretions of a woman showed that but twenty or thirty reached the cervix and from one to three reached the fundus, of all this number. But one might reach the ovum, so that if the original number were diminished by 10 per cent. the result would be sterility. In Dr. Reynolds' own experiments, forty-five specimens, which were washed in (1) undiluted semen, (2) vaginal secretion, (3) cervical secretion, (4) artificial media, were watched by his assistants for forty hours. They were able to determine three types of normal motion: (1) progressive vibratile motion enduring many hours; (2) an undulatory tactile motion; (3) a distinctly pushing motion into some cleft. These three motions were successive in a cycle and were evidently adapted to the function of the sperm cell in reaching the ovum. It was evident that pregnancy was the result of effective ova as well as of effective spermatozoa and ovarian sterility had been considered mysterious. This point of view, however, would cease when there was a definite anatomical conception of the conditions accompanying ovulation. This was evident in gross and microscopically. The normal ovary was of uniform outline with one mature follicle projecting. In the sterile woman the ovaries were hard dense organs with a number of imperfect corpora. Dr. Reynolds here showed slides illustrating three forms of follicles and two forms of corpora. He showed normal ovulating ovaries and those which had undergone a degeneration from pressure and which would be sterile, the former having one mature follicle and the latter numerous imperfect follicles, which pressed upon one another. Experiments showed that if this pressure were relieved by puncture, normal pregnancy could result. Differential diagnosis could be reached only by tactile sense and by careful comparison of this with the clinical history. The flora of the vaginal tract was also dealt with in this paper, the conclusion being that in virgins and fertile women the coccal forms were most frequent and in sterile women, pregnant women, and puerperal women there were bacillus forms. That is, bacillus forms were present in non-ovulating women. Also in hyperacidity of the tract or where a microscopical mucous mesh existed, spermatozoa were destroyed. Thus an accurate clinical and laboratory knowledge was necessary for diagnosis in these cases. Sterility could be treated only in the light of an accurate knowledge of the failures in physiology which caused it.

Dr. EMIL NOVAK of Baltimore said that the degeneration of epithelium was not so common as the changes occurring in the majority of the Graafian follicles. As many as 70,000 follicles were found in the ovary of an infant girl. A great many of these must undergo degeneration. He believed that many degenerating cells gave rise to the cysts characteristic of fibrocystic ovaries, but he did not believe that these follicles ever formed a corpus luteum. Probably they did form atretic follicles, somewhat resembling theca cells.

Dr. E. G. ZINKE of Cincinnati said that the points which the chairman had presented were of great scientific and theoretical interest. No one who had not seen it could realize the manner in which some unfortunate women, who did not become pregnant, were treated by their ignorant husbands. The explanation which the chairman had made relieved in a large measure the blame placed upon these women. One point, however, should be added. Pregnancy depended (as Lawson

Tait had expressed it) upon three wheels traveling around one pivot—a healthy woman, healthy ovum, healthy spermatozoa. If these three things happened at the same time the woman became pregnant. The machinery, however, might suffer serious disorders which prevented pregnancy. He believed, however, in the majority of instances, women were unjustly blamed. The blame should be put on the other side of the house.

The Corpus Luteum; Its Life Cycle and Its Role in Menstrual Disorders.—Dr. EMIL NOVAK of Baltimore presented this subject. Dr. Novak quoted Fraenkel's work in 1903 on the relation of the corpus luteum to menstruation and to early pregnancy, and that of Meyer in 1911, who established the facts that the corpus luteum underwent cyclic histological changes corresponding to the menstrual cycle. His own work was upon the relationship between character and degree of lutein structure to the disorders of menstruation, such as metrorrhagia and menorrhagia. One hundred and thirty-seven cases had been clinically studied at Johns Hopkins Hospital. Cases in which both ovaries were removed were studied, for the better standardization of corpus luteum study. Numerous sections were made and a study of the Graafian follicles and of atretic follicles was done. One point usually overlooked was that in early stages the corpus luteum was very insignificant. It should be studied from the standpoint of origin in the lutein cells, whether granulosa or theca. In all cases a very accurate menstrual history was obtained. Dr. Novak showed slides illustrating corpus luteum formation early and late; the mature Graafian follicle; the endometrium in the early corpus luteum stage; the appearance of blood (sixteenth day of menstrual cycle); the corpus luteum approaching vascularization; the corpus luteum matured, the blood indicating organization; also showing distinctly glandular theca cells. The latter's function, Dr. Novak said, was a problem of biological chemistry. It might be concerned with the fixation of the ovum in pregnancy, the glandular structure indicating some important function, as yet not known. In clinical application, cases of amenorrhea showed characteristically corpora lutea. It was absent in young girls and in the fetus, also in the menopause. With amenorrhea of lactation it was present, the functioning breast probably presenting an inhibiting secretion. In metrorrhagia and menorrhagia there were negative findings and no histological changes could be found connected with menstrual disturbances.

Dr. C. CULBERTSON of Chicago said that this was a very important paper and should not be passed over without recognition because there had long been a question as to where lutein cells originated. He was glad to hear Dr. Novak say that the origin was probably in the granulosa. He had also come to that conclusion, and in his opinion the function of the theca was to provide membrane for the granulosa. That meant that the ovarian hormones used the granulosa cells. In all probability the cells acquired blood supply after the ovum was cast off. There was dilatation of the capillaries of the theca interna which accounted for the formation of a distinct internal theca, that is to say, corpus luteum depended upon folliculation and ovulation and throwing off of the ovum. The blood clot remaining was secondary to the vascularization of the granulosa cells. A clinical application could be made to the metrorrhagia of puberty, in which there were two factors—the presence of the new element of an active ovary and the presence of the mucous membrane of the uterus. That meant over activation of the uterine mucosa which might be nothing more than vascularization.

Dr. NOVAK, in summing up, said that the theca interna instead of advancing from lutein cells simply regressed. The granulosa cells were formed before the lutein cells, and the latter were formed from them. Meyer and others who worked on the subject of making corpus luteum found that the important point was that the internal secretion went back into the blood. The vascularization was a very important point as the lutein was carried back into the blood vessels.

The Role of the Anteposed Uterus in the Causation of Backache and Pelvic Symptoms.—Dr. HENRY T. HUTCHINS of Boston read this paper. He said that the upright position in woman had been the cause of many symptoms, as in this position the uterus was poorly supported. The position of the fundus was of little importance in the causation of pelvic symptoms. It might be backward or forward, but the amount of

descent of the cervix was the determining factor. The chief support of the uterus were the cervix, the broad ligaments, and the pelvic floor. In seeing patients who complained of backache, the important point was to test the drag on the broad ligaments and utero-sacral ligaments. If pain could be produced it was an important diagnostic point. A treatment by tampon for forty-eight hours was given, to push the uterus up, if the backache was relieved, suspension would give permanent relief; if not relieved, another cause must be sought. A pull on the infundibulopelvic ligaments was the cause of congestion of the ovarian veins. These were poorly equipped for extensive circulation. There was frequently need for suspension of a uterus which was anteposed. This would give relief whether the fundus was retroposed or anteposed. Differentiation of cases needing suspension should be exact and proof should be forthcoming from the patient as from the surgeon. In cervical descent the patient often slept on the abdomen to obtain relief and comfort. Retroposition of the fundus to the third degree caused little drag, but unless the cervix was held up there would be pelvic drag.

Dr. C. W. BARRETT of Chicago said this paper introduced a subject which bore upon the general support of the uterus and the entire relationship of intra-abdominal pressure and the ligaments and pelvic floor. But it bore more particularly upon the subject of the anteposed uterus that still had descended. It had been long recognized that the retrodisplaced uterus had a more or less marked degree of descent, but the subject of the anteposed uterus having marked degrees of descent was not so well recognized. Dr. Hutchins had pointed out the difficulties of the upright position. One would hear little of malposition of the uterus if it had retained the horizontal position with an outlet at a higher point, but the changes in position had brought about changes in conditions of support. One of the changes had been the introduction of a firm pelvic floor instead of the pale muscles of animals with the horizontal position. The uterus had changed from a line with the vagina to right angles with the vagina. Dr. Barrett said he would lay more stress upon retrodisplacement than did Dr. Hutchins, because, though there might be retrodisplacement without backache, the uterus in line with the vagina was an undesirable thing, no matter how desirable a horizontal uterus was to an animal. In the human, social habits and the milliners had adapted themselves to this upright position and woman could not go back to the horizontal. In correcting malposition, one should get as near as possible to nature's plan of support of the organ. One must have a good pelvic floor. Besides acquired weakness, by childbirth, there was often atavistic tendency to weakness, and a solid pelvic floor was the first requirement. He would therefore be more inclined to correct retrodisplacement than Dr. Hutchins. He no longer considered anteverted uteri as pathological.

Dr. A. GOLDSPOHN of Chicago said that one saw anteposed uteri and anteverted uteri. In the anteposed the long axis was in the normal position but the organ was too near the symphysis. The uterus that was tipped forward too much was another thing. When a mistake was made in correction of the retroverted uterus, an anteversion was caused by shortening the uterine ligaments instead of the round ligaments. The main point seemed to be that descensus uteri and not retroversion caused symptoms. With this he agreed only partially. The symptoms produced by any kind of uterine displacement *per se* depended upon the inflammatory complication. Long years of observations on living and dead women had revealed retroversion as a pathological entity. Lesions were caused by the torsion of the broad ligaments. The ligaments became cord-like, and though the arterial blood could pass the venous blood was obstructed. Descensus and version were two factors; the one the doctor would relieve, and he should also relieve the other. As to suspension, Dr. Goldspohn heartily agreed with Dr. Hutchins' statements; but he would suspend the uterus higher in the pelvis. He felt that anteversion was a normal position of the uterus in the pelvis, and in the absence of inflammatory conditions caused no symptoms.

Dr. MANTON of Detroit said that he agreed heartily with what the doctor said in his paper. He had for many years been carrying on a similar method of treatment. It only took a very minor degree of abdominal displacement to produce severe symptoms in anteverted or anteposed uteri and consequent fundus congestion. He did not quite agree with the doctor that all of these

cases needed operative treatment. If one could relieve a fraction of a degree of descensus one could obtain the necessary result. He had found in many cases a use for the old-fashioned Smith-Hodge pessary, properly adjusted; this would do as well as suspension or shortening the round ligaments.

Dr. MONTGOMERY of Philadelphia said that he thought that too much attention was frequently paid to displacements and not to the complications associated with it. In a great majority of cases with anteposed or anteverted uteri there were no symptoms unless there was some inflammatory condition. This might be, of course, the result of protracted congestion from the displacement, the veins being thin walled and more susceptible. A good many of these cases of both retrodisplacement and anteplacements could be relieved without resort to operation. The patient should assume the genupectoral position and practise deep breathing, which would allow the blood to be aspirated out of the pelvis during the deep inspiration. Practised for fifteen minutes, this would be beneficial to the condition. The patient could be relieved by palliative measures and graded exercise and wearing of the right sort of clothing.

Dr. CARSTENS of Detroit said that it seemed to him that this was a very complicated subject. Reading of the different operations that had been devised for overcoming this condition showed that there were many difficulties and complications. One man advised one operation, another man strongly advocated another. He agreed with Dr. Montgomery that often uterine displacements caused no trouble, but adhesions to the tube or the rectum, or some kind of infection, would cause trouble. Removal of the adhesions would relieve the patient without further operation. One operation found very successful was to take out a diseased ovary and lift the womb up to the stump and suture it to the stump. This had been very successful, because a woman could again become pregnant. For a woman after the child-bearing period a vaginal hysterectomy was the best operation. There was no positive statement, however, to be made as to the best operation. Judgment should be according to the pathology.

Dr. HUTCHINS said in closing that the discussion had brought out many interesting points. Drs. Barrett and Goldspohn had called attention to the fact that he had paid little attention to retroplaced fundi. This was the point of the paper. He would always correct retroposition where causing symptoms. That was the classical malposition. His paper dealt with anteposed uteri simulating symptoms of retroposition. Dr. Manton called attention to another fault. Dr. Hutchins said he would never advise operation until every other means had been tried, but there were patients who would not do exercises and who did not want to be bothered with a pessary, and in some cases a pessary did not give relief; in these cases he would advise operation for anteposed uteri. He could not agree that in all of these cases symptoms were caused by adhesions or disease. These cases formed a class by themselves. He felt that there was a group of cases of anteposed uteri that would cause symptoms without pelvic disease or adhesions.

The Value of the Wassermann Test in Pregnancy.—Drs. F. H. FALLS and J. J. MOORE of Chicago presented this paper, which was read by Dr. Falls. He said that this subject was important from many standpoints, the sociological, in that many more women than men contracted syphilis innocently and that it had been found that 33 per cent. of pregnant and 30 per cent. of non-pregnant women were syphilitic. The lesions in women were slight, evanescent, and hard to diagnose, but a careful and thorough examination was necessary on account of liability to miscarriage, puerperal sepsis, and the birth of diseased children. Of children born dead, 35 per cent. were proven syphilitic. In those syphilitic children born alive, early and intensive treatment gave them the best chance. A high percentage (50 per cent.) of those mentally deficient had positive Wassermann test. In criminals there was a high percentage of positive Wassermann tests, but it was hard to say which came first, the degeneration or the disease. For the proper protection of society generally care in clothing, towels, drinking cups, etc., should be exercised, and for the protection of physicians rubber gloves should be worn, as chancre of the forefinger was not uncommon. A positive Wassermann in a patient warned medical attendants to be careful. As to the percentages of positive Wassermann tests in primary syphilis, 80 per cent. were positive after three weeks; in secondary syphilis 90 per cent. were positive; in tertiary 95 per cent. were

positive. A positive Wassermann test indicated early treatment, and the latter should be continued till the Wassermann test was negative. The Wassermann test was not purely an antibody-antigen reaction, but recent work with pure spirochete antigens showed that spirochetes contained lipoids and that in cases where fat-splitting ferments were increased, as in pregnancy, syphilis, or pneumonia, or where lipoids were increased, interference might be expected. The value of the Abderhalden test seemed to be mainly negative; that is, it would show when women were not pregnant. Percentage of syphilis in dispensary patients was higher in single than in married women; that is, 13 per cent. to 10 per cent. In negroes syphilis was three times as common as in white women.

Dr. DAVIS of Philadelphia said that this interesting paper conveyed a most important warning. He felt that the Abderhalden test was conclusive only in pregnancy; during the menstrual cycle and in non-pregnant women it was absolutely unreliable. While there was much of possible value in the Abderhalden and Wassermann tests, they must not rely exclusively upon these. The Wassermann test was of value in the detection of latent syphilis, but there should always be a groundwork of clinical observation, which should never be neglected for laboratory findings.

Dr. LOSEE of New York said that in regard to syphilis of pregnant women they had observed 2,000 cases at the Lying-In Hospital in New York, and had found 3 per cent. positive Wassermans. There was a difficulty in treating these, because the patients would not come back. A very large sociological organization was necessary to deal with them properly. In the hospital 50 per cent. of cases of macerated fetuses were syphilitic. Syphilographers would probably put it higher than that. Syphilis had been credited with the death of eighteen fetuses at delivery, but fourteen cases showed complications, so that he thought that more deaths had been attributed to syphilis than were actually due to it.

Dr. FALLS said that he agreed with Dr. Davis about the value of the results of the Abderhalden and Wassermann tests, and that they must be careful about interpreting any biological test without accompanying clinical evidence. But, with the Wassermann reaction in the hands of expert laboratory workers, they had a test which could be relied upon in a large majority of cases. The employment of this test would give the mothers a better chance and the babies a better chance. As to the Abderhalden test, two years ago he had pointed out its fallacies in non-pregnant women. It simply showed that a woman was not pregnant. If it was positive she might or might not be. The Wassermann test also depended upon lipolytic ferments, and in syphilis the ferment content of the blood was altered. It might be supposed that pregnancy would throw out the Wassermann test, but apparently from their study it did not. In regard to Dr. Losee's statement about the death of the fetus, sometimes with a negative Wassermann test, Slemons of Yale found spirochetes in the cord and placenta of a syphilitic mother. There should therefore be a careful search for evidence of syphilis. This was of as great importance to the physician as to the mother and baby.

Adenomyoma of the Rectovaginal Septum.—Dr. T. S. CULLEN of Baltimore read this paper and showed lantern slides illustrating the rectal mucosa in these cases. He stated that Jessup had reported two cases four years ago. Then Lockyer in England had reported two cases. Stevens had reported six. The growths were usually back of the cervix, attached to the cervix and rectum, sometimes in the vaginal vault and sometimes in the broad ligament. The rectal mucosa was usually intact. Painful defecation associated with profuse menstrual flow was the usual symptom. In the early cases the nodules might be shelled out, and where back of the cervix they could be removed without hysterectomy. In some advanced cases it was impossible to remove the growth without taking out the anterior rectal wall. There was no possible excuse for making a mistaken diagnosis in these cases because the rectal mucosa was intact, the growth coming from the outer surface. The cells were typical uterine mucosa with non-striped muscle and fibrous tissue. There were often accompanying small fibroids in the uterus. Sometimes there was involvement of the whole pelvic floor. In this case the cecum had to be cut across and the lower end closed, making a permanent colostomy. When the patient had regained some measure of health, the growth could be taken out of the pelvis.

Dr. CULBERTSON of Chicago said that this was relatively new pathology. It would strike one as being extremely rare and almost a freak at first. However, many cases had appeared in the literature in a short period of time: two of Jessup and six of Stevens, then the cases of Green and Myers. The German idea seemed to be that this was an inflammatory process, especially those cases associated with dense adhesions and retroflexion of the uterus. One worker called it fibroadenomatous serositis, and another paravaginal adenomyositis. These growths, however, seemed to be circumscribed and free from dense adhesions. As so many cases had been noticed in a short time it was likely that in past years many cases had been overlooked. In many cases of hysterectomy where the broad ligament has had to go and the ureters have had to be dissected out and the rectal wall has been approached very closely, this condition has probably been present and has not been recognized. In the Webster clinic this condition had not yet been recognized, but recently a case was seen where Dr. Culbertson suggested this type as a factor. The symptoms were extreme pain, but there was no hemorrhage from the rectum. The general opinion was that there was carcinoma, and the patient refused a second operation, having already had one. He had hoped that Dr. Cullen would bring out the origin of these cases, whether due to inflammatory conditions or not, whether to salpingitis or to embryonic rests.

Dr. T. S. CULLEN said that he had overlooked one case entirely himself. This was the last and most interesting specimen. Inflammation absolutely played no part. In the early cases there was intact peritoneum. There was no polymorphonuclearcytosis. The whole thing was a typical uterine glandular structure.

Obstetrics and Gynecology under Ideal Conditions in a General Hospital.—Dr. F. C. HOLDEN of Brooklyn read this paper, illustrating by charts a general plan of the New York Municipal Hospital. The chief points of interest were the organization of three departments: medical, surgical, and obstetrical and gynecological. A paid resident was over the internes, and he was responsible to the attending, and could take responsibility under him. There was a paid resident pathologist and Roentgenologist. The department of gynecology and obstetrics had two wards with twenty-five beds each, two labor rooms, delivery room, and sterilizing room, examining rooms, quiet rooms, and a large roof garden on the same floor. The roof garden had thirty beds. The dispensary was in close cooperation with the hospital, so that men could follow the treatment of patients sent into the hospital, and also follow the results of hospital treatment afterward in the dispensary.

Dr. J. O. POLAK of Brooklyn said he was interested in this presentation of Dr. Holden, and he was glad that they had been at last able to convince the commissioners that a separate service for gynecology and obstetrics was necessary. There was a similar organization in Brooklyn in the Long Island College Hospital. The appointment of a resident over the interne staff was a feature highly to be commended. The average three-months' interne caused a great deal of harm, and it was impossible to teach them in a short time. With the resident system one could keep a man two to five years, and the night work was taken off the shoulders of the attending. These men would raise the standard of gynecology and obstetrics when they went on to other institutions. The development following this system was shown by the fact that they used to handle 300 cases, and now with this system it had grown to 1500.

Dr. BACON of Chicago said that patients were now flocking to the hospitals for obstetrical care; one-fourth of the cases were often obstetrical. He felt in the plan given by Dr. Holden there should be more arrangement for teaching of the students and more laboratory facilities; there was no provision for research rooms. He would also like to know the cost of the building and equipment.

Dr. NEWMAN of Chicago said he took exception to the teaching of students in gynecology and obstetrics. They wanted more trained men.

Dr. HOLDEN said that they had six senior students as clinical clerks—two medical, two surgical, two obstetrical. They kept patients often a long time because they were poorly nourished and anemic. The students had plenty of time to observe the cases. Internes were trained to take histories and make prognosis and diagnosis. There were five rooms entirely devoted to laboratory and experimental work. The cost of the building was \$900,000, \$4,500 per bed. The cost of feeding

was 16 cents per capita per day and, so far, the patients appeared happy and contented with this rate.

SECTION ON DISEASES OF CHILDREN.

Tuesday, June 13—First Day.

Dr. T. C. McCLEAVE OF OAKLAND, CAL., IN THE CHAIR.

Chairman's Address.—Dental Care in Childhood; The Most Neglected Feature in Pediatric Medicine.—Dr. T. C. McCLEAVE of Oakland, Cal., delivered this address. He said that modern medicine was concerned with the prevention of disease, and nowhere was there a wider field for its application than during childhood. It was during this time that there was the greatest incidence of infections, which determined the disabilities and deformities of later life. If disease was to be prevented in later life, methods of control must be applied during childhood. The importance of caring for the teeth of children was not as widely recognized as it should be. In some of the larger cities there were dental clinics, but in most localities no special provision was made for the dental care of children. Unfortunately, many dentists did not realize the importance of proper care of the teeth in childhood. Most dentists did not care to undertake this work, and argued that it was not worth while caring for the deciduous teeth, and when reminded that the premature loss of the first teeth was likely to result in deformity in the permanent teeth they would say that no one could tell whether the permanent teeth would have been deformed or not. So it seemed that ignorance was the largest obstacle in the way of securing proper dental care for children. The writer then referred to the various deformities due to faulty development which resulted in malocclusion, and this, in turn, had its effect on nutrition. Dental deformities frequently meant much more than merely deformities of the teeth. The bones of the face and jaw were deformed, and this affected the shape of the face and the features. Beauty was more than skin deep, it was "bone deep." Malocclusion not only prevented proper mastication, but was a factor in the production of adenoids, nasal hypertrophy, and tonsillar enlargements. Of the nutritional disturbances, the interference with starch digestion was the first step. The digestion of starches could not be normal if the mastication was defective. Infections of the teeth caused dental caries and pyorrhea. Several theories had been advanced to account for dental caries. The chemicobacterial theory was the one now generally accepted. That was that caries was the result of a fermentative process. In this connection the writer stated that the soft, sweet, sticky foods, mostly the starchy foods of which children were so fond, might be considered as a cause of caries, since it favored the retention of particles of carbohydrate food in the crevices between the teeth. In speaking of pyorrhea the writer said it was always due to an extension of other infections, and it might be responsible for infections such as adenitis, tuberculosis and the numerous focal infections familiar to all. As to the means for the relief of the present situation, first, the medical profession must be made to realize the significance of dental hygiene. Their interest must be stimulated so that they would awaken an interest in this subject in their several communities. Then the dentist must learn that he was not merely an artisan and a mechanic, but that he was working in a definite field of medicine and that the child must be regarded as important. Parents must be made to realize the importance of proper development and care of the teeth in childhood, and that such care was worth paying for if they were able to pay for it. Provision should be made for the care of children whose parents were unable to bear this expense. Every clinic for children should recognize that a dental department was an inherent part of its organization.

The Effect of Cold Air on the Blood Pressure in Pneumonia in Childhood.—Drs. JOHN LOVETT MORSE and DAVID M. HASSMAN of Boston presented this contribution. They stated that the cold-air treatment of pneumonia had been generally adopted during recent years. It had been believed that the blood pressure was diminished in serious and fatal cases of pneumonia and that the good effects of the fresh-air treatment were due to the fact that the blood pressure was raised by this treatment. More recent investigations had shown, however, that there was no constant rule for the blood pressure in pneumonia, and considerable doubt had been thrown on the statement that the blood pressure in

pneumonia was increased by exposure to cold air. The writers had made a study of the effect of cold out-of-door air on the blood pressure in pneumonia in children at the Boston Children's Hospital, during the past winter. In all, 387 observations were made on thirty-two children. They found that the temperature of the surrounding air had no constant effect on the systolic, the diastolic, or the pulse pressure. They further showed that there was no definite relation between the systolic pressure, the diastolic pressure or the pulse pressure and the severity of the disease. The rate of the pulse and respiration were also counted in many instances at the same time the blood pressure was taken to determine, if possible, what effect the temperature of the surrounding air had upon them. In general, the temperature of the surrounding air had no constant effect on the rate of the pulse or respiration. There was, however, a slight tendency for the rate of the pulse and respiration to be somewhat lower out of doors than in the wards. The mortality was high in this series of cases. A study of the cases of pneumonia treated at the Children's Hospital since its foundation by Cunningham, showed that the mortality had been slightly higher since the institution of the cold-air treatment. The writers concluded that there was no constant relation between the systolic, the diastolic, or the pulse pressure and the severity of pneumonia or the temperature of the surrounding air. The patients symptomatically seemed more comfortable when they were out of doors than when they were in the house. No conclusions were justified as to the effect of cold-air treatment on the mortality of pneumonia in childhood.

Dr. HENRY DWIGHT CHAPIN of New York said he simply wished to speak from the clinical standpoint and to say that children with bronchial pneumonia did not do well with the cold-air treatment. Some years ago they had put out all their pneumonia cases, and they had observed that the cases of bronchial pneumonia were depressed by the cold air. A distinction should be made between bronchial and lobar pneumonia, and a protest should be made against treating feeble babies with cold air.

Dr. HENRY POPLIK of New York said that since the open-air treatment of pneumonia had become popular, the general practitioner was prone to treat babies with bronchopneumonia by placing them in the open air. There were certain babies that should not be put in the cold air; they should have fresh air, but not cold air. On the other hand, there were some babies that were restless in the ward and were improved from the clinical standpoint by being placed in the open air. Therefore, the point to be emphasized was that the babies suitable for open-air treatment in pneumonia must be carefully selected.

Dr. E. E. GRAHAM of Philadelphia said he had been treating both forms of pneumonia in wards, and in rooms of the roof garden where they received an abundance of fresh, cool, moving air, and his experience taught him that if they could keep the children warm and their hands and feet well bundled up the cold air never did harm, and it sometimes did good.

Dr. L. R. DEBUYS of New Orleans said he believed in the classification that regarded lobar pneumonia as a secondary pneumonia. The lobar pneumonias did much better with plenty of fresh air. He had been impressed by the short duration of the cases, both of bronchial and lobar pneumonia, when treated with oxygen. He gave about eighteen drops a minute. This was giving the outdoor treatment indoors, and it was very effective in shortening the course of the disease.

Dr. JOHN HOWLAND of Baltimore expressed the opinion that, clinically, children with lobar pneumonia did better outdoors than indoors.

Dr. JOHN ZAHORSKY of St. Louis stated that several years ago they had used cold air in the treatment of pneumonia in young babies with disastrous results. The general impression was that the children were more comfortable in cool air, but not necessarily cold air. On the other hand, there was one bad case with low blood pressure and a weak heart, and after it had been put out of doors for a few minutes the heart stopped. Cold air should be used with a great deal of discretion. In some cases cold air was harmful.

Dr. CHARLES GILMORE KERLEY of New York said that the employment of cold air in pneumonia was a therapeutic measure and, like everything in therapeutics, was applicable to selected cases. In small, weak babies with bronchopneumonia and a tendency to spasm, cold air might be fraught with a great deal of danger. On the other hand, in strong husky children with lobar

pneumonia much benefit might be had by the proper use of cold air. The cases for cold-air treatment must be carefully selected, and after the cold-air treatment has been instituted they must be very carefully watched.

Dr. CLIFFORD G. GRULEE of Chicago said he did not wish to discuss the paper but to discuss the discussion, that it might be emphasized that the keynote of the discussion had been the proper selection of cases.

Dr. E. C. FLEISCHNER of San Francisco said Dr. Grulee had emphasized the point that was important; it lay in the proper selection of case. From observations made in California it might be said that practically all cases of lobar pneumonia recovered, but these cases were of a type not so severe as that seen in the East. In bronchopneumonia they had the same experience in California as elsewhere; they did not do so well when placed in the cold air.

Dr. MORSE of Boston, in closing the discussion, said that he should have mentioned that his paper dealt only with lobar pneumonia, and the cases were in children and not in very young babies. The results of the study should not be taken either for or against the value of cold air in the treatment of pneumonia.

Grip in Children.—Dr. LAWRENCE T. ROYSTER of Norfolk presented this paper, in which he related his personal experience with the epidemic of grip last winter as he had observed it in children. He stated that grip seemed to be endemic, but at times it took an epidemic form and then became more severe. Grip was a general infection. The prevailing type was characterized by sudden onset, a rise in temperature lasting from two to five days, and ranging from 102 to 105 or 106° F. When the onset was sudden and the temperature high and there was great prostration, it was difficult to distinguish this form of grip from pneumonia. The pulse and respiration were often not greatly interfered with. Older children often complained of pains in almost any part of the body; these were described as sharp, violent and boring. There were a few cases with irregular heart action. There was one type of the disease characterized by bronchitis, laryngitis, and coryza which strongly resembled measles. Among the sequelæ were found bronchitis and lobar pneumonia and, in a few instances, bronchopneumonia. There was also a gastric type of cases characterized by persistent vomiting which had been mistaken by some physicians for cyclic vomiting. In these cases the evidence of diacetic acid in the urine was very slight, and they were not like cyclic vomiting. Diarrhea as a complication of grip was to the writer a new experience, and it differed in no way from that type of diarrhea so common in summer; it was not of the cholera infantum type, neither did it follow the catarrhal type in any instance. Some of these cases convalesced rapidly, and in others convalescence was long drawn out, and in others again there were exacerbations. In some there seemed to be a reinfection. In some cases there was an irregular pulse, and he felt that there was a myocardial involvement. Other complications that were encountered were otitis media and pyelitis. These conditions probably existed before the grip developed, but the lowered degree of resistance incident to the disease gave these other infections a chance to develop. In some children there was a persistent cough, which was harsh and peculiarly distressing. In a number of cases he obtained Despine's sign and thought it was caused by enlarged bronchial glands. A positive von Pirquet reaction was frequent in these children. It might be said that grip was second only to measles and whooping cough as an inciting cause of tuberculosis. As a means of prophylaxis in grip it was advisable to keep children from older persons having the disease. If a mother had grip and was nursing her infant, she should cover her mouth and nose when near the child. It was also well to protect the child from exposure in dry, windy weather. In the treatment of grip the writer had been using sodium salicylate and preferred the natural to the synthetic product. In the catarrhal conditions he used menthol, camphor, and white oil. When there was a severe bronchitis, opium should not be withheld. Cases with diarrhea should be treated as summer diarrhea was treated. When there was a persistent cough lasting for a long time after cod liver oil and general hygienic treatment, many of these patients, in spite of all care, continued to cough until warm weather came. Grip should be a quarantinable disease; especially was this true with respect to the schools.

Dr. ISAAC ABT of Chicago said he wished to ask with reference to the etiology of grip. Bacteriologists had studied grip during the past winter, and, unless the

bacillus of influenza was so illusive that it could not be identified, there was no ground for assuming that the bacillus influenza was the cause of the grip seen during the past winter. There seemed that seasonal or weather conditions were a factor in determining the incidence of grip. He believed that the adenitis and enlarged bronchial and mediastinal glands were not necessarily tuberculous, but might be due to something else. Pyelitis frequently followed grip, especially in children who had had pyelitis before. Urotropin was commonly given in this condition in young children. This practice was to be deplored. Urotropin should not be given to children under three years of age. More nephritis and acute hemoglobinuria were due to use of urotropin than to the organism of grip. These babies with grip should not be physiced.

Dr. THOMAS F. REILLY of New York said that the type of grip varied in different localities. In New York the most of it had been of the respiratory type, and they had dealt with a peculiar type of pneumonia. It began with a long piping r  le, and a few days later one was sure he was dealing with a pleurisy with effusion, but one did not get fluid. Pneumonia did not begin in the center of the lung but practically always peripherally, and one did not get signs of consolidation until it reached the roots of the lung, when the sounds could be carried through. One thing in the treatment was important and that was the use of creosote, and another thing that had proved useful was a hot poultice. This might sound heretical and old-fashioned, but it gave relief.

Dr. J. P. SEDGWICK of Minneapolis said he was interested in what Dr. Abt had said of the relation between cyclic vomiting and grip infections. He had studied this matter several years ago, and felt that there was some connection between the cyclic vomiting and grip, and during the past winter he had been following these cases closely with the x-ray and the fluoroscope and had found some of the older ideas incorrect. In some cases of grip, in which there was nasal obstruction, the careful use of epinephrin gave relief.

Dr. F. S. CHURCHILL of Chicago said he thought they ought to make an effort to be more specific. In most of these cases the bacilli of influenza had not been found, but they had found streptococci and other organisms. He asked Dr. Royster how if they retained the term grip to designate his respiratory cases which he had described, he was going to explain its etiology.

Dr. JOSEPH BRENNEMANN of Chicago said he had had children with much the same symptoms as had been described and there were two symptoms that stood out conspicuously, one was abdominal pain. When he was told a child had pain in the stomach, he always looked in the throat or searched for an otitis media. He knew of one child operated on for appendicitis and it was found afterward that the glands were very much enlarged. There was also a tendency to hemorrhage in connection with the abdominal pain that seemed to have something to do with the pain. Grip also had a relation to some forms of exanthema. Early in the winter the rashes were not observed, but later there appeared a scarlatina-form rash in connection with the grip.

Dr. JAY I. DURAND of Seattle said they had had such an epidemic of grip in Seattle, and there was no doubt but that they were dealing with a clear-cut clinical entity, and he believed it was purely a respiratory infection. They had prevented cross-infection in this disease by a double gauze partition between beds and the avoidance of drafts. In the wards where this was done they had no cases of cross-infection, while in the other wards every child got the infection.

Dr. N. S. EVERHARD of Wadsworth, Ohio, said she had obtained better results in the treatment of grip with potassium citrate than with sodium salicylate.

Acidosis.—Drs. HENRY DWIGHT CHAPIN and MARSHALL C. PEASE of New York presented this paper. They reviewed the various theories that had been advanced to account for the condition described as acidosis and referred to the work that had been done in estimating the degree of acidosis by the sodium bicarbonate in the blood and the carbon dioxide tension of the alveolar air. They stated that in 1913 they had their attention called to a certain class of intestinal cases. Many of these cases did not show acetone or diacetic acid in the urine, and the illness was out of all proportion to the symptoms. The children became cyanotic, then stuporous, and finally coma supervened. The tongue might be coated and might have a red margin. The temperature was not high except that the ante-mortem tem-

perature might rise to 104° F., or more. There might be early vomiting which ceased as the stupor and coma came on. The cases were characterized by a modified Cheyne-Stokes respiration. The condition seemed to be due to a negative alkaline balance. Dr. Chapin advanced the theory that the acidosis might be due to damage to the epithelium of the intestinal tract, making it easier for the split proteins to find their way into the blood. It might be due in a less degree to the withdrawal of water. They had studied thirty-four cases in all, six of these dying within a few hours after admission to the hospital. Later sixteen more died, or 45 per cent. Twenty-six of the cases did not show acetone or diacetic acid in the urine. They all showed a lowered carbon dioxide tension. The lowest gave a carbon dioxide tension of 22, while the average was 28. In some of the cases after the administration of sodium bicarbonates the carbon dioxide tension rose for a brief period and then fell below the normal gain. In some children the acidosis produced a permanent effect, as shown by recurrent attacks. In such children milk modifications containing high protein and fat content should be avoided. Dr. Chapin said he had not met a case of acidosis in a child fed on a carbohydrate diet. The conclusions in reference to diet were based on experiments with sugar-free diet, fat-free diet, sugar and fat-free diet, low-vegetable proteid and starch diet, and starvation. The cases were treated by the employment of sodium bicarbonate administered in the various ways—by mouth, rectum, hypodermically, and intravenously. They felt that they had shown conclusively the relation of cow's milk to this form of acidosis.

Conditions in Infancy and Childhood Associated with the Production of Abnormal Quantities of the Acetone Bodies.—Drs. JOHN HOWLAND and W. McKIM MARRIOTT of Baltimore presented this contribution. They said that acidosis in children was dangerous, but often an acute, self-limited disease. It was not merely an acetoneuria, but depended on a loss of the acid-base equilibrium of the blood. Hyperpnea was the clinical sign: laboratory tests were the indexes, these being carbon dioxide tension of alveolar air, H-ion concentration of blood, and alkali reserve of blood. The natural low level of carbon dioxide tension and low H-ion concentration in the young explained susceptibility to acidosis. Onset of acidosis was marked by hyperpnea; coma soon ensued, the alkali reserve might be restored, but unless done quickly, death followed. The presence of acid phosphates in the blood in excess (from five to fifteen times the normal), continued long enough would rob the body of bases. Restoration of bases did not always stop the accumulation of acid phosphates. Acidosis was seen in many diseases of infancy and childhood, and should always be kept in mind; its early, rational treatment might be the means of saving life.

OFFICERS.

At the meeting of the House of Delegates on Thursday afternoon the following officers for 1917 were elected: *President*, Dr. Charles H. Mayo, Rochester, Minn.; *First Vice-President*, Dr. L. F. Barker, Baltimore, Md.; *Second Vice-President*, Dr. John F. Leaming, Chicago, Ill.; *Third Vice-President*, Dr. J. Henry Carstens, Detroit, Mich.; *Fourth Vice-President*, Dr. George F. Keiper, Lafayette, Ind.; *Secretary*, Dr. Alexander R. Craig, Chicago, Ill.; *Treasurer*, Dr. William Allen Pusey, Chicago, Ill.; *Chairman of the House of Delegates*, Dr. Hubert Work, Pueblo, Col.; *Vice-Chairman of the House of Delegates*, Dr. Dwight H. Murray, Syracuse, N. Y.; *Members of the Board of Trustees*, Drs. A. R. Mitchell, Lincoln, Neb.; E. J. McKnight, Hartford, Conn.; Oscar Dowling, Shreveport, La.; *Member of the Judicial Council*, Dr. H. A. Black, Pueblo, Col.; *Member of the Council on Health and Public Instruction*, Dr. Frank Billings, Chicago, Ill.; *Member of the Council on Medical Education*, Dr. William D. Haggard, Nashville, Tenn.; *Member of the Council on Scientific Assembly*, Dr. J. Shelton Horsley, Richmond, Va. New York City was selected as the place of meeting in 1917.

(To be continued)

Tabes and Mixed Sclerosis of the Cord.—At a meeting of the Philadelphia Neurological Society, on April 28, Dr. F. P. Clarke read a paper on the type of ataxia in these two affections, in which he said he had been unable to demonstrate that proximoataxia preceded acroataxia in tabes, in contradistinction to subacute mixed sclerosis due to profound anemia, in which it had been maintained that the reverse order of development took place.

MEDICAL SOCIETY OF THE STATE OF NEW YORK

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16-18, 1916.

(Special Report to the MEDICAL RECORD.)

(Continued from page 1068.)

SECTION ON PEDIATRICS

Wednesday, May 17—Second Day

DR. T. DE WITT SHERMAN IN THE CHAIR

A Lanternslide Demonstration of Achondroplasia.—Dr. CHARLES HERRMAN of New York gave this demonstration. He stated that this condition was apparently recognized in antiquity, as a number of statuettes representing typical examples had been found in Egyptian and Assyrian tombs. The old masters had frequently depicted this form of dwarfism in their paintings, those of Velasquez being especially well known. On account of their grotesque appearance and liveliness these dwarfs were much sought after as court jesters. The proportions of the different parts of the body in achondroplasia or fetal chondrodystrophy were similar to those of the normal fetus in the early part of intrauterine life. This would suggest a lack of proper growth of certain parts from that time. Dr. Herrman said he had studied twelve cases, and had observed them over a number of years. It has been stated in the literature that subjects presenting this form of nanism were always of normal intelligence, that they usually showed a marked lordosis, that the process affected only endochondrial ossification, and that therefore the vertebræ escaped, that the vast majority of these individuals were females, and that the proximal portion of the extremity was usually shorter than the distal portion. He has found that in a certain percentage of patients the mentality was subnormal; a large number had a flat back, the apparent lordosis being often due to the tilting upward and backward of the sacrum; the vertebræ were sometimes affected; the sexes were almost equally attacked, and in only a small percentage of cases was the proximal portion of the extremity shorter. The series of slides demonstrated the principal features of the condition; the large head, with prominent brow and depressed bridge of the nose; the nearly normal trunk; the prominent buttocks, with the saddle due to the tilting of the sacrum upward and backward; the short muscular extremities, with peculiar articulation, especially at the knee, the "trident" hand with fingers of nearly equal length; the spoon shape of the hands, and the broad nails, the folds in the skin of the lower extremities, and the normal genitals. The changes in the bones and joints were also shown in the reproductions of the roentgenograms. The essential feature in the lack of growth of the bones was a disturbance of the normal ossification of the primary cartilage, an absence of the normal columnar formation of cartilage cells. Dr. Herrman also demonstrated the difference between this and other forms of dwarfism.

Dr. GEORGE DOW SCOTT of New York said that the fact that these dwarfs were court jesters and entertainers showed that achondroplasia coexisted with brains. The cause of this peculiar condition was unknown, whether it was from local nutritive disturbance in the cartilage, whether from infection both hereditary and direct, whether from intoxication both endogenous and exogenous, whether from genetic influences, race peculiarities, degeneration, defective function of the thyroid, mechanical pressure in utero, syphilis, alcohol, or as the result of diseases unknown to them; Reisman declared the condition had nothing to do with cretinism. It might be due to hypothyroidism. Many of these abnormalities were born prematurely or were dead at term. If they lived they often acquired great strength. A shortening of the extremities was found in both rickets and achondroplasia, in the former due to curvature of the long bones, in the latter due to insufficiency in the length of the bones. The achondroplasia remained so for life, not so the rickets. In achondroplasia the thyroid gland was found normally developed, which was a point against cretinism. These conditions might be treated, however, and were often found coincidental.

Dr. CHARLES HERRMAN, in closing the discussion, said that possibly from what Dr. Scott had said the impression might be left that these persons were of nor-

mal intelligence. He had found that about one-half of these individuals were not of normal intelligence. In many cases they had sufficient intelligence to earn their living as court jesters, vaudeville entertainers, etc., because of their peculiar appearance and a certain cleverness.

A Case of Leucemia in a Boy with Some Observations on Benzol.—**DRS. FLOYD WINSLOW and WALTER D. EDWARDS** of Rochester presented this communication. They said that leukemia was a disease of the hematopoietic system characterized by an enormous hyperplasia of the leucocytic elements. In all probability the whole hematopoietic system, marrow, spleen and lymph glands, was involved in every case of leukemia, the essential changes being an enormous leucocytic hyperplasia. In some cases the process was localized and proceeded slowly; in others of the lymphoid type it was so rapid as to produce death before there was much involvement of the parts of the blood making system. The etiology of the condition was obscure. Streptococci had been demonstrated in the blood in some instances, but there was the question whether the demonstrated microorganism was the principal infection or merely a subinfection. The case reported was that of a boy, fourteen years of age, and the following observations were recorded: (1) Benzol produced a marked diminution of the white cells and its use was attended with benefit. (2) Benzol frequently produced marked irritation when given by mouth, by rectum, subcutaneously, or intravenously. (3) Benzol was a dangerous drug and its administration should be carefully watched for both the symptoms of benzol poisoning and for a too marked or too rapid reduction of the white cells. (4) Benzol could not be used intravenously.

Dr. JOSEPH ROBY of Rochester said the interesting points in Dr. Winslow's and Dr. Edwards' paper were the rarity of this condition in children, the unusually high leucocyte count and the unusual size of the spleen, and that at one time the proportion of red cells to white was about $2\frac{1}{2}$ to one. It was also worthy of note that the benzol seemed to have a stimulating effect. In another case, an adult weighing twice as much as this boy, a smaller dose of benzol reduced the count from 500,000 to 30,000 in a short time, but the blood count had gone back to the place where it had been before the administration of the drug. In this case the rectal administration of the drug worked beautifully. In both cases the blood transfusions seemed to have the effect of holding up the red cells, possibly acting as an antitoxin and increasing the general resistance of the patient.

Dr. WILLIAM A. GROAT of Syracuse said he did not believe in the use of benzol in this malady, since benzol was a toxic agent. If one used benzol the urine should be closely watched, as its toxic effect was just the same as that of phenol.

Dr. CHARLES GILMORE KERLEY of New York cited one case of leukemia in a child four years of age that had come under his observation. This patient he had treated with benzol. The leucocyte count in this case was about 200,000, and as this count diminished the red count went up and there was a decrease in the size of the liver. He kept this child along on small doses of benzol given on a full stomach for some months, but the child finally died at the end of a year.

The Cell Counts of Cerebrospinal Fluids.—**Dr. JOSEPH ROBY** of Rochester said that the purpose of his paper was threefold: (1) To defend more or less a statement made in an article in the *Journal of the American Medical Association*, and to mildly criticize Abrahamson, DuBois and Neil for their technique in estimating cells; (2) to repeat the details of making a cell count of spinal fluid and to demonstrate the apparatus used in searching for the tubercle bacilli; and (3) to show some preparations of tubercle bacilli actually found. The spinal fluid removed by lumbar puncture would be one of four kinds microscopically; distinctly cloudy and even purulent, slightly hazy, bloody, or perfectly clear, with possibly some flakes in it when examined by transmitted light. A cloudy fluid meant a meningitis caused by the meningococcus, the pneumococcus, the influenza bacillus or one of the pus-producing organisms, usually a streptococcus. When the fluid was distinctly cloudy it was allowed to stand a short time and the clot or sediment should then be smeared thinly on slides, dried, and stained. It was not necessary to count the cells in this sort of fluid. A slightly hazy fluid might mean the early or late stage of one of the groups already mentioned, the ad-

mixture to a perfectly clear fluid with a trace of blood, might mean serous or tuberculous meningitis. It was here that the count would be of value. If there were quite a good many red cells and a few whites, it surely ruled out a meningitis due to the first set of organisms. With a distinctly bloody fluid one could also proceed as with a perfectly clear fluid, and such a fluid, or one containing a few flakes, might be any of the following: normal cerebrospinal fluid, meningismus, functional nervous disease, epilepsy, chorea, tetany, spasm, hydrocephalus, serous meningitis, a brain tumor, brain abscess, poliomyelitis, syphilis, or tuberculous meningitis. Often bloody fluid was rejected for counting purposes, but this need not be, for all one had to do was to subtract from the white count one white for every thousand reds counted. With spinal puncture in the functional nervous diseases he said that he had had no experience except in chorea and spasms, and in these there had been no increase in the cell count, nor was there any increase in hydrocephalus. In brain tumors he found no increase of the cells. These findings did not agree with those of Pfaundler and Schlossman, who found an increase of cells in functional nervous diseases and brain tumors. In syphilis he said he had never found more than 100 cells, and usually 30 to 50 in cases of tabes and general paresis. In tuberculous meningitis the limits of the counts had been 45 and 454, the vast majority running between 100 and 300. From these findings it might be concluded that in distinctly cloudy fluids it was not necessary to do a cell count. Smears might be made and the organism searched for. The cell count would not absolutely differentiate syphilis, poliomyelitis, or tuberculous meningitis; but a cell count between 5 and 50 would probably be syphilis or poliomyelitis; a cell count between 100 and 300 would in the majority of cases be tuberculous meningitis. Taken in connection with the onset of the disease and the clinical symptoms, it ought not to be difficult to make a diagnosis of tuberculous meningitis by a cell count alone, even if tubercle bacilli were not found. In searching for tubercle bacilli, the film method modified by the glass cylinder and cover slip had been most satisfactory.

Dr. WILLIAM A. GROAT of Syracuse said Dr. Roby was to be congratulated on his paper, his logic was reasonable and his conclusions sound and well drawn. He could agree that a count above five was abnormal, but he could not agree that it was no sign of inflammatory change. The presence of globulin meant inflammation, but its absence did not exclude inflammation. By Dr. Roby's method it was possible to make counts in bloody fluids, but one should not draw conclusions if the count was near normal. The test could not be depended upon to make a diagnosis in the borderline cases, and it was in these that it was needed most. One could be sure that when there was no true meningitis the count would remain down, and that in meningitis one would have a cloudy fluid, and that this was often the first sign of intracranial involvement.

Dr. T. WOOD CLARKE of Utica congratulated Dr. Roby on his device for finding the tubercle bacilli as we all knew that there was nothing more difficult than doing that with the ordinary means. It gave us a test that could be used by the busy practitioner and the man who was not doing a great deal of laboratory work or did not have a laboratory conveniently near.

Dr. JOSEPHINE B. NEAL of New York City (Research Laboratory, Department of Health) said the counting of cells in the spinal fluid had not seemed to them of sufficient importance to warrant their doing it, inasmuch as, except in luetic conditions, it was not of definite diagnostic or prognostic value. The most difficult differentiation to make in clear fluids was between tuberculous meningitis and anterior poliomyelitis. While the cell count was usually higher in tuberculous meningitis, averaging between one and two hundred or under, and that of poliomyelitis averaged one hundred or under, there was such a wide range where they overlapped that very little reliance could be placed on the count. If too much reliance was placed on cystology, the bacteriology might be missed. The cell count was sometimes relied upon for treatment, and this might lead to very grave error as it occasionally happened that the number of cells decreased practically to normal while the organisms were still present. The complete disappearance of the organisms was the only trustworthy indication for ceasing to vigorously push serum treatment. The type of cells was of importance. In cases of tuberculous meningitis and anterior poliomyelitis there was almost always a high percentage of

polymorphonuclears (90 per cent.), except in the early cases of poliomyelitis. It occasionally happened that in rather acute cases of tuberculous meningitis the number of polymorphonuclears was in excess. In the purulent meningitides the polymorphonuclears were in excess, except sometimes late in recovering cases. In their experience in the examination of over 1900 fluids the bacteriology was found to be of first importance in diagnosis. A good deal of reliance could be placed on thoroughly estimated quantitative chemistry, albumin, globulin, and reduction of Fehling's. In a general way the albumin and globulin were less increased and the Fehling's better reduced in anterior poliomyelitis than in tuberculous meningitis, but there were exceptions to this. From their experience they felt that the cell count had been too much emphasized, often at the expense of other and more important factors.

Dr. JOSEPH ROBY of Rochester, in closing the discussion, said his purpose had been to disagree with Dr. Neal. He had presented his personal observations and not the textbook views on the globulin test. The average man could not estimate the amount of globulin, but with this method he could estimate the number of cells. The same was true of the reduction with Fehling's solution. He had not yet failed to make a diagnosis by this method within half an hour, and he had not yet made a mistake in a diagnosis when using this method. Poliomyelitis, tuberculous meningitis, and syphilis did overlay, and there was no way to make a diagnosis from the count alone without taking into consideration the clinical symptoms. Dr. Roby said it was possible to make an accurate count within ten to fifteen minutes after the spinal fluid was withdrawn.

Eczema in Infants and Young Children.—Dr. CHARLES GILMORE KERLEY of New York read this paper. Eczema in young children might be due to widely different causes; it might be the expression of faulty processes relating to food utilization or the evidence of an immediate reaction against specific food substances. Again it might be due to conditions entirely external, such as irritations. The application of strong soap, mustard, etc., might cause eczema as well as the wearing of woolen garments, exposure to moist and cold air, excessive perspiration, parasitic disease, discharges from the navel, ears, or nose. There was a wide variety of foods that might cause this trouble. He had repeatedly known children to tolerate eight, ten, or twelve ounces of milk daily, but when a larger amount was given, eczema resulted. In these cases by a gradual increase in the amount given, a tolerance might be established. Whole milk in sufficient amount for nutrition might be taken without inconvenience. Some infants possessed no tolerance whatever for orange juice; in some infants it caused a reaction in the form of red scaly patches about the mouth and an erythema of the cheeks and other parts of the body. Beef juice acted in like manner. Butter fat, milk and cane sugar, and orange juice had been proven through processes of elimination to be the most frequent dietetic cause of eczema in making observations on a large number of cases. Cow's milk protein was a rare cause of eczema. The Schloss scratch skin test for proteins had been of little value in determining protein capacity in infants for the reason that there were many cases not anaphylactic to protein that would tolerate but a given amount. In addition to eczema, asthma and urticaria were not infrequently results of protein incapacity. Cases of eczema due entirely to external agencies were readily relieved by removing the source of the trouble and by the application of protective dressings, soothing or stimulating in character. The most difficult of relief was the eczema intertrigo in infants. In such cases the child was taught to evacuate the bowels night and morning. Over the genitals a large bunch of absorbent cotton was placed to catch the urine, and citrate of potassium was given internally. As a protective dressing unguentum aqua rosæ, to which white wax was added in the proportion of 10 per cent., was used. The involved areas must be protected from scratching and irritation. In eczema in breast-fed infants, the first step should be to examine the mother's milk and if a high fat content was found to reduce it through dieting processes if possible. These children might be improved, but rarely cured. The baby, however, would almost always be cured by weaning and suitable bottle feeding. It was not, however, advisable to wean a thriving baby because of eczema. In the bottle fed, the best results had been obtained by the use of plain skimmed milk or evaporated skimmed milk cooked with starch, preferably rice or wheat. A high protein and a high starch

food was given, often with the addition of olive oil to raise the caloric content. As early as the seventh month, squash, carrots, and mashed potato were added to the diet. The salt of fresh vegetables possessed an undoubted therapeutic value. In older children past the bottle age the treatment was along the same lines. Among the drugs for internal administration, citrate of potassium sufficient to neutralize the urine was the most valuable. Not all cases of eczema admitted of cure, but all might be cured if they dared draw their dietetic lines sufficient rigid. This might mean a clear skin, but it would be at the expense of a certain degree of faulty growth and malnutrition. There were cases in which it was not well to cure completely. Proper growth and right development were more important than personal appearance.

Dr. GODFREY R. PISEK said he thought the weight in these cases could be kept up by a careful regulation of the diet. One could give a sufficient amount of sugar and fat if they were properly diluted. In some cases small doses of thyroid might be helpful. Exposure to the air and moderate sunlight, as was now being done with burns, was also beneficial. Any one of the bland ointments was suitable as a protective dressing, and its use should be continued for a time after the eczema had disappeared in order to protect the sensitive skin. The exudate diathesis did not cause eczema, but it might be that a child of this type more easily acquired the disease. When a child having eczema was breast-fed, one should question the mother carefully as to her diet, for it sometimes happened that she had dislikes for certain foods or a craving for sweets, and that by properly regulating her diet the eczema in the child could be benefited.

Dr. CHARLES HERRMAN of New York said that it had been said that many of these cases had nothing to do with the exudative diathesis, that they were due to external irritation, etc., but there was a constitutional type which they were accustomed to speak of as the exudative diathesis. In the study of 200 babies and in following them up for some time he had found that 25 per cent. of them had the exudative diathesis. Dr. Herrman asked Dr. Kerley whether in following these children up for a number of years he found that they showed peculiarities other than skin diseases. He had heard his report-cases, and of recurrent bronchitis, and states that the children had had eczema in childhood. Many of these babies had a tendency to sprue during the first two weeks of life, and they all had peculiarly sensitive skins and respiratory symptoms. He did not think thyroid deficiency was an important factor in eczema.

Dr. CHARLES GILMORE KERLEY, in closing the discussion, said he had tried thyroid extract without much result. In growing children, not in babies, with malnutrition and dry scaly skin, he had given 1/15 or 1/20 of a grain two or three times a day, but it should not be given in large quantities because it was a great stimulator and caused wakefulness in children that were not appreciably abnormal. A child with eczema was likely to have associated conditions, such as urticaria, or cyclic vomiting, and was taken sick easily. That type of child was more susceptible to food conditions than a normal child, and hence they treated cases of common cold, frequent colds, cyclic vomiting, and recurrent bronchitis along lines similar to those outlined in this paper.

Hypertrophic Stenosis of the Pylorus in Children.—Dr. ALFRED HAND, Jr., of Philadelphia read this paper by invitation. He said he had been looking for cases of pyloric stenosis in children ever since attending the British Medical Association, when it met in Toronto some ten years ago, but until a little over a year ago he had seen none. Very few had been reported in this country. He had reported a case before the American Pediatric Society in May, 1915. Last September he had two cases in one week, and last week while preparing to attend this meeting he had another. He had found that the diagnosis was either easy or difficult according to the stage of the condition. The specialist in diseases of children did not often see these cases early, and hence it was frequently easy for him to make a diagnosis. When he was consulted at the time of the initial vomiting it was more difficult. The great preponderance of these cases occurred in the male sex. The history of the cases showed great uniformity. A majority of the breast-fed infants progressed satisfactorily for from two to six weeks before the vomiting began. Some children vomited and lost weight until the irreducible minimum was reached, constipation was

constant and obstinate, but not absolute. Laxatives might only serve to increase the visible peristalsis. One valuable diagnostic point in hypertrophic stenosis of the pylorus in children was the projectile character of the vomiting, but this was not sufficient evidence upon which to base a diagnosis. The tumor if present might be felt by deep pressure in the hypochondrium. When one had located it, it was possible to detect a hard cartilaginous lump, which was characteristic of the growth. It seemed to him that the history of these cases showed that the hyperplasia was progressive. When all the symptoms enumerated were present, there was no question as to the diagnosis. In the early stage it must be differentiated from catarrhal gastritis and spasm of the pylorus. No stated rules could be laid down for the dietetic treatment of these cases, but in making changes in diet one should be guided by some definite reason. At the Drexel Hospital in Philadelphia they had operated upon fifteen cases, with two deaths. The writer had had four cases, two in bottle-fed and two in breast-fed infants. They all required stimulation after operation. All of these patients were doing well, but one of them occasionally vomited a little bile.

Dr. GODFREY R. PISEK cited a case of pylorospasm treated successfully by lavage and careful diet. The x-ray was valuable in distinguishing between pylorospasm and pyloric stenosis. The only operation suitable for this condition in children was the Ramstedt operation, because it could be completed in twenty minutes and gave very good results.

Dr. EDWARD W. PETERSON described the Ramstedt operation, and said that he had performed it successfully in eight minutes. For some hours after the operation no fluid could be given by mouth, and he had given instead 150 c.c. of normal saline intramuscularly by means of a record syringe. This was quickly taken up. The postoperative care of these cases was very important.

Dr. CHARLES GILMORE KERLEY of New York related two instances in which children having this condition and apparently doing well on medical treatment died very suddenly. These cases served to show the danger of temporizing and of being too optimistic in the presence of pylorospasm or pyloric stenosis.

Dr. CHARLES HERRMAN of New York said that hypertrophic stenosis was rather a rare condition, and that when anyone reported a series of sixty cases, as Dr. Downes had done, it gave a rather false impression as to the frequency of this condition. It was probable that nearly all the cases of pyloric stenosis in children were sent to Dr. Downes, and consequently his statistics might give one a wrong impression as to its frequency. Dr. Herrman said he saw a great many babies, but he only saw about two cases of pyloric stenosis a year. The Ramstedt operation was the operation of choice. Papaverin had been used with some success in this condition. It is not always easy to distinguish between pylorospasm and hypertrophic stenosis, since one sometimes got the same symptoms in both.

Dr. T. WOOD CLARKE of Utica said he had had an experience at Ormsby in England, where he saw eight cases in three years, while during a service at the Vanderbilt Clinic he had seen only one case. The condition seemed to be more frequent in England than in this country. He said he had seen these children do well on skimmed milk and sodium citrate.

Thursday, May 18—Third Day.

Dr. T. DEWITT SHERMAN OF BUFFALO IN THE CHAIR.

The Early Diagnosis of Pott's Disease.—Drs. STEPHEN L. TAYLOR of Kenwood and BYRON C. DARLING of New York presented this paper, which was read by Dr. Taylor. He said that in spite of the advance that had been made in the treatment of tuberculosis of the vertebrae and the improvement in the methods of diagnosis, it still happened that the appearance of a fluctuating mass in the groin or elsewhere was the first suspicion that the physician had of the real nature of the trouble he was trying to treat. If it were possible to make a diagnosis before the bodies of one or more vertebrae were destroyed, it was obvious that much would have been done to prevent the most serious results of the disease, severe deformity and general tuberculous infection. Before the appearance of kyphosis or the development of an abscess the symptoms shown by the child were very indefinite and unpronounced, and likely to be overlooked. Symptoms, such as general debility, pallor, failure to gain in weight, lack of interest in play, disinclination to run or jump, unnatural attitude, change in gait, night cries, paroxysmal ab-

dominal pain, or persistent attacks of pain in the chest or stomach should arouse suspicion, and the child should be examined with the clothes removed. On inspecting the spine it might then be noted that there would be a tendency to support the chin with the hands when sitting, when the disease was cervical. When the lesion was in the dorsal region, one or both shoulders might be elevated, the spine was held rigid in walking, or the child placed the hands on the thighs to relieve the spine when sitting. If the disease was lumbar, there was an exaggeration of the lumbar curves, throwing the abdomen forward. In asking the child to pick something up from the floor there was a characteristic squat instead of stooping. The degree of extension of the spine and the amount of lateral motion might be tested with the child lying with the face downward. The presence or absence of psoas contraction might be ascertained in this position also. In the analysis of a large series of cases J. Hilton Waterman and Charles H. Yager found that in young children the most frequent symptoms were unnatural attitude and pain. The pain was due to the sensitive articular surfaces and to irritation of the nerve roots. The former accounted for the muscular rigidity and the effort of the child to protect the spine in every way. The latter accounted for the location of the pain in so many parts of the body, it being referred to the periphery of the irritated nerve. In its early stages Pott's disease might resemble rickets, suppurating glands of the neck, lateral curvature, or a weak and atonic condition. The essayist cited a number of cases that showed the possibility of error in diagnosis and impressed one with the necessity of making repeated examinations. A number of the conditions that might be confused with Pott's disease could be excluded by the discovery of muscular rigidity. In doubtful cases the x-ray was often helpful, though if negative in the early stages it was not conclusive. Pictures should be taken in the anteroposterior position as well as in the lateral, and repeated x-ray examinations were often necessary.

Dr. BYRON C. DARLING of New York gave a lantern-slide exhibition illustrating this paper and demonstrating the value of the x-ray in making a diagnosis of spinal caries.

A Scheme of State Control for Dependent Children.—Dr. HENRY DWIGHT CHAPIN of New York read this paper. (See page 1081.)

Dr. T. WOOD CLARKE of Utica congratulated Dr. Chapin on his work at Morristown, but thought the conditions in all institutions were not so bad as Dr. Chapin had stated. They had an institution at Utica which was admirably conducted, and they had had but ten deaths in thirty-five years. He was not always in favor of taking a child from an institution, placing it in a home, and then leaving it there. If this was done, very careful supervision should be kept over the child.

Dr. T. DEWITT SHERMAN of Buffalo also congratulated Dr. Chapin on his pioneer work at Morristown and related his experience in an institution in which there was an appallingly high mortality rate, from which he withdrew because he was unable to get the cooperation necessary to improve existing conditions.

Dr. CHAPIN, in closing the discussion, spoke further of the dangers of institutional life to young children, emphasizing particularly the danger of specific vaginitis among girls. He also emphasized the need of providing close supervision over all children boarded out. He said in New York they had 400 babies boarded out and only four nurses to look after them, so that the nurse saw these babies only about once a month; a nurse should see these babies every day. Doctors were responsible for prevailing conditions; they were always ready to accept positions in connection with these institutions, but they were not sufficiently independent to insist that the institution be conducted for the highest welfare of the babies. The doctor should be the law-giver of the community instead of subservient to a board of managers.

Pinworms as a Cause of Appendicitis.—Dr. ALFRED W. ARMSTRONG of Canandaigua contributed this paper. He first made observations on the change of opinion that had taken place in modern times, that whereas formerly worms were supposed to be the source of all evil, it was now believed that they but rarely produced serious lesions. Pinworms were understood to be the most common of the intestinal parasites found in children, and they generally inhabited the lower portion of the colon, although they sometimes might be found in the small intestine, the stomach, and not very infrequently in the appendix. His attention had been attracted to this subject by four cases of appendicitis in

children in which pinworms were found in the appendix. These cases all presented the classical symptoms of appendicitis, and after the removal of the appendices there had been no return of the old symptoms. The presence of parasites in the appendix was admitted by all to be rare and yet it was true that the female lived in the cecum until impregnation took place and then moved toward the rectum, it was easy to see how the appendix got its share. The literature on this subject seemed to be limited to reports of only a few cases in which the oxyuris had been found in the appendix, and most of the observations which had been recorded had been made in Europe. Bacterial infection was of course the real cause of appendicitis, but with the presence of numerous forms of bacteria constantly in the intestinal canal, their sudden activity on the occasion of an acute appendicitis must be accounted for. There seemed to be a pretty well established form of appendicitis in which the oxyuris had been found, which was characterized by considerable pain without marked inflammation. In these cases the gross appearance was one in which small hemorrhagic areas appeared in the mucosa and were confined to that part in which the worm was found. His experience in the four cases cited suggested the following practical thoughts in the treatment of intestinal diseases in children: (1) The possibility of the presence of pinworms in the intestines of children should not be disregarded. (2) Appendicitis was one of the most serious results of parasites in the appendix. (3) Treatment directed against the oxyuris might save some child from the necessity for the removal of his appendix.

Dr. FREDERICK H. FLAHERTY of Syracuse said it had been known for a long time that pinworms had been found in the appendix. To get a clear idea of the relation of pinworms to appendicitis one must consider the causes of appendicitis. Many causes had been suggested, but he believed there must be an exciting and an underlying cause. The anatomy of the appendix showed a poor circulation, which favored inflammation of the lymphoid tissue, and this plus the exciting causes produced appendicitis. As an exciting cause foreign bodies were not as common as was thought, and in a series of 500 cases of acute appendicitis in which the appendices were examined microscopically pinworms were found only once. In the speaker's case, in which pinworms were found, there were two masses, each containing thirty or forty pinworms, and they had precipitated the inflammation. What Dr. Armstrong said about the Chinese not having appendicitis as frequently as Western races could be explained by the fact that there was a difference in the anatomy in different races which might modify the blood supply of the appendix. It was well known that Indians rarely had appendicitis. There is one point with reference to the diagnosis of appendicitis in children to which attention might be called, and that was the value of rectal examination. There was no other one method by which one could so well find out if there was an inflammatory mass in the abdomen.

Dr. EDWARD W. PETERSON of New York said that they had had several of these cases in which pinworms were found in the appendix, but that this was one of the rare causes of appendicitis. In one instance in doing a hernia in which the hernial sac was large they had removed the appendix as a prophylactic measure and found half a dozen pinworms in that appendix. This case was reported in the *New York Medical Journal* several years ago. Whether or not they meant anything in this case he could not say, but in two of the cases reported there was no question but that the pinworms were the cause of the appendicitis. It might be advisable to take precautionary measures and see if by appropriate treatment directed against the worms one could clear up the symptoms of appendicitis.

Dr. SHERMAN of Buffalo emphasized the importance of examining the stools oftener than was generally done. Whether treatment directed against the pinworms would do any good depended on the sex of the worms. The males stayed up in the cecum, while the females traveled down. If the focus then was one of males, it might be that treatment would be of no avail.

Typhoid Fever in Children.—Dr. GEORGE C. SINCERBEAUX of Auburn presented this paper. He said the object of his paper was not to present anything new, but to emphasize the importance of the milk supply in relation to the spread of typhoid fever and to give a few facts gathered from his experience in the epidemic in Auburn last year. The pathological findings in typhoid

fever in children were much less typical than in adults. Ulceration, while not infrequent, was often wanting. The course of typhoid fever in children was relatively mild, except in infants, and was liable to be shorter than in adults. The prodromal symptoms were slight. The attack was usually ushered in by slight malaise, gastrointestinal disturbance, vomiting, and constipation, the diarrhea, if any, appearing later. The temperature rose slowly for the first few days, running evenly with slight morning remissions during the second week, and declining slowly until normal at the end of the third week. The tongue might be clean, but more often was covered with a thick white covering with clean tip, the margins often exhibiting the red place, or typhoid triange, in the center of the tip, which was claimed to be pathognomonic of typhoid fever. The disease most likely to be confused with typhoid fever in children was miliary tuberculosis. But in this disease there was the irregular temperature, the spleen was not likely to be so large, the Widal reaction was negative, and there was an absence of bacilli in the blood. The essayist said his treatment might be considered empirical, but for the past few years he had been using collargolum and colloidal silver, one-half to one grain in capsule every six hours and salol in one or two-grain doses every four hours. The diet consisted of boiled water in plenty, milk, broths, gruels, eggnog, cereals cooked six hours, orange juice, and home-made ice cream. In the Auburn epidemic there had been thirty cases reported, of which sixteen occurred in children under seven years of age. The source of this epidemic was traced to milk from one creamery, and it was then learned that on one of the farms supplying milk to this creamery the son of the owner had had typhoid fever and that two wells on that farm were polluted. Admonition was given the people to drink only distilled or boiled water, and all the milk from that creamery was ordered pasteurized. With the institution of these measures the epidemic soon abated. In order to lessen the chances of cases and carriers of typhoid fever and to control them when once they were known the following means were suggested: (1) Cleanliness in milk production. (2) Vaccination of dairy employees against typhoid fever. (3) Isolation of infected persons. (4) Official supervision of dairies during the presence of illness. (5) Official supervision of the pasteurization of all milk.

Notes on Protozoan Infections Occurring at the King George Hospital.—H. M. Woodcock and W. J. Penfold, during the last six months, have examined the feces of 384 different cases, returned soldiers from Egypt and Gallipoli, for protozoan parasites, nearly all being examined two or three times. Of these, ninety-eight cases have shown one and sometimes more than one variety of protozoan parasite; the proportion of positives is 25.5 per cent. of whole. *E. coli* has proved the commonest of the parasites, occurring in 14.8 per cent. of the total number of cases and in more than one-half of the total positives. *Lambli*a has been the next most frequent, having been found in 5.7 per cent. of the total number of cases. The other flagellates have been less frequent. In ten cases in which *Isospora* has occurred the number of parasites in the feces has been scanty and there has been no sign of pathogenicity in connection with their presence. The *Entameba* of amebic dysentery and liver abscess, generally regarded as *E. histolytica*, has been found in one form or another in eight cases. The incidence of the cases of amebic dysentery in this hospital has been most interesting in relation to the occurrence of cases of bacillary dysentery and illustrates the liability to error of random sampling on a small scale when attempting to obtain any idea of the general numerical ratio between the two types. It is worth noting that out of fifty-nine known cases of either amebic or bacillary dysentery, only in one, or at most two cases, can it be said definitely that both types have occurred together. In the treatment of *Lambli*a infections beta-naphthol, together with bismuth salicylate, appeared to have effected a complete cure in two cases in which the remedies had been tried. Another drug was the French turpentine preparation, térébenthine, which when administered in small doses for some days, was also apparently successful in two cases, but had failed in two others. In one of the cases of cyst carriers the cysts were markedly different from the usual type of those occurring in infection with *E. histolytica* and the authors believe this was an instance of *Entameba "minuta."*—*British Medical Journal*.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA BUREAU OF MEDICAL EDUCATION AND
LICENSURE.

January, 1916.

(Concluded from page 1028.)

ANATOMY AND SURGERY.

1. In a patient upon whom an abdominal operation is to be performed, what local and general preparation would you advise?
2. In posterior luxation of the hip joint: Give method of reduction, with anatomical and mechanical reasons for manipulations employed.
3. What conditions may cause gangrene of the leg? State indications for and against the amputation of a leg in which gangrene has occurred.
4. Name the more usual localities in which carcinoma appears. State the more usual early symptoms present.
5. What surgical conditions may cause hematuria? Give the special symptoms of any one surgical condition capable of causing hematuria, and outline the surgical procedure for its correction.
6. What blood vessels may be involved in severe epistaxis? Describe methods of controlling severe epistaxis.
7. In fractures of the bones of the forearm, state three forms of splints that may be employed. Indicate location of fracture in which you would employ each, with anatomical reasons for the selection of the same.
8. Enumerate the conditions that would warrant the amputation of a leg. Outline the technic of amputation of the leg (upper third). State the anatomical structures severed.
9. For what conditions may resection of the elbow joint be performed? Outline the technic of the operation, giving the surgical anatomy of the parts.
10. Enumerate the various forms of hernia found in the groin. Upon what is the anatomical classification based? Describe a method of reducing by taxis in any one form selected, naming the form selected. Briefly outline the anatomical points to be considered in the radical operation for femoral hernia.

PRACTICE, MATERIA MEDICA, THERAPEUTICS AND HYGIENE.

1. Give the medicinal and dietetic treatment, and state your reasons therefor, of a case of vomiting of pregnancy.
2. Outline in brief the effects of the excessive use of: (a) Coffee, (b) tea, (c) chocolate, (d) alcohol, and (e) tobacco.
3. Describe the therapeutic action of: (a) Cocaine, of (b) veratrum viride, and of (c) apomorphine.
4. Outline the treatment of a case of pneumonia: (a) during the onset, (b) during the height of the disease, and (c) during convalescence.
5. (a) Describe the administration of spinal anesthesia. (b) What are the dangers of ether or chloroform anesthesia? (c) What precautions would you take in furtherance of their avoidance?
6. Outline the medicinal and dietetic treatment of chronic constipation. Describe any other means or measures you consider of importance in such a condition.
7. How would you combat therapeutically: (a) Excessive cough in tuberculosis? (b) a paroxysm of angina pectoris? (c) puerperal eclampsia?
8. Describe the local effects produced by a solution of: (a) Atropine sulphate, and of (b) pilocarpine hydrochlorate when dropped into the eye. What strength of the solution of each would you prescribe for the usual purposes for which they are used? What are the contraindications to the use of each?
9. State what articles of diet you would prohibit and what ones you would permit in a patient with arteriosclerosis and high blood pressure. What benefits would you expect from a reduction in weight of the patient?
10. How would you treat, other than by operative measures, abdominal ascites and the general edema occurring as a complication in hepatic and renal disease?

ANSWERS.

ANATOMY AND SURGERY.

- "1. If possible, the patient should be under observation for at least twenty-four hours prior to the oper-

ation. During this time a careful study is made of the urine and the condition of the heart and lungs, and necessary treatment instituted. The diet should be restricted, and a purgative given the night before, followed by an enema on the morning of the operation. No breakfast, or merely a cup of beef tea, should be given on the day of the operation. The abdomen should be shaved and scrubbed thoroughly with tincture of green soap and sterile water for at least ten minutes on the night before the operation. A general bath should then be taken, giving special attention to the inside surfaces of the thighs and to the umbilicus. A soap poultice is applied to the abdomen and allowed to remain for several hours; this is removed, and the abdomen is scrubbed with alcohol and washed with mercuric chloride solution (1:1000). A towel wet with this solution is placed over the abdomen, and a binder is applied. (*Pocket Cyclopedia*).

2. In posterior luxation of the hip joint, the patient is placed on a mattress on the floor, and anesthetized. The leg is then flexed on the thigh and the thigh on the abdomen; this relaxes the Y-ligament, and brings the head of the femur down to the lower part of the acetabulum. The leg is then circumducted outward; this brings the head of the femur to the rent in the capsule. The limb is then extended to bring the head of the femur into the acetabulum.

3. The causes of gangrene are thus given by Stewart: (1) *Indirect gangrene*, which is caused by interference with the blood supply, includes senile, presenile, diabetic, post-febrile, Raynaud's, ergot gangrene, anhidrosis, gangrene from embolus, ligature of the principal artery of a limb, thrombosis of an artery, the result of injury, and obstruction of the principal artery and vein; (2) *direct gangrene*, the result of trauma, includes gangrene from severe crushes, prolonged pressure, chemical injuries, the x-ray, frost bites, and burns and scalds; (3) *mixed or microbic gangrene*, in which the tissue cells are directly killed by bacterial toxins and the blood vessels occluded by thrombosis, includes traumatic spreading gangrene, and hospital gangrene.

Amputation is indicated in all cases except, perhaps, senile gangrene with marked calcareous arteries and albuminuria or general debility; (2) diabetic gangrene with pronounced acidosis or beginning coma; (3) acute infective gangrene which has already invaded the trunk or in which septicemia is present.

4. *Carcinoma* is most usually found in the breast, uterus, stomach, pylorus, rectum, ovary and testicle. The chief *early symptom* is often impairment of function, without swelling or pain, these latter occurring later. Pain is due to the involvement of nerve-endings; when ulceration occurs, cachexia becomes marked. Other symptoms depend upon the location of the lesion.

5. *Hematuria* may be caused by renal calculus, tumors or injuries of the kidneys, cystitis, vesical calculus, prostatic congestion or ulceration or tumor, traumatism of urethra, parasites (especially the *bilharzia hematobia*). Symptoms of renal calculus consist of pain in the loin, markedly increased by exercise, especially on jolting. The pain may be referred to the thigh, groin, or testicle. The colic is associated with hematuria, and often pyuria exists with frequency of micturition. The kidney may be enlarged, and tender on pressure. A large stone may exist without any symptom whatever.

The most typical symptom consists in a sudden attack of excruciating and paroxysmal pain shooting down the loin to the bladder and testis. The attack is accompanied by vomiting, faintness, and collapse. Frequent efforts to pass urine are made, but only a scanty amount of blood-stained urine is passed (strangury). The pain ceases suddenly when the calculus slips back into the pelvis or reaches the bladder. (*Aids to Surgery*).

6. The blood vessels liable to be involved in epistaxis are: The spheno-palatine and descending palatine branches of the internal maxillary artery; the anterior and posterior ethmoidal branches of the ophthalmic, and the artery to the septum from the superior coronary branch of the facial.

Treatment.—In severe epistaxis, examine the nose by means of a head-mirror and a speculum. If a little point of ulceration is found, touch it with a hot iron. If the bleeding is a general ooze, if it is high up, or if the cautery does not arrest it, pack the nares. It may be necessary to pack one nostril or both. Pass a Bellocoq cannula along the floor of one nostril into the pharynx, project the stem into the mouth, tie a plug of lint or gauze wet with Carnot's solution of salt and gelatin to

the stem, and withdraw it. Hold the double string which emerges from the nostril in the hand and pack gauze wet with gelatin solution from before backward. Tie the strings together over the plug; if both nostrils are plugged, the strings from one nostril are fastened to the strings from the other. Do not use subsulphate of iron, as it forms a disgusting, clotty, adherent mass. If a Bellocq cannula is not obtainable, push a soft catheter into the pharynx, catch it with a finger, pull it forward and tie the plug to it. Remove the plug in two or three days. Do not leave it longer. It blocks up decomposing fluids and may lead to blood-poisoning. Pick out the front plug first, hold the string of the second plug in the hand, push the plug back into the pharynx, catch it with forceps, and withdraw plug and string through the mouth. (DaCosta's *Modern Surgery*).

7. In *fracture of the shaft of the radius*, above the insertion of the pronator radii teres, the forearm is placed in full supination on an anterior angular splint, in order to bring the lower fragment in contact with the upper.

In *fracture of the shaft of the ulna*, an internal angular splint is used; this immobilizes the elbow, and places the forearm in a position half way between pronation and supination, and so keeps the two bones as far away from each other as possible and thus minimizes the danger of their union by a callus.

In *Colles' fracture*, a padded Bond splint or Levis splint may be used, so that the hand is semiflexed and adducted. A pad is placed on the back of the forearm over the lower fragment, and another on the flexor surface over the lower end of the upper fragment.

8. *Indications for amputation of the leg*: Compound fracture, compound dislocation, fracture with great comminution of bone, extensive laceration, laceration of important vessels, gunshot injuries, gangrene, extensive bone disease, elephantiasis, snake-bite, aneurysm; provided that these conditions are not amenable to less radical treatment.

In Sedillot's "method of *amputation of the leg* the point of the knife is entered a finger's breadth external to the spine of the tibia and carried outward, grazing the fibula, and is brought out as far as possible to the inner side; a flap three or four inches in length is then cut from within outward; the extremities of the incision are next united by an incision across the inner side of the limb, involving the skin only; any remaining muscular tissue is next divided and the bones are sawed. The long external flap is then brought over the ends of the bones and fastened to the edges of the incision on the inner side of the limb. Ashhurst modified this operation by cutting the long external flap from without inward, and made also a short internal flap in the same manner. By either method the resulting stump is a good one, with the ends of the bones covered by the tissues of the external flap." (Wharton's *Minor Surgery*).

The parts cut through in amputation at the upper third of the leg are: Skin, fascia; bones, tibia, and fibula; interosseous membrane; muscles, tibialis anticus, tibialis posticus, extensor longus digitorum, extensor proprius hallucis, flexor longus hallucis, flexor longus digitorum, peroneus longus, peroneus brevis, soleus, gastrocnemius, and the tendon of the plantaris; arteries, anterior tibial, posterior tibial, peroneal; veins, the venae comites of the arteries, external saphenous, internal saphenous; nerves, anterior tibial, posterior tibial, external saphenous, communicans peronei, musculocutaneous.

9. *Excision of the elbow* is performed for: Chronic joint disease (generally tuberculosis); wounds; faulty ankylosis, or other deformity; disease of the articular ends of the bones; fracture dislocation; compound comminuted fracture.

"In excising the elbow joint, the forearm is slightly flexed and a longitudinal incision is begun about two inches above the olecranon process and a little to its inner side, and carried about three or four inches down in the line of the ulna; the tissues are then divided down to the bones, and the ulnar nerve is dissected from its groove behind the inner condyle of the humerus and held aside by a retractor; the tendon of the triceps is divided, and its attachment to the fascia and periosteum over the olecranon process is separated with an elevator or periosteotome and turned downward; the joint is next opened and the lateral ligaments divided as the forearm is flexed upon the arm. The upper part of the ulna and the head of the radius are freed with a probe-pointed knife and removed with a narrow-bladed saw,

care being taken in making the section of the radius to divide its neck so that the attachment of the biceps muscle is not interfered with. The condyles of the humerus are next freed and removed with a saw. In freeing the bones at the anterior portion of the joint, great care should be used to avoid injury of the brachial artery and vein and the median nerve." (Wharton's *Minor Surgery*).

10. The various forms of hernia found in the groin are inguinal and femoral hernia.

The anatomical classification is based on the relation of the hernia to (1) the inguinal canal and inguinal rings, and (2) to the femoral opening. The former are above Poupart's ligament, the latter below it.

The forms of inguinal hernia are:

- (1) *The Direct*, in which the hernia does not occupy the inguinal canal, but leaves the abdomen to the inner side of the deep epigastric artery, through the space known as Hesselbach's triangle. There are two forms of this variety: (a) the hernia may escape between the epigastric artery and the obliterated hypogastric artery; (b) or it may escape between the obliterated hypogastric artery and the outer edge of the rectus muscle.
- (2) *The Indirect or Oblique*, in which the hernia occupies, wholly or in part, the inguinal canal. An *oblique inguinal* hernia may pass into the scrotum or labium majus, when it is called *complete*; or may be retained in the inguinal canal, when it is called *incomplete* or a *bubonocoele*. Other varieties are the *congenital*, *infantile*, and *encysted*.

Femoral hernia leaves the abdomen through the femoral ring and descends into the femoral canal; this canal is funnel-shaped, is about half an inch in length, and ends at the saphenous opening. Its course is first vertical, then forward, then upward over Poupart's ligament. The neck of the hernia is situated at the femoral ring; to its outer side lies the femoral vein, and to its inner side is Gimbernat's ligament; in front of it is Poupart's ligament, and behind it are the pubis, the pectineus, and the public portion of the fascia lata.

"*Taxis*, or the manipulations for the reduction of a hernia, should always be gentle, and should rarely be tried for more than five or ten minutes, because of the danger of rupture of the bowel. It should not be employed in the presence of inflammation or gangrene. Reduction is facilitated by having the patient recumbent, the thighs flexed (and that of the affected side adducted in femoral or inguinal hernia), and the pelvis raised. The administration of opium and belladonna and the application of heat or cold also are useful in securing relaxation. One hand is used to steady the neck of the sac, while with the other the hernia is compressed and pushed back into the abdomen. In direct inguinal and umbilical hernia the pressure is backward; in oblique inguinal hernia it is upward, outward, and backward; in femoral hernia it is at first downward and inward, then upward and backward. The successful reduction of bowel is sudden and accompanied by a gurgle; omentum is forced back slowly without gurgling." (Stewart's *Surgery*).

In addition to the points given above on femoral hernia, it must be remembered that sometimes the obturator artery arises (abnormally) from the deep epigastric artery. When this abnormal artery passes down the outer side of the crural ring, it is out of harm's way; but when it passes down the inner side of the crural ring it is very apt to be wounded in herniotomy.

PRACTICE, MATERIA MEDICA, THERAPEUTICS AND HYGIENE.

1. The vomiting of pregnancy is generally viewed as a toxemia with disordered protein metabolism and pathological conditions in liver and kidneys. The treatment then consists in diminishing the intake of protein food, and the administration of cathartics and diuretics. If the stomach rejects food, enemata may be tried. Sodium bicarbonate is useful because it hinders the production of acetone bodies and acidosis. Irrigations of the colon, particularly with solution of sodium bicarbonate, remove toxins from the colon and also supply fluid and an alkali to the body. The best food is milk, and cereals. Many drugs have been used in the past with doubtful benefit, such as: Cerium oxalate, bismuth subnitrate, iodine, bromide of potassium, citrated caffeine and chloral.

2. The *excessive use of coffee* retards peptic digestion; incites or keeps up gastric catarrh; induces muscular tremors, anxiety, nervousness, palpitation, brady-

cardia, heartburn, vertigo, constipation and insomnia.

The *excessive use of tea* retards digestion; causes gastric irritation and catarrh, flatulency, constipation or diarrhea, nervousness, insomnia, muscular tremors and palpitation.

The *excessive use of chocolate* may cause gastric dyspepsia.

The *excessive use of alcohol* may cause changes (chiefly cirrhotic) in the blood vessels, liver, kidneys, and other tissues; the brain and nervous system are likely to be affected by degenerative changes; it is said to be a predisposing factor in the following: gastritis, liver disorders, dilatation and hypertrophy of the heart, arteriosclerosis, aneurysm, nephritis, neuritis, apoplexy.

"The *continued use of tobacco*, by smoking or chewing it to excess, produces granular inflammation of the fauces and pharynx, atrophy of the retina, dyspepsia, lowered sexual power, sudden faints, nervous depression, cardiac irritability and occasionally angina pectoris. Used by the young it hinders the development of the higher nerve centers and impairs the nutrition of the body by interfering with the processes of digestion and assimilation. It has been credited with causing cancer of the lips and tongue, blunting of the moral sense, mental aberration and even insanity." (Potter's *Materia Medica*, etc.)

3. "*Cocaine* is a protoplasmic poison and induces complete local anesthesia. Coca leaves, when chewed, relieve hunger and fatigue and allay irritability of the stomach. The drug tends to stimulate the vagus centre, increase the pulse-rate, constrict the arterioles, and cause a marked rise in blood-pressure, though later the blood-pressure falls; the respiratory functions are at first stimulated and afterwards depressed, and under poisonous doses death occurs from asphyxia. The higher parts of the brain are at first stimulated and the muscular power greatly increased, while the various medullary centers are first stimulated and then depressed. There is primary stimulation of the spinal cord also, with exaggeration of the reflexes, and very large doses may cause strychnine-like convulsions. In the eye mydriasis is produced and accommodation impaired. Cocaine is eliminated chiefly in the urine. Cocaine is more largely employed to produce local anesthesia than any other agent; injected into the arachnoid space of the spinal cord it has also been used to cause general anesthesia for surgical operations. The preparations of coca are prescribed as stomachic tonics and in the debility of convalescence from acute diseases, and cocaine has been given internally in chorea, paralysis agitans, alcoholic tremors, and senile trembling." (Wilcox's *Materia Medica*.)

Veratrum viride: "On the skin it causes tingling, numbness and anesthesia, and, applied to the mucous membrane of the nose and throat, violent sneezing and coughing. Internally it produces gastrointestinal irritation, prolonged relaxation of striped and cardiac muscle, reduction of arterial pressure, depression of respiration, convulsions from stimulation of the spinal cord, free diaphoresis, and reduction of temperature. As a circulatory depressant, given early, in croupous pneumonia, pleurisy, hepatitis, maniacal delirium, etc., with strong, bounding pulse and other sthenic conditions; in puerperal convulsions and the early stage of peritonitis, phlebitis and other inflammatory affections of the puerperal state; also acute rheumatism, tonsillitis, aneurysm and wounds of the head, pericardium and peritoneum." (Wilcox, *Materia Medica*.)

Apomorphine acts on the vomiting center in the medulla, hence is emetic; it increases pulse, blood pressure, and rate of respiration; it is also an expectorant. Its *indications* are chiefly those requiring a prompt emetic; also as an expectorant in bronchitis and lobular pneumonia.

4. The *treatment of pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there a full bounding pulse? Is the pulse feeble, irregular, or intermittent? "In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset.

"In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding

of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset, and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to. Many prescribe it from the outset.

"The diet should consist of milk, beef-tea or broths, white of egg, and so on. The patient should be as little moved as possible, and the bed-pan must be used. As in other fevers, an airy room and good nursing are essential.

"Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but *if pain be excessive* a hypodermic injection of morphine does *more good* than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated, are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided.

"The results of *serum treatment* are not unequivocally encouraging, but vaccine treatment would seem to be of better promise. Where possible, an autogenous vaccine should be used." (Wheeler and Jack's *Handbook of Medicine*.)

5. By spinal anesthesia is meant the employment of subarachnoid injections of cocaine or eucaine for the purpose of producing analgesia for surgical purposes. Between the fourth and fifth lumbar vertebra is the spot usually selected. The surface is sterilized and the skin is made anesthetic by injecting into it one of Schleich's solutions. An exploring needle is then made to find its way into the subarachnoid space, which is evidenced by the escape of some fluid. The syringe containing the cocaine or eucaine is then attached, and the anesthetic is injected. Rigid asepsis is necessary, and even then the procedure is dangerous. (*Pocket Cyclopaedia*.)

The dangers of *ether anesthesia* are asphyxia (failure of respiration), and to a much less extent, heart failure. In *chloroform anesthesia* the chief danger is sudden death from reflex arrest of the heart; failure of respiration, and fall of blood pressure may also occur; delayed chloroform poisoning or toxemia is also possible.

The *chief precautions* against these dangers are: The employment of an expert anesthetist, and the use of the purest anesthetic; a thorough examination of the patient and due preparation for the operation; the elimination of all unnecessary dangers, such as undue exposure or prolongation of the operation, and having in readiness everything likely to be needed in an emergency.

6. *Treatment of chronic constipation*: "The cultivation of habits of regularity is of the utmost importance. The patient should go to stool at the same time every day, whether there is a desire to evacuate the bowels or not, and every such desire should be immediately gratified. The diet should comprise considerable fruit and vegetables (which leave a residue). A glassful of cold water before breakfast, an orange or oatmeal at breakfast, and stewed fruits and salads at dinner subserve a useful purpose in many cases. Persons of sedentary habits are often benefited by exercise; abdominal massage is useful in some cases, and an abdominal binder is of value to those with a pendulous flabby abdomen and visceroptosis.

Drugs should be dispensed with as long as possible. Medicinal measures when necessary vary with the nature of the causal factor, which must be diligently searched for. At the beginning of the treatment it is often advisable to clear the intestine thoroughly with castor oil, a blue mass pill, or calomel, followed by a saline aperient. In many cases, the best results are obtained by a daily injection of tepid water with or without soap; in other cases injections of oil are much better; but enemas should not be too long continued. Some patients are much benefited by a saline aperient water, sodium phosphate, or other saline, taken a half hour before breakfast. Should a course of medicine be necessary, the desired results may usually be secured by the use of cascara sagrada, which has the advantage that, having been continued for some time, the dose

necessary to secure a daily evacuation may be gradually reduced, and the drug ultimately dispensed with, should the patient continue habits of regularity. The pill of aloin ($\frac{1}{2}$ grain), strychnine ($\frac{1}{40}$ grain), and extract of belladonna ($\frac{1}{10}$ grain), though much abused, is very useful in many cases." (Kelly's *Practice of Medicine*.)

7. For *excessive cough in tuberculosis*: Rest, fresh air, and drugs such as creosote, guaiacol carbonate, codeine, heroine, morphine, and diluted hydrocyanic acid; the ordinary expectorants should be avoided on account of their nauseating tendencies.

In *angina pectoris*: Inhalation of amyl nitrite, and a hypodermic of morphine and atropine or inhalation of chloroform.

In *puerperal eclampsia*: "The treatment of the attack consists of the administration of chloroform by inhalation, chloral hydrate (gr. 60) by enema, and the fluid extract of veratrum viride hypodermically (gtt. 15 followed by gtt. 5, repeated frequently enough to keep the pulse at about 60 beats a minute, to control the convulsions, and free purgation by croton oil (gtt. 2, or 3, in sweet oil or glycerin), free sweating by the hot pack, and sometimes depletion by venesection to eliminate the poison. The after-treatment consists of free purgation by the salines, restriction of diet, and later the administration of tonics and stimulants. The obstetric treatment is usually noninterference." (*Pocket Cyclopaedia*.) Sometimes *accouchment forcé* is indicated.

8. *Atropine sulphate*, when dropped into the eye dilates the pupil, destroys the power of accommodation, and increases intra-ocular tension. As a simple mydriatic a solution of $\frac{1}{4}$ grain to the ounce is generally used; as a cyclopegic a solution of 4 grains to the ounce may be used. It is contraindicated in glaucoma and old age.

Pilocarpine hydrochloride, when dropped into the eye causes the pupil to contract and lessens intra-ocular tension; it may also produce spasm of accommodation. It is used in solution of 1 to 4 grains to the ounce. It is said to be contraindicated in severe cardiac or pulmonary lesions.

9. In *arteriosclerosis*, the following should be *prohibited*: All indigestible food; dried, salted or preserved meats; cheese, pastry, sweets, nuts, cabbages, carrots, turnips. The following may be *allowed*: White fish, chicken, rabbit, game, one potato a day, mutton or well-grown lamb once a day, spinach, asparagus tops, onions, tomatoes, peas, beans, water, milk, weak tea, alcohol only when necessary. Only as much food should be taken as is necessary.

If the reduction in the patient's weight is due to the lessened intake of food, we may expect diminished blood pressure, less toxemia or intoxications, and general amelioration of health. If the patient had been overweight, a reduction should be accompanied by diminution in blood pressure, avoidance of the danger of impending apoplexy, and amelioration of subjective symptoms such as headache, dizziness, dyspnea, precordial oppression.

10. Purgatives and diuretics may be of use; elaterin, in doses of $\frac{1}{20}$ grain; compound jalap powder. 30 grains; if salines are used they should be given in concentrated or saturated solution; citrated caffeine, and pilocarpine may be of service; the external application of heat may be tried. The amount of fluid ingested should be limited, and meat and meat products should be avoided; in renal cases salt is prohibited.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE ART OF ANESTHESIA. By PALUEL J. FLAGG, M.D. Published by J. B. Lippincott Company, Philadelphia and London. 136 Illustrations. 341 pages. Price, \$3.50.

A TREATISE ON BLOOD PRESSURE IN OCULAR WORK. With Special Reference to Factors of Interest to Refractionists. By EUGENE G. WISEMAN. Published by John P. Smith Printing Company, Rochester, N. Y. Illustrated, with 19 engravings. 267 pages.

Miscellany.

Rules for Typhoid Carriers.—The following instructions for the guidance of typhoid carriers have been issued by the New York City Health Department:

1. You must not have anything to do with food or drink to be used by others, either in your business or at home. Don't go to the icebox or refrigerator. Don't hand anything at the table. Have your own plates, cups, glasses, spoons, forks, etc., separate from the others, and washed and kept for you alone. If you happen to leave any food or drink, it must be thrown out and not be used by others.

2. Every movement from your bowels not passed into a toilet flushed with water and connected with a sewer must be disinfected with some good disinfectant, such as chloride of lime or cresol, letting it stand for some minutes. Keep a supply of the disinfectant on hand for this purpose. When a toilet with running water is used, thoroughly clean the bowl daily.

3. After using the toilet wash your hands with plenty of soap and water. Do this every time. Dry your hands well. Do not let other people use your towel.

4. Do not have a movement of your bowels except at a regular toilet. Try not to use the toilet when away from home during the day. If you have only an out-door privy to use, keep it disinfected all the time with quick lime, and screened from flies.

5. Keep yourself and everything about you very clean. Disinfect your underclothing before sending it to the laundry.

6. Every person with whom you live must be immunized against typhoid fever.

7. Keep the Department of Health informed of your whereabouts. Call for a personal talk and advice as to treatment or help in some other way. See that your stools are re-examined from time to time.

If there is a physician in attendance these instructions are sent to him to be transmitted to his patient; if there is no physician in attendance, they are sent directly to the typhoid carrier.

A Cancer Expert Defends a Nature Healer.—According to a communication in the April 18 number of the *Muenchener medizinische Wochenschrift* Dr. Zeller, assistant to Professor Czerny in the latter's Heidelberg Cancer Institute, gave expert testimony in favor of a nature healer of Dresden, who was under trial for malpractice in failing to give proper treatment to a woman dead of cancer of the breast. There had been no diagnosis, and the healer had promised to "take the hardness" out of the tumor. Later he had realized that the case was one of cancer and had sent the patient to a surgeon, who pronounced the condition no longer operable. Dr. Zeller took the stand, and was backed up by two other practitioners, Drs. Rohr and Böhm. None of the three admitted any evidence of malpractice. Zeller held that a non-medical man could not be held responsible for what he might say of a condition like cancer, so long as the profession itself was in such darkness as to the nature of the malady. He placed no faith in statistics. It was not the general custom, he said, to make a microscopical diagnosis after extirpation of a tumor, although he himself always insisted upon this practice.

WHAT IS THE POSITION TO-DAY AS TO THE VALUE OF BLOOD AND CEREBRO- SPINAL FLUID EXAMINATIONS IN THE DIAGNOSIS OF SYPHILIS OF THE NERVOUS SYSTEM?*

By EDWARD D. FISHER, M.D.,

NEW YORK.

PROFESSOR OF MENTAL AND NERVOUS DISEASES, UNIVERSITY AND
BELLEVUE HOSPITAL MEDICAL COLLEGE.

IN speaking on this subject I would in no way discountenance the value of the laboratory investigations. No one to-day would be satisfied that he was doing justice to his patient, did he not have serological and cytological examinations made of the blood and spinal fluids, not only for diagnosis but also for information as to the course of treatment to be followed out. The clinical findings, however, are, in my opinion, most important and conclusive. Positive laboratory findings are merely confirmative and complementary, but negative findings by no means negate the clinical evidence.

Serology is a subject of recent date and has not attained accuracy. Contradictory reports are very common, and, even in cases with full knowledge of a positive luetic history, negative findings are not infrequently presented.

The reaction is due to the presence of a globulin in the blood produced by the destructive action of the syphilitic virus or its toxin upon the neuron. Why then should there be a negative reaction in blood as well as the spinal fluid, or again a positive reaction in the blood and a negative one in the spinal fluid? Pathologically speaking there is a meningomyelitis or encephalitis with an extensive exudate of plasma cells and lymphocytes in the perivascular lymph spaces with an accompanying endarteritis. The globulin, therefore, can not permeate through these vessels into the cerebrospinal fluid and the result is a negative Wassermann reaction. The reverse may be true, so that the fluid may be positive and the serum negative. If on the other hand the syphilitic virus be latent, no tissue destruction goes on and no reaction may be obtainable in either serum or spinal fluid. We may also find an explanation of the negative Wassermann reaction in Ehrlich's theory of immunity of an animal as due to the great energy of the cells of its body, which are able to appropriate nutritious substances for themselves, and in so doing to deprive parasites of them. It may not be illogical to assume that the neurons maintain their specific energy, as they are able to absorb all the nutriment and oxygen in the circulating fluids. And it is only when this specific

energy fails that the parasites, glia cells, lymphocytes, and plasma cells absorb this nutriment and oxygen and actively proliferate while the neurons decay. This theory is hypothetical.

Clinically, however, the study of syphilis of the central nervous system goes back many years, and by the best minds in the medical profession. The various symptoms have been confirmed by pathological findings and experimental physiology with respect to the functions of the central nervous system. Clinically, therefore, we stand on sure ground.

The special methods of diagnosis are familiar to the laboratorian as well as to the clinician. It is the latter, however, who has evolved them and is the most familiar with them. He is the expert in diagnosis, and it is just here that the laboratory expert is apt to fail, for he depends on his findings without a painstaking clinical examination of the case and therefore may readily believe he has a disease which in reality is not present.

If this were merely an academic question it would be of no importance, but it is far from this, as it involves treatment which may not be carried out by the laboratory expert, but will be by the physician who reviews his reports.

The well known physical signs of diseases of the central nervous system consist of the disturbance in the motor, sensory, and reflex fields and diseases of various sense organs. In regard to motor changes we may have irritative or destructive conditions, *i. e.*, convulsions, tremors, or paralysis; in the sensory field, pain or loss of or impaired sensation. Reflexes may be lost or exaggerated, involving the brain, as in the eye reflexes, or the spinal cord. All these to the trained examiner are of positive value; are indeed all explainable from his knowledge of the anatomy and physiology of the nervous system. In other words, to-day we understand in a large degree the organic diseases of the central nervous system.

The question can be put, therefore, do we need this further method of investigation? My answer is yes, as it is confirmatory of the etiology of the affection we may be treating, and also as it is a guide as to our method and continuance of treatment.

Clinically I have always held, in various monographs, that cerebrospinal syphilis, using that term in contradistinction to meta- or parasyphilis, marked itself out by its early onset after the primary lesion and was acute in its course, sharing involvement of the blood-vessels and meninges, what Mott defined recently as the meningovascular form. Parasyphilitic diseases are slow in their onset and usually occur many years after the primary infection and involve the parenchymatous structures of the brain and cord as observed in general paralysis and tabes. The meninges are also involved in both these diseases. The serological findings are of

*Paper read before the Medical Society of the Borough of the Bronx April 12, 1916.

greatest aid to the clinician, especially when positive. Should, however, these findings be negative, while the clinical symptoms are present, I would make a diagnosis from them alone. So much so that if patients come with positive serological findings but without clinical manifestations of the disease, I advise against specific treatment.

Numerous cases illustrative of the points I have made have been reported in recent literature, and of many I shall briefly report three in my experience:

CASE I.—Christine H., 30 years old, married, English. *Family history* negative. *Personal history*: Of the infantile diseases had measles, scarlet fever, varicella, parotitis, and pertussis. Pneumonia two years ago and made recovery. She began to menstruate at eleven. Denies venereal disease and never miscarried. She gave birth to five living children. Suffers from chronic obstipation. *Present illness*: Since April, 1915, patient began to suffer from stiffness of the neck and pain on motion. Gradually both shoulder joints, the elbows, and wrists became involved in the same manner. There was no swelling of joints. After a few weeks both hands became numb and pain increased in severity, being most intense at night. Toward the end of July there appeared edema of the legs, the right becoming involved first and accompanied by pain which was partially relieved on walking.

In addition to the above symptoms she now complained of loss of power and feeling in the arms and numbness and pain in the right epigastric region. Soon loss of power and feeling involved the right and then the left leg. This progressive involvement extended over the time between April and August 14, when she was still able to stand when supported. After this date she was completely paralyzed in the upper and lower extremities. Since the beginning of her illness she experienced a burning pain on micturition and had difficulty in starting. Later on there was retention and she had to be catheterized. At times she would have incontinence and dribbling without being aware of it. Toward the end of July she began to suffer from a continuous dull headache. There was no difficulty in vision, speech or hearing. Off and on she would have some difficulty in swallowing.

A month before admission to Bellevue Hospital she was delivered of her fifth child with very little pain after a normal labor. She did not feel the head coming. Nursed her child until Aug. 28.

She was admitted to Bellevue Hospital in the service of Dr. Carlisle on Aug. 29, 1915, complaining of pain in the back of the neck, with a complete paralysis of upper and lower extremities and incontinence of urine. *Status on admission*: Patient is poorly nourished, unable to move arms and legs. She appears not to suffer, although there is a toxic expression of her facies. The pupils were irregular and unequal and reacted sluggishly to light, but well to accommodation. There was pyorrhea of her teeth. The tongue was normal. The uvula deflected to left. The apex of the heart was in the sixth space one-half inch inside the left nipple line; sounds of poor quality and rapid; pulse fair, 116. Lungs, expansion practically nil, intercostal spaces exhibit very little excursion, breathing sounds faint, no rales. Nothing abnormal with abdominal viscera. There was a profuse perspiration over left face and arm. Bones: slight tenderness over fifth to seventh cervical and first dorsal vertebrae, also a slight curvature to right over this region. Rigidity of neck and limited motion.

August 30.—*Upper extremities*: Atrophy of extensors of forearm, interossei and flattening of thenar eminences of both hands, most marked in the right. At times one notices twitchings in the muscles. Complete spastic paralysis. Elbow and wrist reflexes were increased. Touch sense was good, pain diminished. Complete thermanesthesia, deep muscle sense normal.

Lower extremities: Some atrophy in both, occasional twitchings, complete spastic paraplegia. Superficial and deep reflexes increased in both, ankle clonus and Babinski phenomenon present in right but not in left foot. Touch sense normal, pain diminished, complete thermanesthesia, deep muscle sense present.

Trunk: Chest emaciated, abdominal muscles wasted, paralysis of intercostals. Abdominal reflexes absent. Touch sense good, pain diminished, complete thermanesthesia.

On September 2, patient developed an area of com-

plete anesthesia beginning at the last dorsal vertebra and extending down the entire body. This sensory disturbance progressed rapidly upward, and on Sept. 18 there was a complete anesthesia up to the level of the third rib except the inner sides of the calf, where there was an appreciation of deep pressure sense rather than pain sense. Babinski reflex and ankle clonus were now present on both sides.

A lumbar puncture was made on Aug. 30, 15 cc. of fluid were withdrawn under normal pressure. Blood was also taken on this date. The Wassermann of the spinal fluid and blood serum was negative. There were four cells to the cmm. of the fluid, globulin was negative, reduction test positive, there was also a trace of urea present. A vaginal smear was positive for gonococci. The radiographic examination was negative.

The urine analysis was made on several occasions. It was acid, of a varying specific gravity, 1010-12, contained faint traces of albumin, an occasional leucocyte and a few erythrocytes.

Blood-count.	Aug. 31, 1915.	Oct. 13, 1915.
Leucocytes	6,200	8,400
Polynuclears	59 per cent.	62 per cent.
Lymphocytes	31 per cent.	32 per cent.
Large Mononuclears.....	8 per cent.	4 per cent.
Eosinophiles		2 per cent.
Basophiles	2 per cent.	
Hemoglobin	53 per cent.	80 per cent.
Red blood cells.....	3,860,000	4,820,000
Platelets	many	

A tentative diagnosis of a cord tumor was made and the operation performed by Dr. Stewart on Dec. 28, 1915. The cord was exposed between the seventh and second cervical vertebra. Cord appeared normal and no tumor was found. Her respiration, which became shallow and labored before the operation, improved somewhat after, but the general condition was unchanged and she expired on March 5, 1916.

Postmortem Examination (Dr. Douglas Symmers).—The meninges covering the cervical enlargement of the cord for a distance of about 3½ cm. are thickened, especially on the posterior aspect. The thickening is largely confined to the leptomeninges and sometimes reaches 3 mm. in depth. Microscopic examination of the leptomeninges of the cervical region reveals great thickening due to the overgrowth of fibrillar connective tissue and to the presence of hyaline material. Embedded in the thickened meninges are large numbers of markedly distended, thin walled blood vessels, each of which is encircled by a thick layer of round cells. In occasional instances the vessel wall is thickened and in at least one instance the vessel shows the lesions incident to a well marked end-arteritis obliterans. The meninges lying between the distended vessels are richly infiltrated by small round cells of the lymphocytic type. The meningeal prolongations into the cord are marked by the presence of enormous numbers of small round cells of the lymphocytic type, and many of the smaller vessels in the substance of the cord itself show circumferential cellular infiltration.

Microscopic examination of a posterior root ganglion removed from the upper cervical region shows the following changes: At one point the periphery of the ganglion for a considerable distance shows the presence of overgrowth of fibrillar connective tissue, some of which has undergone hyaline transformation. The tissue for the most part is richly cellular, the cells being partly of the type of fibroblasts and partly of the type of small round cells of the lymphocytic variety. The substance of the ganglion itself shows scattered areas of hyalinisation, small areas of necrosis, and foci composed of finely granular, pinkish staining substance in which rounded or cylindrical nuclei are to be made out. Many of the vessels embedded in the substance of the ganglion are thickened and some show the typical changes of endarteritis obliterans. At one point in the substance of the ganglion there is a focus made up for the greater part of small round cells with a sprinkling of epithelioid cells, and in the center is what appears to be a typical Langhans' giant cell.

Microscopic examination of the nerve fibers proceeding from the posterior root ganglion shows the presence of enormous numbers of small round cells lying in the perineurium as well as in the connective tissue septa between the individual nerve fibrils. The blood vessels in the perineurium are markedly distended, and all of them show a mantling of lymphocytes.

Microscopic examination of the smaller vessels at the base of the brain shows the presence of widespread

hyaline transformation of the adventitia. The adventitia is diffusely and more or less abundantly infiltrated by small round cells. The muscle layer is apparently well preserved. The hyaline lamina is noticeably thickened, and the sub-endothelial connective tissues are irregularly but markedly sclerotic.

Histological diagnosis: Syphilis of the meninges and of the posterior root ganglia of the cervical cord.

CASE II.—John F., 52 years, elevator man, Irish. Family history negative. *Personal history*: Had gonorrhea thirty-five years ago, denies a chancre, was alcoholic, is an inveterate smoker. Otherwise denies having ever been ill. *Present illness*: Four years ago had shooting pains in his limbs and a beginning weakness in the lower extremities. This condition became progressively worse until three years ago, when he became partially paretic. At present he has no pain and his paresis has markedly improved.

Physical examination: The pupils are equal but irregular, they react very sluggishly to light and well to accommodation. The ocular fundi are normal. Abdominal reflexes are absent, knee jerks and achilles reflexes are exaggerated. Ankle clonus present on both sides but no Babinski. *Sensory disturbances*: There is an area of marked hyperaesthesia around the body about four inches in diameter corresponding to lines between the lower border of the ribs and the crests of the ilia, the anterior and posterior aspects of the parts below this line and the lower extremities are hypæsthetic. No ataxia of the upper extremities, but sways considerably with eyes closed. The Wassermann reaction of the blood serum and spinal fluid is negative. The spinal fluid contains one cell to a cm., globulin reaction is negative, reduction test normal. *This seems to be a case of combined sclerosis.*

CASE III.—*Cerebrospinal syphilis simulating multiple sclerosis*. Henry K., æt. 23 years, salesman, American born of Russian parents. Family history negative. *Personal history*: Denies venereal disease, alcohol and tobacco. Was operated for trachoma ten years ago; had a hydrocele of his testicles. Otherwise negative.

Present illness—Seven years ago his vision began to be blurred. He did not pay much attention to this eye defect until he developed a diplopia a year later, when he consulted Dr. Weeks. Four years ago his speech became slow and somewhat scanning and at times stuttering. In June, 1913, the Wassermann of his blood was strongly positive and he received five salvarsan injections intravenously in intervals of five days followed by inunctions of mercury. After the last injection he developed an intention tremor in his hands which soon became very active and ataxic, so much so that he was unable to even hold a pencil or other objects and had to be fed.

In March, 1914, Dr. J. E. Weeks referred him to me with a diagnosis of a double optic atrophy following a neuritis. His Wassermann of the blood and spinal fluid at this time was negative; there were six cells to the cmm. of the fluid all lymphocytes, globulin normal and reduction test normal. He still had a diplopia with a paralysis of the right external rectus of the eye and lateral nystagmus. The pupils were unequal and sluggish to light. His gait was of the spastic-parietic type. The abdominal reflexes were absent, the cremasters present, the patellar and achilles reflexes markedly exaggerated, ankle clonus present on both sides, extension toe reflex to the Oppenheim method on right side only, no Babinski on either side. A few months after this examination the Babinski reflex appeared on both sides. The Wassermann of the blood remained negative up till to-day. The optic atrophy in the right eye is complete now and seems to be at a standstill in the left. His visual field in the left eye is concentrically diminished. During the time under our observation he has received injections of a soluble salt of mercury for a year alternately with iron arsenate. During the rest of the time no treatment whatever.

His tremor has since then completely disappeared, his speech has improved and there is no diplopia. His gait is fairly good. He is employed for the last six months as a clerk and writes as well as ever.

46 EAST FIFTY-SECOND STREET.

Rice Water.—To make rice water, which is serviceable in diarrhea and vomiting, especially of children and also as a drink in febrile diseases, boil one ounce of washed rice in a quart of water for an hour, strain through muslin, and flavor with honey and lemon juice.

MEDICAL TREATMENT OF GASTRIC AND DUODENAL ULCER.*

By FENTON B. TURCK, M.D.,

NEW YORK

ALL cases of ulcer of the stomach and duodenum are primarily cases for the internist. Their symptomatology has been widely discussed by surgeons, largely with a view to the indications for operative procedure, while the role of the internist has not received the recognition it deserves. Even in such cases as seem to demand surgical relief, preliminary treatment, except in emergencies, is a most valuable and necessary factor in the problem. Again, after the surgical indications have been met, a prolonged after treatment by the internist is a vital necessity and fortunately is recognized as such and recommended by the modern surgeon. Moreover, there is a wealth of clinical experience which goes to show that many cases of gastric and duodenal ulcer yield to scientific and painstaking medical treatment with apparently complete restoration of digestive function, and it is such cases that compare very favorably with the statistics of surgical procedure, where temporary relief is followed so often by recurrence of symptoms.

It goes without saying that the prime requisite for any course of treatment is a convincing diagnosis, and this is not always a simple matter in the early stages of peptic ulcer.

Petren regards the following symptoms as cardinal: (1) *Periodicity*, in the course of the affection, i.e. periods free of illness several times as long as those in which typical symptoms are manifest. (2) *Distress*, attending food ingestion. (3) *Vomiting*, almost invariably followed by abatement of distress. (4) *Tender points* behind and lateral to vertebral column. (5) *Intestinal hemorrhage*. (6) *Hyperchlorhydria*. (7) *Constipation*, or rather absence of diarrhea.

These make up a syndrome, entirely characteristic, but the stage of the ulcerative process and the personal equation of the patient may considerably modify the clinical picture.

Eusterman² of the Mayo Clinic, in an analysis of 2,400 cases of gastric and duodenal ulcer that have come to operation and the diagnosis thus verified, has found that "the diagnosis of uncomplicated peptic ulcer was made in 80 per cent. of the cases." He says, "The complex of chronicity and periodicity of attacks in which pain and distress and the usual association of symptoms, repeated uniformly day by day during the attacks and having a fairly definite relation to food intake and control, is of primary importance in the diagnosis." "The remaining 20 per cent. of the cases presented many difficulties to the diagnostician."

Naturally no practitioner would neglect the obvious laboratory tests for the determination of the degree of acidity and amount of retention of the stomach contents, the presence or absence of occult blood in the stools, etc., etc., and modern radiography may contribute to the diagnosis, although all agree that it has its limitations. But what is most fervently to be desired is an attitude of mind which will recognize the importance of rational and continued treatment of the gastrointestinal tract in such cases as show a frank disorder but without positive diagnosis of ulcer. Such

*Presented at the nineteenth annual meeting of the American Gastro-Enterological Association, Washington, D. C., May 9, 1916.

cases promise exceedingly well; unfortunately it is not the rule but the exception for cases of ulcer to seek professional advice in their earliest stages.

On the other hand it must be remembered that not a few cases are rushed to operation on the suspicion of an ulcer, in which no ulcer is found on laparotomy, even after a suggestive history and in spite of apparent radiographic findings. In this connection Cole³ recently followed up 33 cases to the operating table. Twenty-one cases were symptomatically diagnosed ulcer of the stomach, and no ulcer could be demonstrated at the operation. The other eleven cases were of spasm of the pylorus and other functional disorders. Certainly, such cases are not the province of the surgeon. Whether or not we acknowledge a "pre-ulceration stage" of the same gastric disorder, the weight of argument is entirely for systematic medical treatment at the earliest possible moment. Joslin,⁴ from the study of a large series of cases, found that on the average they did not come into the hands of the internist until they had suffered from the disease at least six years and that they did not reach the surgeon until the disease had been present ten years. This suggests the need of a campaign of education which shall serve to focus the attention of the practitioner on the earliest recognizable symptoms of peptic ulcer. The lay mind, too, should be taught that indigestion that does not yield to ordinary dietetic care and hygienic measures, requires the attention of one specially skilled in the treatment of these digestive disturbances which, if neglected, may lead to chronic ulceration and even carcinoma. It may be that the vagueness of ideas as to the etiology of gastric and duodenal ulcer has been responsible for the conflict of opinions as regards their treatment. There remains very much yet to be determined in regard to the production of ulcers in the stomach and duodenum, but it is no longer safe to consider such lesions as purely local in their causation and in their systemic influence. Since the demonstration ten years ago by the author¹ of peptic ulcer induced in dogs by continued feeding of bouillon cultures of *Bacillus coli communis*, a basis has existed for the consideration of ulcer as a result of long exposure of the individual to the effects of intestinal flora multiplying in conditions favorable to their continued virulence and at the same time conditions which gradually break down the normal resistance of the system to a toxic invasion, which is in no sense inflammatory and by no means an infection. All factors which may render the tissues more vulnerable come into play as contributory causes for the production of ulcer on this hypothesis. Faulty or low grade metabolism, nervous exhaustion, insufficient nutrition or the opposite extreme of over-feeding with accumulations of waste products, stasis, distention and atony of the wall of the intestinal tract, all seem to predispose to the gradual yielding of the natural protective antiferments of the gastric and duodenal mucosa with the possibility of an autolysis.

In a contribution in 1914, the author⁶ was able to demonstrate that bacteria diffusing into the intestinal wall are unchanged until they permeate to the areolar zone lying just beneath the muscularis mucosæ, where they are at once killed and disintegrated. This normally protective power of the so-called zona transformans is, under abnormal conditions, very much impaired; shock, obstruction, venous stasis, atony, and overfeeding being among

the causes operating to lower the bacteriolytic function of this portion of the intestinal wall.

These findings are highly significant for the solution of the riddle that peptic ulcer has always been to the scientific mind. There would seem to be confirmatory evidence in clinical experience for this concept of the etiology of gastric and duodenal ulcer, in the marked improvement and ultimate recovery of cases where treatment was directed largely toward a readjustment to normal of the gastrointestinal tract as a whole, with special reference to relief of congestion and atony of the colon, and a reduction of the intestinal flora and retardation of their growth.

The results of operative procedure on the other hand are open to discussion and even criticism by competent authorities.

Kuttner⁵ performs resection in every case of tumor-forming callous ulcer, as he is convinced that this ulcer is in reality of cancerous nature, but the development of other forms into cancer does not occur in his opinion. He adds that gastroenterostomy must be attended by mechanical stenosis to be efficient. Faulhaber and von Redwitz⁷ state that mere gastroenterostomy is followed by various complications. Mayo⁸ explains that where the pylorus is open much of the food passes out through the pylorus instead of through the gastrojejunostomy opening. Hamburger and Leach,⁹ after careful research, explain these operative failures. They show that if the pylorus is left patent, a vicious circle is set up; stasis in duodenum, spasm, or secondary contraction of the opening, are liable to continue the abnormal gastric function or to increase it. This is corroborated by Martin and Carroll¹⁰ who find that roentgenographical examination in man as well as in animals shows that "a patent pylorus continues to functionate in the presence of a patent stoma." E. von Herczel Pester strongly criticises the operative procedures employed in gastric and duodenal ulcers and materially disagrees with both English and American surgeons. His criticism confirms the suspicions previously aroused by Zweig¹¹ that these failures "stand in marked contrast to the rosy reports from surgical clinics." Rodman¹² expresses the regret that "while patients make operative recoveries they are not cured." Moynihan¹³ says: "If the ulcer is small its scar may be inconspicuous and offer little or no obstacle to the easy escape of food. The pylorus then again transmits all or much of the food; the ulcer subjected to renewed irritation breaks down and the symptoms are repeated. The last state of the patient is the same as the first."

M. Leriche's statement¹⁴ of eight years ago that statistics do not tell us whether gastroenterostomy is or is not the treatment of choice in chronic ulcers can be answered by the general advice given by Connell.¹⁵ "I would emphasize the necessity of awaiting remote results before drawing conclusions, as the immediate result is invariably most encouraging and relapse far from uncommon." Cases reported after several operations—"temporary improvement, then return of original complaint."

It seems evident that the error that has been made in the surgery of ulcer is that more attention has been paid to the morphology than to the etiology of the condition, it being generally attributed to local arterial thrombosis or sclerosis. This idea originated with Virchow but has never been established. Brun¹⁶ states that the failures to relieve symptoms when surgery was confined to the operations on the stomach resulted in the adoption of

Lane's methods of excision of the colon or ileosigmoidostomy, with a considerable following in England and in this country. Experience has shown, however, that operative procedures for the correction of intestinal stasis are attended with a high mortality, a realization which has somewhat halted the enthusiasm in this country, especially since it is becoming more evident that far less drastic measures can be employed with success.

The United States ought to be able to give the best résumé on the value of surgical operation in all forms of peptic ulcer, for there seems to have been no hindrance to the operative attempts to cure ulcer of every form. Indeed, operative procedures for the relief of ulcer have assumed almost a national passion in which the internist has acquiesced because of the inadequacy of the usual methods to obtain curative results. Because of medical failure we should not cast the responsibility on the surgeon, who, only too often, adds a surgical failure. In 1906 the late Nicholas Senn, Dean of American Surgeons, in a manuscript communication now in my possession, did not hesitate to crystallize definitely the results of his experience. "I regard ulcer of the stomach," he writes, "a strictly medical disease and treat it as such. The only indications for surgical interference are obstructions from cicatricial contraction and dangerous hemorrhage. I look upon gastroenterostomy in all other cases or any other surgical procedure as irrational treatment and one that is liable to be followed by grave remote disturbances of digestion by making a physiological exclusion of the most important part of the intestinal canal and by establishing an abnormal opening between the stomach and the intestinal canal."

Ten years have passed in which surgical endeavor has had its greatest vogue. And now the pendulum swings back again and the words of Senn are echoed by Sir John Bland Sutton." In his Hunterian lecture in February of this year, he observes that "since the treatment of duodenal ulcer passed into the province of surgery it has become the routine practice to perform gastroenterostomy." He protests that "this procedure is inefficient with a patent pylorus, for the chyme ignores the new stoma as the x-rays readily demonstrate. Again, if the pylorus is obstructed, the chyme passes directly into the jejunum, where a remarkable transformation occurs. The wall of the jejunum receiving the impact of the chyme ejected through the new stoma becomes attenuated, the valvulae disappear and the jejunal walls assume the peculiarities of the supra ampullary segment of the duodenum. This change entails the liability to jejunal ulceration so commonly found; thus a new ulcer has been evolved in this generation by alterations in the environment of the jejunum brought about by surgery." As we have shown, the evidences are fast accumulating, and give weight to the statement that operation should be reserved for those cases in which it is clearly indicated because of mechanical obstructions, not functional resistance. The cure of ulcer remains a biological or physiological problem.

To the clinician the cure is a very practical problem as well; acute symptoms are to be alleviated, the bodily strength is to be maintained and eventually the digestive function is to be restored to normal. It is unfortunate that the medical treatment of ulcer has largely been a matter of a routine, not merely because the healer should adapt his procedures to the daily progress of the patient, but because many of the routine diets are both theoret-

ically faulty and clinically unsatisfactory. The common procedure, for example, is to institute, after a short period of fasting, a diet of *cold milk* and *eggs* in small quantities every hour. These amounts are gradually increased with the addition, during the second week, of *sugar, rice, scraped beef, raw ham* and *butter* as advocated by Lenz. hartz.

To this my experience bids me take exception on several points. Firstly, I oppose frequent feedings with the system of the one- and two-meal day, for it has been found that small quantities in an atonic stomach remain nearly as long as larger amounts, while at each taking of food fresh stimulus to the flow of HCl is induced. Again the addition of food to a stomach which may already contain partially digested material is certainly non-physiological. With the two-meal system the caloric need of the body is better satisfied and incidentally the patient's appetite and general comfort is spared the insult of an interminable series of feedings.

As regards the food given, I have felt that eggs are not well borne, from their tendency to putrefy in the intestine just at the time when it is most desirable to maintain adequate function of the colon. Among the split products of lecithin are highly toxic cholin and neurine, to which many patients seem to be very susceptible. Milk, as a dietary basis, does not enter my scheme of treatment; its clotting in the acid stomach delays emptying, while the casein serves too readily for pabulum to the intestinal flora. When peptonized it is unpalatable in the extreme and indeed patients, in most cases, rapidly develop a repugnance for milk in any form when pushed to the extent necessary to give even a moderate share of the caloric requirement. Furthermore a milk diet contains a quite unnecessary excess of fluid and is frequently followed by a distressing amount of gas in the intestine with abdominal distension.

To make my position clear, I propose to outline a method of treatment capable of broad adaptation to the mildness or severity of the individual case, yet concrete and definitive enough to illustrate my principles and my purpose.

It will now be desirable to give in some detail the means employed in this method of treatment with a discussion of the scientific basis and practical aim of each. Rest in bed is required for the first two weeks and advised for the third. There is a preliminary period of three days fast during which small amounts of water may be allowed. On the fourth day a single meal of about 800 c.c. of corn starch gruel is allowed; following this the patient is given two meals a day with gradually increasing amounts of rice, steamed vegetables, and hydrolyzed meat. Naturally the diet must be adapted to each case and changed to suit the symptoms which may come out under treatment. When meat is allowed early in the second week, the extractives must first be removed by soaking the ground meat in cold water for 12 hours, then by pressing out the juice and discarding it.

The indication for this removal of meat extractives is the gastric hyperchlorhydria, for it has been demonstrated that their presence has a definitely stimulating effect on acid production. The meat pulp that remains is placed in boiling water and steamed for one or two hours until the connective tissue is hydrolyzed to gelatine, the larger part of extractives removed and the stearin fat, so difficult of digestion, is driven off. This process leaves

a meat residue of rich protein value (50 per cent.), very digestible and of high acid binding power; it is rapidly absorbed leaving no protein residue to augment bacterial growth in the intestines. Vegetables, similarly, should be steamed for two or three hours, to render them demulcent to the stomach and lessen the tendency to intestinal fermentation. When so treated, vegetables do not lose their alkaline properties nor their caloric value as when boiled; and aside from their nutrient value act as a colloidal paste on the mucosa of the gastrointestinal tract.

OUTLINE OF TREATMENT

DIET	TREATMENT
1. Week. 1 day } <i>Fasting. Rest in bed.</i> 2 day } 3 day } Analgesic emulsion before feeding. 4 day } 1 meal 500 cc. corn-starch gruel to be sipped in one hour after morning lavage. 5 day } 6 day } 7 day } 2 meals of rice, steamed vegetables and mashed potatoes.	Aspiration of gastric fluid 1 hr. each day. Filter washed with NaHCO_3 . Alkaline powder $3\frac{1}{4}$ when required with water. Lavage with AgNO_3 1:10,000 left in $1\frac{1}{2}$ minutes. Washed with green soap. Alternate days. Colon stimulation with pneumatics. Alternate days.
2. Week. 2. <i>Rest in bed.</i> Two meals a day of rice custard, mashed potatoes. Vegetables steamed 3 hrs. under pressure, hydrolyzed to paste. Meat (small amounts) chopped fine and extracted in cold water for 12 hrs., steamed to hydrolyze connective tissue and remove extractives, also to drive off stearin fat. Minimum of milk and eggs. Sugar allowed. Keep up calories.	Aspiration every day. Colon stimulation. Alternate days. Lavage with AgNO_3 1:2000 (500 c.c.) for $1\frac{1}{2}$ minutes. Alternate days. Alkaline powder when required.
3 & 4. Week. 3 & 4. <i>Rest, not necessarily in bed.</i> Increase food amounts gradually, still insisting on hydrolyzed meat and vegetables.	AgNO_3 lavage and colon stimulation only at intervals. Vaccines of <i>B. coli communis</i> . Autogenous, sensitized to patients' serum. Start with 50 million, watch reaction, increase doses every 6 days.
5. Week. 5. Get out into sun and open air. Stimulate interest and appetite.	Iron and iodides if needed. Gastric exercise by double tube insufflation of hot moist air with aromatics, and Hot water intragastric bag 115 deg. x 800 c.c. Thyroid gr. $\frac{1}{4}$ three times a day. Pituitrin if indicated. Colon stimulation twice a week.

Drainage.—Among the non-surgical procedures, which, in the experience of the writer, have been found helpful in dealing with gastric and duodenal ulcer, is continuous drainage, from the stomach by the use of a tube filter which I devised and used since 1894. The filter is a gold plated metal bulb attached to the end of a rubber tube of small caliber which passes through the mouth into the stomach and is left there for an hour or more, thus draining the excessive acids and toxins from the stomach. As I stated, when I first published this method,¹⁸ this stomach tube filter is "for the purpose of withdrawing fluid contents from the stomach in cases of hypersecretion, allowing the solid food to remain behind. By removing the excess of fluid that accumulates in the stomach and the toxins which are in solution it permits the digestion to continue and obviates the necessity of removing the solid food which is so essential to nutrition. For the purpose of withdrawing the fluid through the filter by suction an exhaust pump is used; or the outer end of

the tube may be inserted into a vacuum bottle which exerts a continuous suction. At the same time the fine openings in the bulb of the stomach tube filter prevent aspiration and injury to the mucous membrane, something which will always occur with the plain stomach tube without the filter bulb; furthermore, unless the tip is well weighted, the end of the tube will not sink into the fluid at the bottom of the stomach." The tube may even be passed through the nose after cocainizing the nasal tract. The patient soon becomes used to its presence and it is not so objectionable as when passed through the mouth. The relief is so great that the patient prefers its use.

This drainage not only relieves the stomach from liquid contents of the hypersecretion, but so lessens the degree of the hyperacidity that spasm of the pylorus is reduced, and the food particles more readily escape into the intestine. The daily removal of the fluid load also relieves the stretching and atony of the stomach wall.

A similar bulb of small caliber and open end may be passed through the pylorus into the duodenum. As I showed in 1895, being I believe the first to make this demonstration, we may thus furnish nutrition fluid directly to the intestine, giving complete rest to the ulcerated stomach area.

If the stomach findings indicate gastritis with continuous acidity, local treatment is required.

The use of alkalies and the fixation of stomach acid by albumin will not permanently reduce the hyperacidity, but indeed may increase it. On account of the tendency of ordinary lavage to increase atony of the stomach, its use is limited. It is my custom to begin this course of treatment with a few cleansings of the stomach and then to proceed along other lines. Gastric lavage with silver nitrate is very helpful in cases of ulcer with high acidity.

The first effect of the silver nitrate on the stomach is a superficial coagulation of the surface; the dead epithelium, debris, and mucus are washed away with the lavage water. An intense hyperemia then follows, but the end result is a normal circulation of the stomach. The venous congestion is reduced and fresh arterial blood and lymph course through muscle and glands, with a resultant stimulation of new antibodies. In this procedure some albuminate of silver is formed and carried down into the duodenum, causing an intense hyperemia of the mural structures. The common duct is narrowed and the liver becomes engorged, percussion sometimes showing an increase of one inch in liver dulness. In three to twelve hours a reaction takes place, the duct opens wider, and the retained secretions flow out in abundance. Their alkaline reaction influences the pylorus so that the stomach can empty itself; the acid contents of the bowels are neutralized, and intestinal digestion is assisted; constipation is relieved; the stool may even be loose for a time. One or two applications of the silver nitrate lavage may start the patient permanently in the right direction; it should not be repeated more often than every other day, and should always be given to a fasting stomach, never when food is present. The strong solution should be used for a short time, and the treatment then continued with a weaker one. Soap lavage is also useful in hyperchlorhydria, increasing the circulation and stimulating the glands to fresh secretions. By adding oil of cloves, oil of cinnamon, and menthol, the douching solution may be rendered slightly antiseptic. A 5 per

cent. slippery elm infusion makes a useful demulcent lavage.

Intragastric Hyperemia.—Januschke,¹⁰ in the treatment of stomach ulcer and related conditions states that hyperemia produced by heat decreases irritation, quiets pain, and exercises a curative effect in the diseased tissues. The most brilliant and prompt results possible to obtain are secured by the application of heat within the stomach by a unique but simple method devised by me many years ago.²⁰ A thin rubber bag is carefully tied to the end of a long stomach tube (preferably the double recurrent tube) and introduced into the stomach. The thin rubber does not materially enlarge the tube. Water at a temperature of 110° F. is allowed to run into the bag within the stomach until the patient becomes sensible of the pressure. At the end of two or three minutes the water is returned and a new supply is introduced and the process repeated. The temperature may be increased according to conditions, as high as 118° F., which insures prompt hyperemia of the splanchnic vessels, and reduces venous stasis. The patient for comfort may remain in a reclining position during the treatment. By this means we obtain a gentle passive exercise for the gastric muscles with the immediate application of heat; as a result the pain disappears, the pylorus relaxes its spasm and a great advance has been made toward the healing of the ulcer.

My experiments and clinical observations lead me to the conclusion that peptic ulcer is intimately related to intestinal disorder and abnormal function. This is the conclusion of most operators throughout the world after a careful analysis of all factors that have been presented. Those who hold that it is the result of local infection or localized infection from the blood still regard the intestinal stasis as providing conditions that allow ulcers to form that otherwise would not. The treatment of the intestinal stasis by operative procedures has resulted, it is claimed, in many cures. After failure by surgical operations on the stomach or duodenum, many cases are reported by Lane, Jordan, and other operators, of successful results by Lane's methods for the cure of intestinal stasis. But prompt, effectual and permanent improvement is obtained by a treatment of the colon which I have mentioned on previous occasions.^{21 22} The intermittent introduction of hot water alternating with air, excites peristalsis, relieves atony, and reduces venous stasis as well as cleansing the cecum and ascending colon." While some prefer to place the patient in a lateral position, I find that by elevating the hips to a considerable height, the dorsal position can be employed with advantage and I have, therefore, constructed a special table adapted to my purpose; by means of this table the patient can be raised to any angle desired.

To avoid the evil effects of over-distension with water, it has been my custom for many years to allow only a small quantity of fluid to enter the bowel at one time—100 to 300 c.c., then disconnecting the reservoir, this fluid is allowed to escape through the tube, as in lavage of the stomach. By increasing the temperature (110°, 115° 120° F.), according to the condition, a high degree of stimulation is obtained. Repeating this process produces a form of exercise for the colon. In weakened and atonic conditions, the water used, even in the careful manner described, is not all recovered, but remains part-

ly in the bowel; this results in fatigue and tends to increase the atony. By inflating the bowel with air and pressing upon the abdomen, the air is forced out. Repeating this a few times induces peristalsis, which drives the water and fecal matter through the tube out of the bowel. By connecting the tube with a Politzer bulb and alternately compressing the bulb and releasing the pressure, the entire column of air as far as the cecum is set in vibratory motion; this stimulates peristalsis, and brings about a condition of healthy tone in the muscle wall of the colon.

In repeating the indications for treatment emphasis must be placed in directing this treatment to the local and general condition simultaneously, and nothing should be neglected which lends itself to this end. In 1908 I called attention to the importance of inoculation with autogenous intestinal vaccines sensitized by the sera of the patient. At that time I said, "So far the most practical results have been obtained by the injection of dead bacilli." Now I have found, in addition, after certain reaction with the patient's serum, that sensitized *group* vaccines can be more advantageously administered.

The value of injection of diphtheria antitoxins which I previously suggested has been shown to be due to the horse serum itself, and its effect in checking hemorrhage. The use of human serum may have value in obdurate cases of peptic ulcer as contributing antebodies which the ulcer status so markedly lacks. This phase of the problem is so intricate that we can do little more than feel our way in the light of a few guiding principles.

Veeder,²³ Schmidt,²⁴ Flesch,²⁵ and Cheinisse²⁶ show that ulcer so common before the first year in infancy is due to lack of immunity and the immunity is acquired later as the child develops. Stoerck²⁷ shows that in status lymphaticus this immunity fails to develop as the child grows, and ulcer then continues to form. In producing ulcer by experimental means the reduction of this general resistance is sought by various methods before attempting the local trauma or infection to produce the ulcer. Injection into blood with pyrogallie acid, pyroin, tetrahydro B.-naphthalene, marked venous congestion, repeated hemorrhages, subjecting animals to unsanitary conditions, are all intended to reduce the normal degree of immunity before attempting to induce ulcer. Accordingly we should bear in mind that no pains should be spared to restore as far as possible the normal resistance of the organism to the subtle action and reaction of the underlying toxemia.

Blood transfusion, now utilized only in cases of anemia and hemorrhage, may be practised in the future with this aim of arming the weakened bodily fluids with vigorous protective elements.

It is not infrequent that a general metabolic deficiency is in the background of this condition of lowered resistance. In many cases I have observed a distinct advantage in the use of thyroid gland beginning with doses of a quarter of a grain twice a day which may be gradually increased with careful reference to the effect upon the patient. The dried pituitary to-day has served as a corrective to the thyroid and seems to contribute to general intestinal tone.

Drugs.—The use of drugs for their *palliative* effect has been considered a makeshift and of but little scientific interest. Since ulcer is regarded by surgeons as a process kept in activity by gastric

secretions, a new value has been added to that class of drugs that restrict the production and irritating effects of the gastric juice. Hence atropine, as it controls hypersecretion, is useful. "It breaks into the vicious circle by giving rest to the ulcer, thus aiding its healing." Westphal and Kasch,²⁸ Bergmann²⁹ recommends 0.001 to 0.004 grams daily dosage continued for a long time. Januschke³⁰ shows that atropine stops spasm while anesthesin will lessen the pain, and papaverine will save the mucous membrane from irritation, giving the ulcer an opportunity for healing. Bismuth has been used successfully for years, especially by the older practitioners, for local effect. Insoluble colloids exert a still further advantage; they remove the bacteria from the mucous membrane by mechanical adsorption. I have called attention to the manner in which bacteria colonize on the surface and pass up between the glands. The removal of these microorganisms can be accomplished by various colloid and insoluble demulcents. I have used and recommended bran, slippery elm, Irish moss, or bismuth, for many years, to remove these bacteria and to inhibit their growth upon the surface of the mucous membrane. Hektoen³⁰ finds that kaolin has this same property of removing bacteria by adsorption and is of service in a wide field of mucous membrane infections since it will inhibit bacterial growth in the intestines, and will act as the other colloids mentioned in preventing the passage of bacteria or their toxins into the tissues. Ordinary antiseptics as formerly used have been found of no practical value. For the relief of the outstanding symptoms of gastric distress in ulcer, mixed alkalis with analgesics have proved to be a reliable resource, especially when administered before the hour of feeding.

In conclusion, I may say that the treatment of gastric and duodenal ulcer by the means and method that I have very briefly reviewed is the result of painstaking care and observation of many cases. If it were not for the gratifying results of the application of these principles, results oftentimes achieved to my own surprise in cases for which operation had been considered imperative, I should not urge so strongly the need, opportunity and hopeful prognosis of the medical treatment of ulcer of the stomach and duodenum.

FERMENTED MILK IN INFANT FEEDING;

A FURTHER STUDY.

BY ALBERT E. MUCKLOW, M.D.,

BROOKLYN, N. Y.

SINCE completing a previous article¹ a persistent effort has been put forth to make the method there described more exact.

Fermented milk and whey² mixtures were tried for a year in a series of cases. The results, while excellent, were no better than those obtained from fermented milk and water mixtures and the added expense and labor in preparing the former made them impractical in many cases; hence, they were discontinued.

The method described in the first article,¹ with the refinements presented herewith, is exact, easily executed, and adaptable to all conditions with a minimum of mental effort.

The flexibility of the accompanying formulas, whereby the percentage of fat, proteins, or sugar may be increased or diminished individually or collectively, is shown herewith.

	2.50 per cent
	3.50 per cent
	4.50 per cent
	5.50 per cent
Formula No. 1—Proteins 1.00 per cent; sugar 7.50 per cent; fat	2.50 per cent
	3.50 per cent
	4.50 per cent
	5.50 per cent
Formula No. 2—Proteins 0.80 per cent; sugar 7.50 per cent; fat	2.50 per cent
	3.50 per cent
	4.50 per cent
	5.50 per cent
Formula No. 3—Proteins 1.00 per cent; sugar 7.50 per cent; fat	2.50 per cent
	3.50 per cent
	4.50 per cent
	5.50 per cent
Formula No. 4—Proteins 1.20 per cent; sugar 7.50 per cent; fat	2.50 per cent
	3.50 per cent
	4.50 per cent
	5.50 per cent

Formula No. 5—Proteins 1.40 per cent; sugar 7.50 per cent; fat.....	2.50 per cent 3.50 per cent 4.50 per cent 5.50 per cent
Formula No. 6—Proteins 1.60 per cent; sugar 7.50 per cent; fat.....	3.50 per cent 4.50 per cent 5.50 per cent
Formula No. 7—Proteins 1.80 per cent; sugar 7.50 per cent; fat.....	4.50 per cent 5.50 per cent
Formula No. 8—Proteins 2.00 per cent; sugar 7.50 per cent; fat.....	5.50 per cent

The formulas are based upon the analyses of cow's milk formerly reported;¹ upon the fact that 0.69 per cent. of the sugar content of milk is lost during fermentation; and upon the knowledge that the richness of a bottle full of milk that has been bottled immediately after milking and undisturbed after bottling, can be determined by the depth of its cream layer.¹

The ideal formula to insure proper nutrition and growth is one containing 5.50 per cent. of fat,¹ 7.50 per cent. of sugar,³ and a percentage of proteins varying from 0.60 per cent. at birth to 2.00 per cent. at twelve months.

The percentage of fat should be reduced in the presence of any of the following: Persistent vomiting. Soap stools⁴ (putty stools). These consist of soaps of calcium and magnesium. Fat stools.⁴ These contain a large amount of free fat and are visibly oily.

Under any of these conditions the fat should be temporarily reduced to 4.50 per cent., 3.50 per cent., or in very feeble infants, to even 2.50 per cent., the subsequent return to the higher percentages being as prompt as possible on account of the value of the butter fat *per se*, and the "vitamins"^{5,6} associated with it.

The proteins should be increased with sufficient rapidity to insure a weekly gain of 6 to 8 ounces.

Malt sugar should be used in raising the sugar content of the formulas to the desired percentage. It is the most readily assimilated⁷ of all the sugars. By its use the fermentative disorders caused by commercial lactose, or cane sugar, are avoided, with a consequent better absorption of the fat.⁴ A convenient form of malt sugar is a malt extract in which 1 ounce by volume contains 1 ounce by weight of combined maltose and dextrin.

To facilitate the construction of the formulas and to simplify their description, larger amounts of the several ingredients than are needed in practice have been given in some of the tables. They may be proportionately reduced for everyday use.

The addition of bicarbonate of soda to the fermented milk to decrease the acidity, and thereby make it more palatable, has been discontinued. The milk is sufficiently palatable without it, and the greater acidity is desirable, being more antagonistic to pathogenic bacteria. The germicidal effect of lactic acid in milk has been emphasized by Heine-mann⁸ of the Department of Bacteriology and Hygiene at the University of Chicago.

The ideal temperature for fermenting the milk has been found to be 98° Fahr., in which temperature a sufficient amount of lactic acid to destroy harmful bacteria is most speedily produced.

The armamentarium has been increased, consisting in its entirety of the following: The fermenter described in the previous article,¹ lamp, two thermometers, one for the fermenter and one for the water bath used in warming the feedings, Kremer No. 8 wash boiler in which to sterilize the utensils, large-sized enameled skimmer to remove small articles from the boiler after sterilization, Chapin 1-ounce cream dipper, fine-meshed strainer, six 1-

quart lightning preserve jars with rubber washers, two 1-pint glass tumblers, two 3½-quart enameled pitchers, two enameled pans, one to be used as a sterile receptacle for the small utensils while preparing the mixtures, and the other to be kept filled with boiling water to quickly sterilize any article that may become contaminated while in use, and a No. 50½ Chatillons straight spring balance scales graduated in quarter pounds and weighing up to 30 pounds.

In estimating the depth of the cream layers, measurements as small as quarter dipperfuls have been found practical. Hence, the following has been adopted to secure greater accuracy in judging the richness of a given bottle full of milk:

4.00 Per Cent. Fat Milk	4.40 to 4.80 Per Cent. Fat Milk	5.20 to 5.60 Per Cent. Fat Milk
Cream layer, less than 5½ dipperfuls	Cream layer, 5¼ to 6¼ dipperfuls	Cream layer, more than 6¼ dipperfuls

In preparing a formula in which whole milk is used the richness of the bottle full of milk from which the whole milk is to be taken should be first determined by dipping off the cream into a pitcher and noting the number of dipperfuls removed. Then proceed to prepare the formula as follows:

Pour the rest of the contents of the bottle into the same pitcher. Pour the entire amount back into the bottle. Again pour the contents of the bottle into the pitcher and back into the bottle; that is, four pourings in all to mix the milk thoroughly.¹

Dip off into the empty pitcher—dipperfuls of this mixed milk.

Skim off the top—dipperfuls from another bottle full of milk that has not been disturbed and add these to the above milk in the pitcher.

Add either the contents of — vials of the Bulgarian bacillus culture (add these every fourth day) or — teaspoonfuls of the preceding day's fermented milk.

Pour the above into a preserve jar. Seal it and stand without disturbing in 90° to 100° (best 98°) Fahr. for twenty-four hours.

Rub the fermented milk through a fine meshed strainer, being sure to leave none on strainer.

Excepting every fourth day, take — teaspoonfuls of this fermented milk and add them to the next milk to be fermented.

Add to the above fermented and strained milk — dipperfuls of cold water and — dipperfuls of malt extract.

Pour the completed mixture into one or more preserve jars. Seal them and immediately place them on ice.

In preparing a formula in which only top milk is used, the richness of the bottle full of milk from which the top milk is to be taken should be first determined as follows:

Dip off the top four dipperfuls into a pint tumbler. Dip off the fifth dipperful into a second pint tumbler. Dip off the sixth dipperful into a half-pint tumbler to avoid confusion. Dip off the seventh dipperful and retain it in the dipper. Note the number of dipperfuls of cream removed. The amount of top milk required in the formula should then be fermented as *aforescribed*.

As a temporary expedient only while awaiting the fermentation of the first lot of milk in a given case or while traveling, the casein may be made digestible⁹ by boiling the milk for five minutes in-

stead of fermenting it. However, other than raw milk should not be used for any protracted period. The danger of malnutrition from the use of heated milk, not only when sterilized, but even when pasteurized, is a real one. The study of infantile scurvy by Hess and Fish¹⁰ has shown the danger of using pasteurized milk even when a temperature as low as 145° Fahr. is employed.

The following are imperative:

Use Certified Milk.

The bottles of milk, when received from the dealer, and the jars containing the completed mixture, should immediately be placed in the ice chamber of a refrigerator, either in the middle of the chamber, with a cake of ice on either side of and in contact with them, or what is better, but usually impractical, in a pail full of cracked ice. They should be kept in an upright position until needed.

COMPOSITION OF ABOVE FORMULAS.

Fat 5.50% in each.
Proteins 0.60% in 1st, 0.80% in 2nd, 1.00% in 3rd, 1.20% in 4th, 1.40% in 5th, 1.60% in 6th, 1.80% in 7th, and 2.00% in 8th.
Sugar 7.50% in each.
Ash 0.12% in 1st, 0.16% in 2nd, 0.20% in 3rd, 0.24% in 4th, 0.28% in 5th, 0.33% in 6th, 0.37% in 7th, and 0.41% in 8th.

Use a Chapin cream dipper that has been accurately made to hold exactly 1 fluid ounce, to measure the milk, water, and malt extract. The first dipperful from a bottle full of milk should be removed with a teaspoon to avoid spilling.

A dozen vials of a culture of Bulgarian bacilli should be purchased as often as required direct from the laboratory of the manufacturer, immediately placed in the ice chamber of a refrigerator next to the ice and there kept until used.

The water used in the formulas should be cold and should have been either distilled or boiled for 5 minutes.

All utensils should be boiled for 5 minutes just before using them.

Make each feeding warm (not hot) by standing the nursing bottle containing it in a kettle full of water for fifteen minutes, the water being kept at 98° Fahr. by the frequent addition of warm water.

To summarize: The formulas should be prepared with clean hands and sterile utensils.

The milk used should have a low bacterial count; should be raw on account of its greater nutritive and antiscorbutic properties; bottled at the dairy in order to be able to judge its composition by the depth of its cream layer, and iced from the time of bottling until planted with the Bulgarian bacilli.

The casein should be made digestible, not by boiling, but by lactic acid fermentation, the lactic acid having the additional advantages of being germicidal to pathogenic microorganisms, of preventing putrefactive changes in the milk or intestinal tract, and of being a laxative.

Tolerance to the requisite amount of fat should be obtained by preventing fermentative and putrefactive disorders in the intestinal tract. The fermentative disturbances should be avoided by the use of malt sugar; the putrefactive changes should be obviated by the use of clean milk, by the milk proteins being in a readily assimilated form, and by the presence of lactic acid.

The composition of human milk and of the various layers in bottles of cow's milk of different degrees of richness should be known.

Formulas providing any needed percentage of fat, proteins, or sugar, should be at hand.

The percentage of fat should be governed by the gastric tolerance and the character of the stools, and the percentage of proteins by the gain in weight.

300 SUMNER AVENUE.

FETAL DYSTOCIA AND CESAREAN SECTION.*

By HERMAN GRAD, M.D., F.A.C.S.,
NEW YORK.

ATTENDING SURGEON, WOMAN'S HOSPITAL.

THE obstetrical consultant who is called into a case of pathological labor is beset with a great many difficulties, and the responsibilities he has to shoulder are at times indeed very great. He has to face the situation of the parturient woman and the unborn child, and take account of two lives that are, as it were, a part of the whole, yet both have problems to solve that have an individuality of each. In no obstetrical complications are there problems more difficult to solve than in conditions of fetal dystocia. Here we have the fetus whose presenting part will not engage in the true pelvis. Many hours of labor have passed by, the mother has suffered untold agonies, but her hard and painful labor has brought forth nothing. The obstetrical consultant must solve the problem why the presenting part had failed to engage, and how to disentangle the snarl and terminate the painful and dangerous situation.

To the obstetrician the greatest interest centers

*Read at the meeting of the alumni of the Woman's Hospital, February, 1916.

itself on the true bony pelvis and soft parts of the birth canal. Through this bony ring of the true pelvis he must bring the tender baby unharmed and usher into the world a new life.

The true obstetrical pelvis is that part of the birth canal that lies below the iliopectineal line. It is the inlet of the true pelvis, and is a rigid bony ring throughout its entire circumference. It is solid and unyielding to the tender passenger, and is the crux of the whole obstetric situation. Anything that passes through this gate must measure in diameter less than the ring itself.

In considering this bony ring, we take notice of the diameter of the birth canal. There are two points to bear in mind, namely, the space at the inlet of the pelvis and the diameters of the outlet, and in both of these the anteroposterior and transverse diameters are of importance.

In fetal dystocia the examination as a rule should be conducted under anesthesia. The examining fingers note the diameters of the pelvis. The anteroposterior diameter of the pelvic outlet are the pubococcygeal, which in normal cases should measure $3\frac{3}{4}$ inches, and the sacropubic diameter should be one inch more. The transverse diameters of the outlet should be $4\frac{1}{4}$ inches. With the parturient canal empty, the presenting part not being engaged, the ascending finger reaches upward toward the promontory of the sacrum and takes note of the diagonal conjugate, the distance between the center of the promontory to the inferior surface of the symphysis. In the normal pelvis this diameter is 5 inches long (13 cm.). The examining finger takes note of the presenting part, whether a cephalic presentation or otherwise. To make this examination accurate and complete, it may be necessary to introduce the whole hand into the vagina, if it is feasible. In a vertex presentation, the position of the head should be determined, and if the fontanelles are not easily felt, an ear of the fetus should be palpated. It may be of interest here to make note of the normal diameters of the fetal head. The greatest diameter of the fetal skull is the occipitomenal diameter, which is $5\frac{1}{2}$ inches, the occipitofrontal $4\frac{1}{2}$ inches, and the diameter is the same whether measured from the root of the nose to the occiput along a horizontal line or measured from the occipital protuberance to the upper edge of the vertical portion of the frontal bone. The suboccipitobregmatic and the cervicobregmatic are both $3\frac{3}{4}$ inches. The biparital is $3\frac{3}{4}$ inches and the bitemporal is $3\frac{1}{4}$ inches. These measurements are more of an academic interest, because, after all, what the obstetrician wishes to know is whether the presenting part in this particular case of fetal dystocia can be made to engage in the birth canal. With the patient anesthetized, and if possible the whole hand in the vagina, an attempt is made to engage the fetal head. As the largest diameter of the pelvic inlet is the transverse, namely, $5\frac{1}{4}$ inches, the occipitofrontal diameter of $4\frac{1}{2}$ inches of the head finds ample room, while the biparital diameter of the head which is $3\frac{3}{4}$ inches finds sufficient room in the $4\frac{1}{2}$ inches of the true conjugate of the pelvis. The problem, however, is not as simple as it would appear from the description here given to engage the head in the true bony pelvis. In the vast majority of cases of fetal dystocia, when the consultant arrives, the uterus has become firmly contracted about the fetus, the waters have come away, the pains as a rule are ineffectual, and one is confronted with the question

what is best to do for this particular case. By all means attempt should be made to engage the head, allow the patient to come out of the anesthesia and wait for more efficient pains to further engage the head so that either a mid forceps or low forceps operation would terminate the labor.

Fetal dystocia may be classed under four different headings.

A. Fetal dystocia from faulty attitude. (1) Excessive flexion of the head, Roderer's obliquity. (2) Bregma presentation, incomplete flexion. (3) Brow presentation. (4) Face presentation. (5) Presentation of anterior parietal bone or ear, Naegele's obliquity. (6) Presentation of posterior parietal bone or ear, Litzmann's obliquity.

B. Fetal dystocia from faulty presentation. (1) Pelvic presentation. (2) Shoulder presentation.

C. Fetal dystocia from faulty position. (1) Persistent occipitoposterior position. (2) Persistent mentoposterior position.

D. Fetal dystocia from general fetal conditions. (1) Multiple or compound presentation. (2) Multiple birth. (3) Malformations. (4) Deformities. (5) Anomalies.

E. Oversize of fetus.

F. Oversize of head.

G. Premature ossification of head.

H. Congenital hydrocephalus.

In a pelvis not deformed, where the true conjugate is 9 cm. or more, many of the faulty attitudes and positions of the head will become corrected by allowing labor to continue, the head will become finally engaged, the excessive or incomplete flexion will disappear and the vertex come down on the perineum. Even in face presentation or persistent occipitoposterior position where the mechanism of labor is taxed to a greater extent, the labor may terminate favorably either with or without interference. The face presentation can often be converted into a vertex by judicious manipulation. But each and every one of these faulty attitudes of the presenting vertex when combined with an oversized fetus or oversized head, or perhaps with premature ossification of the head, may form insurmountable obstacles to the delivery of a live fetus.

Text books tell us that when delivery is impossible "embryotomy is justifiable." It is here that the modern obstetrician steps in with his high ideals and his humanitarianism. He is striving to protect the interest of the unborn baby without jeopardizing the life or health of the mother. Many are the problems that confront the obstetrician at this stage of the situation of fetal dystocia. Shall this case be terminated by a forceps delivery, by a version or cesarean section? A high forceps delivery should be avoided at all times, as it cannot but prove harmful to both mother and child. It can only prove of benefit under exceptional circumstances. To terminate the labor by version means a high fetal mortality. It is not in the best interest of the child, and while the maternal mortality in version is practically negligible, it is not so with maternal morbidity. In a large number of cases laceration of more or less severity accompanies the version, and the morbidity that follows the traumatism and laceration of the soft parts of the birth canal is quite considerable at times. Everyone of us can recall cases where severe laceration of soft parts inaugurated invalidism that lasted for months and years. How many of these patients date their aches and pains from the confinements. These cases have to undergo burdensome plastic opera-

tions before they can be restored to anything like normal health. So that we must admit a high degree of maternal morbidity in cases of version.

There can be no doubt that cesarean section is the ideal way of handling fetal dystocia. It is a humane way of treating these cases. A clean cesarean section in a clean case gives ideal results to both mother and baby, but before we decide on a cesarean section we must take into serious consideration two important points. First, the maternal mortality of the operation, and, second, the condition of the unborn baby, its viability, its probable health. Unfortunately both of them, namely, viability of child and danger to mother, are factors not definitely determinable.

We may profitably discuss, first, the determinable factors about the baby, and, secondly, the dangers of cesarean section to the mother. About the baby we have certain facts that will help us to formulate an opinion about its viability. First, we have the period of gestation; second, length of fetus, Ahlfeld's method; third, Perret's method or external cephalometry; fourth, we have the fetal heart sounds. The activity of life as experienced by the mother—beyond this we cannot go. The clinical symptoms may all point to the viability of the baby and yet when the baby is delivered it may be found to be in very poor condition of health and not even viable. So while we wish to be humane in the interest of the baby, we cannot lose sight of the fact that we are dealing with an unknown quantity, and while in the majority of cases a full-term baby should be viable and vigorous, we will come across cases where all our calculations are upset. The baby is not viable, and it might as well have been delivered by some other method which is less dangerous to the mother than a cesarean section.

The dangers to the mother from cesarean section can be classed under three headings, shock, hemorrhage, and sepsis. There is also a factor to be considered in connection with sepsis, namely, resistance to sepsis, but this is not a determinable factor. There can be little doubt that the shock attending a cesarean operation is somewhat greater than the shock of even a difficult forceps delivery or a difficult version. However, these terms, after all, are relative. We all have seen considerable shock after a forceps delivery or version. It is true that in forceps delivery and version the element of hemorrhage must of necessity cloud the differentiation between shock due to hemorrhage and shock due purely to traumatism. But taking all factors into consideration, the shock after cesarean delivery is only a trifle greater than in other operative deliveries. Regarding hemorrhage one must admit that there is a better control of bleeding in cesarean section than in version or forceps. The third factor of danger in cesarian section, namely, sepsis, is a factor that looms large and ominous in the domain of operative delivery. Yes, sepsis may crowd in from many and various sources. The sepsis of omission, the sepsis of commission, the sepsis arising from within or from without, the sepsis from sources that can be controlled and those that cannot be controlled, the sepsis whose source may be a nonsterile amniotic fluid or a nonsterile birth canal. Sources of sepsis to the right of us and sources of sepsis to the left of us volley and thunder. This is the real danger of cesarean section, and no wonder that the conservative obstetrician shakes his head at the progressive accoucheur and raises a finger of warning. Is there anything

more pathetic than to have a live and healthy baby and a dead mother after cesarean section? It is pathetic enough to present the expectant parent with a fully developed dead infant after a difficult version or forceps delivery, but it is thrice more pathetic to present the father with a live but motherless infant. Even with this picture before us, we must not be discouraged.

Cesarean section has a place in fetal dystocia, and what we must do is to strive for better technique, better diagnosis, a clear vision of placing indication for cesarean section, weighing the pros and cons of each case as they present themselves, not to generalize but to individualize. Each case is a law unto itself, each case demanding serious consideration. Modern obstetrics clearly shows that we must give up the formerly firmly established dictum, that there is only one indication for cesarean section, the text-book indication, namely, pelvic obstruction. There are cases of pelvic obstruction where cesarean section is contraindicated and an embryotomy is justifiable. While there may be cases with ample pelvic measurements both external and internal, where a cesarean section conserves the best interest of both mother and baby. The entire obstetrical field must be surveyed in determining what is best to be done in a particular case of fetal dystocia. The pelvic measurements are insufficient to go by, the forces supplied by nature, the particular conditions that present themselves, the general state of both mother and infant must all be taken into consideration in deciding on so serious a step as a cesarean section. Yet with all this considered, abdominal section for fetal dystocia offers a vast field of usefulness and humanitarianism in saving the life of the defenseless infant and sparing the mother much suffering, great morbidity and perhaps a lasting invalidism.

In fetal dystocia not alone have we to consider all those causes enumerated before, faulty position, faulty attitude, faulty presentation, excessive size of fetus, oversize of head, and premature ossification of head, but we have to consider conditions that have reference to maternal dystocia. Inertia uteri, inefficient pains, feeble natural forces, contraction ring, enfeebled condition of the mother are all determining factors. In a great many cases of fetal dystocia, it is not only one cause that is operative but we have many etiological factors to contend with, a dystocia from incomplete flexion, for instance, or from excessive flexion or a Naegle's or Litzman's obliquity will disappear if vigorous pains and efficient uterine contraction assails them, but the dystocia will persist for hours and hours if the natural forces of the mother are enfeebled. Add to this picture a ruptured membrane or perhaps a contraction ring and one has a formidable condition to deal with. In cases of this kind, if we are reasonably sure that the birth canal is clean, that the labor has been conducted in a clean manner, cesarian section offers the best means of delivery. If the section is done before the mother has become exhausted from useless attempts at delivery, the prognosis are good for both mother and baby. I beg leave to recite a case from practice:

Mrs. R., aged 36, Para IV, was seen in consultation with the attending physician who had been in attendance on the case for sixteen hours. The patient had been in hard labor for ten hours, and as no engagement had occurred, a consultation was called. The patient was a vigorous woman, who had given birth to three children and always with a low forceps operation. She could not understand why the labor was being pro-

longed so much. In her former deliveries, the babies averaged from 6 to 7 pounds in weight. The examination showed the fetal ovoid to be quite large, 40 cm. from the symphysis to the top of the fetal ovoid. The pelvis was still empty and the vertex presenting. External measurements normal. Diagonal conjugate 12 cm. External os open three to four fingers, internal os less. Fetal heart, 140 sounds, loud and vigorous. Bregma easily felt. It was evident that we were dealing with a case of fetal dystocia; an oversized head, insufficient flexion of head with membranes ruptured. As the case had been conducted in a clean way, with a normal temperature and pulse of mother, as the condition of the fetus was satisfactory, a cesarean section was decided on, believing it to be the safest procedure for both mother and child. The patient was prepared for a section and the abdomen was opened in the midline above the umbilicus. The intestines were packed away carefully, to guard against peritoneal soiling as much as possible. The uterus was opened by a longitudinal incision and a live male child weighing 9 pounds and 14 ounces was extracted. The baby thrived but the mother's convalescence was retarded by a sharp rise of temperature, which however subsided by the third day with primary union of the abdominal incision.

In contrast to this successful case of cesarean section, I shall report another case:

Mrs. A., aged 23, in labor with her first pregnancy. The patient is somewhat anemic, of medium height, not unduly vigorous and had been in labor nearly twenty-four hours. There were two physicians in attendance when I arrived, and every preparation was made for a forceps delivery. Ten vaginal examinations had been made but all under careful preparation and with aseptic gloves. The patient's condition was good, pulse and temperature normal. Fetal heart sounds good. The external conjugate 18 cm., diagonal conjugate 11 cm., pelvis empty, head floating. Membranes intact, cervix open three fingers and dilatable. Attempt to engage head under anesthesia unsuccessful. I gave my opinion that the case was one for cesarean section and that on operative delivery would be in the best interest of both mother and child. I was promptly dismissed from the case and a second consultant called. After several attempts with forceps a dead baby weighing 8 pounds was delivered by version. The patient sustained severe lacerations not alone of the birth canal but of the bladder and rectum, and to-day, nearly three and one-half years after labor, the patient is still a semi-invalid and has not conceived again. For several weeks after delivery her life was despaired of from sepsis, and it was months before she was able to be out of bed. When I saw the case, she was clean and a cesarean section would have resulted in a live baby, spared the mother great morbidity, much suffering and a lasting invalidism.

Called into a case of this kind it will be well to bring a calm mind to bear on the conditions as they present themselves in the chamber of accouchement. There is no necessity for haste. If the case is one of fetal dystocia as I have tried to picture above, haste is not necessary. A hasty conclusion is apt to precipitate an immature one, and this is to be avoided in every way possible. The obstetrical field, which must pass in survey in a case of this kind, is a considerable one, and we must give the matter time for its considerations. Let me try and enumerate all the conditions that we must take into consideration when we arrive as obstetrical consultants in the chamber of delivery in a case of fetal dystocia. We must pay attention to the history of the labor up to the time of our arrival, and also the history of the period of gestation. Is she on time or overdue? When did labor begin and how has it progressed? Have they been real labor pains or not? How have they behaved? At about what intervals did they occur; have they been severe, etc.? The effect they had on the patient. Is the mother bearing the ordeal well or not? Have the waters broken, or has there been any other vaginal discharge? Has the pulse and temperature of the woman been changed or influ-

enced in any way? What is the condition of the rectum and bladder? By inquiring carefully into conditions that had preceded our visit much valuable information will be gained and these inquiries will help greatly in formulating our conclusions as to the best mode of procedure in this particular case of dystocia. Having obtained the history, we advance another step by making a physical examination of the mother and determine the general condition of the patient, and, so far as possible, that of the baby. These examinations should also outline for us, so far as possible, whether expediency is necessary in terminating the labor or not. The external measurements should be taken if possible, but if not expedient at least the external conjugate and the oblique diameters should be measured, it will be of assistance in making final deductions. The internal measurements are of great importance, because a knowledge of them will materially help in deciding for or against the version and the possibility of delivering a live baby. A diagonal conjugate of five inches and normal oblique diameters will give a fair chance of a live baby by version, while a smaller pelvis means a high fetal mortality. Our examination must take into consideration the condition of the baby, its size, its heart sounds, and its viability, and perhaps the history of the condition of the former babies will be of help to us in forming our opinion as to the general condition of the baby. Our next consideration is as to the character of the labor pains and the existing uterine force. I think this is of vast importance. If one could only measure these forces of uterine contraction. Uterine inertia is at times a very serious complicating factor, and one must give the matter careful consideration. Nor is it easily determined, under certain conditions, whether a uterine inertia exists or not. We all have experienced cases where we were convinced of the existence of an inertia and were surprised to find, after a short time, very efficient pains set in with a rapid termination of labor. When inertia does exist the suffering of the mother may be extreme and with absolutely no progress in the labor. So that in the diagnosis of fetal dystocia the character of the uterine contraction is of great importance, and it behooves one to make note of the character of the pains and uterine contractions in order to place properly the indications for interference. As has already been mentioned before, in fetal dystocia, even a few vigorous uterine contractions may change the entire aspect of the case and turn an apparently hopeless case into one of easy forcep delivery. In many cases of inertia not alone are the uterine contractions weak, irregular or tetanoid but the patient does not cooperate with her abdominal muscles, the diaphragm does not become fixed and the uterine contraction is not augmented by external forces. Having determined, if necessary under anesthesia, the presenting part, its position and other determining factors, and having become evident that interference is essential, the obstetrician has the choice of several methods of delivery. Forceps, version, pubiotomy, craniotomy, and cesarean section. With pubiotomy I have had no experience, so will leave it out of consideration, although in recent years there has been a tendency to revive the operation and competent men have claimed advantages for it.

High forceps is a dangerous procedure for both mother and the baby and is justifiable in use only under exceptional circumstances. Version has a

high fetal mortality and considerable maternal morbidity. Craniotomy destroys the life of an innocent being, and is not in accordance with the high ideals in medicine, and yet we must admit the operation, cruel as it is, has a field of usefulness much as one abhors its performance. Cesarean section as a method of delivery in fetal dystocia, is the peer of them all. It is a humane operation, it is merciful and tender, but it has its sting—a sting of cruelty. It behooves the obstetrician to rob this merciful operation of its cruel sting. The operation is to be advocated under clear and precise indications, to deliver a healthy child from a clean uterus, a clean amniotic fluid, and a clean birth canal. If these indications can be met with in a case of fetal dystocia, then nothing can take the place of this form of operative delivery.

40 EAST FORTY-FIRST STREET.

VOMITING IN INFANCY.

By J. EPSTEIN, M.D.,

NEW YORK.

A PROPER diagnosis of vomiting in infancy may at times save the life of the infant. Leaving out of consideration the vomiting which is a part of the general symptomatology of various diseases and which may be diagnosed by the other symptoms and physical signs, there is a group of gastric disturbances in which vomiting is the only or chief symptom.

Vomiting in infancy may be the result of: (1) Improper feeding. (2) Improper food. (3) Congenital pyloric stenosis. (4) Rumination.

Improper feeding is the cause of vomiting in a large number of infants. The diagnosis is easy and can be made from the feeding history. These infants whether breast-fed or bottle-fed get the right kind of food but are fed in the wrong way. They receive either too much food at a time or too frequent feedings, with the result that the stomach is filled to overflowing, and the consequent gastric regurgitation or vomiting. These infants have no digestive disturbances, they simply retain as much food as they need and eject the rest by vomiting. To treat such a condition with drugs is worse than useless. Strict directions in writing must be given to the mother or nurse as to the exact quantity of food at each feeding, the number of feedings in twenty-four hours, and the regular intervals. While there is no absolute means of telling exactly how much food each infant requires at each feeding and how frequently it must be fed in order to supply it with sufficient calories for all its needs of energy and growth, the age, weight, digestive capacity, and general condition will aid in determining the quantity of food at each feeding and the number of feedings in twenty-four hours. The following simple practical rule though not exactly scientific is very useful, especially to the general practitioner, in the feeding of healthy infants. An infant should get at each feeding as many ounces of food plus one as it is months old; that is, a baby three months old will take four ounces of food at each feeding, and one four months old five ounces of food. The intervals of feeding may for practical purposes be as follows:

From 1 to 3 months old every.....	2	hours
From 3 to 6 months old every.....	3	hours
From 6 to 9 months old every.....	3½	hours
From 9 to 12 months old every.....	4	hours

After six months of age an infant should get other food besides milk. Orange juice, well cooked cereal, beef juice, and zwieback may be gradually added.

In bottle-fed infants the correction of faulty feeding is very simple because the mother or nurse can easily regulate the quantity of the food at each feeding and the number of feedings according to the directions, but in breast-fed infants the mother can nurse the infant at regular hours, but she cannot tell how much the baby takes at each feeding. For general practical purposes, the weight and the condition of the infant afford the simplest and best guide to the amount of food the baby is getting in twenty-four hours. A large overfed infant tells its tale that it takes too much food for the size of its stomach and therefore vomits the surplus. The remedy, of course, lies in cutting down the time of each feeding. A more exact method consists in weighing the infant before and after nursing, and in this way gain a knowledge of how much food it takes at each nursing. Knowing the number of ounces of breast milk the baby requires at each feeding, the nursing time can be regulated so that the infant will take as much food as it needs to thrive upon and no more. While this method of weighing before and after nursing is exact and scientific, it is not practical. The general condition of the infant and its size and weight are in many cases sufficient.

Improper food is a frequent cause of vomiting in infancy. The quantity and the intervals of feeding may be right, but the quality of the food or the amount of its different constituent elements may not be suitable to the infant's digestion. Impure milk, or milk which is not kept at the proper temperature, or too much fat or protein or sugar may so irritate the stomach that the baby will reject the food by vomiting, and this, when long continued, will cause gastric or gastrointestinal indigestion with other symptoms and signs of ill health. The treatment of vomiting from improper food is more difficult than that of vomiting from improper feeding. In cases of faulty feeding all that is necessary is to regulate the quantity and the hours of each feeding, for there are probably no chemical or anatomical changes in the stomach. The baby simply spills the excess of food from its stomach by vomiting. In feeding with improper food for some length of time there is usually a chronic gastritis or gastric indigestion with abnormal changes in the chemistry or the anatomy of the stomach. The treatment, of course, consists in giving the right kind of food. If the infant is breast fed an analysis of the milk should be made, and the result of the analysis will largely determine the line of treatment. In bottle-fed infants fresh, raw certified milk should be given, beginning with a weak formula and small quantity and gradually increasing in quantity and strength till the infant gets the proper food suitable for its age and digestive ability. The stomach should be washed every day or every other day with plain warm water or a weak solution of sodium bicarbonate. In the majority of cases the infant will get well in a short time under this treatment without any medication. Should medication become necessary an initial dose of some mild laxative may be given. Bismuth subcarbonate in fairly large doses three or four times a day a half an hour before nursing will soothe the irritated gastric mucosa.

Congenital pyloric stenosis or congenital hypertrophic stenosis is not an infrequent disease, and upon an early correct diagnosis may depend the life

of the infant. Though this congenital lesion was long known, it did not receive general medical attention till within recent years, when its frequency and importance became better appreciated. The diagnosis of congenital pyloric stenosis is not difficult and can always be made on the following three chief symptoms and three chief signs:

The three chief symptoms are: (1) Persistent projectile vomiting. (2) Persistent constipation. (3) Persistent loss in weight.

The three chief signs are: (1) Visible gastric peristalsis. (2) Palpable pyloric tumor. (3) Gastric retention of food.

The history of these cases is always very suggestive. The infants are healthy at birth, may be breast or bottle fed, frequently of the male sex, and the first born. The vomiting may begin at any time from a few days to three months old, but in the majority of cases from three to six weeks old. The treatment may be medical or surgical. Since in every case of congenital pyloric stenosis there are probably two factors present, pyloric hypertrophy and pyloric spasm, medical treatment may be directed to the spasm. This consists in feeding small quantities and at longer intervals with human or modified cow's milk low in fat. Sodium bicarbonate or potassium citrate may be added to the food or given before each nursing. Daily gastric lavage is very beneficial. In the majority of cases, however, surgical treatment gives better results and should be advised before it is too late.

Rumination or merycism is a condition in which the food is regurgitated into the mouth in limited amounts and is again masticated and either re-swallowed or ejected. It is uncommon in man, but is common in certain animals. It is probably due to a reverse peristalsis and is usually present in neuropathic children of neuropathic parents. A diagnosis can usually be made from observation of the patient who habitually regurgitates some food and after chewing it either swallows or ejects. The treatment of this form of vomiting is difficult. In some cases feeding with a thick food made up of some cereal well cooked with milk does much good. Water should be given between feedings. Gastric lavage may be beneficial.

METHODS AND MYDRIATICS IN REFRACTION.

By E. A. POND, M.D..

BROOKLYN, N. Y.

INSTRUCTOR IN THE DEPARTMENT OF OPHTHALMOLOGY AT THE NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL; CLINICAL ASSISTANT AT THE MANHATTAN EYE, EAR AND THROAT HOSPITAL; FORMER OPHTHALMIC AND SURGICAL ATTENDANT TO EASTERN SEVEN GENERAL HOSPITAL, CHILDREN'S HOSPITAL, JACOB J. AVED WOODS, M.D.

Is It Necessary to Use a Mydriatic to Find the Correct Refraction of an Eye?—That means that the patient must suffer the inconvenience of blurred vision for several hours or perhaps ten days or more according to the drug used.

If the patient happens to be in business, it also means a loss of valuable time, and that means money—which, added to the fee charged, makes a pair of glasses expensive. Is it any wonder, then, that a great number of people are going to the optometrist, who will, can, and does give them an examination and glasses in a few hours, without the inconvenience or loss of time? To be sure the patient takes the chance of having glasses prescribed when he may need treatment, for we know

there are many conditions where the eye is diseased, and glasses will improve the vision for a time. Nevertheless, he does take the chance. I find it is not necessary to use a mydriatic in any case of refraction.

To begin with, one never prescribes the correction found under atropine, and homatopine does not act long enough to be of much use. Refraction is not an exact science. Let several experts refract the same person and there probably will be a difference in each prescription for glasses, and all will be good. The whole surface of the lens is not used in the field of vision; only the part exposed by the pupil. If the patient is put at ease in a dark room and made to look at twenty feet, or told to look "a mile away," the accommodation is soon relaxed, and the pupil dilates enough so that the eye can easily be measured by the skiascope. By this means that part of the eye that is actually used is measured.

In more than eight thousand refractions, I have had fewer recorections without a mydriatic than with one; the patient lost no time from business and suffered no inconvenience. In many cases where I first tested without a mydriatic and then with one, I invariably found the first result to be correct.

There are many methods of testing the refraction. My method is simple and verifying: (1) Take the vision of each eye separately; (2) examine pupil reflex, cornea, and conjunctiva; (3) muscles by finger test (roughly); (4) ophthalmoscope; (5) skiascope; (6) ophthalmometer; (7) test case to verify; (8) Maddox rod and red glass or double prism; (9) color field for red, green, and blue.

Place test cards at twenty feet. If you have a room of ten feet use a mirror, and double the distance, using reversed type. Have adjustable bracket, test case, and ophthalmometer so arranged that your patient does not have to move during the test.

After taking the vision and recording it—a very important step—examine the pupil reaction, the cornea for opacities, etc., conjunctiva, and then with the ophthalmoscope examine the fundus. This method saves time. Try convergence by having the patient follow the point of a pencil or the end of your finger. Next use the skiascope.

The most accurate way to use the shadow test is to ascertain the refraction of one of the principal meridians with a spherical glass; then, leaving this glass in situ, to place a cylindrical glass with its axis in the meridian thus corrected and keep on changing the cylinder until with the two glasses, spherical and cylindrical, a complete and uniform reversal (or block) is obtained in all meridians at once. This method indicates both the axis and amount of astigmatism with great precision (Fuchs).

Most authorities say to reverse the shadow. I find the best results when the pupil is *blocked*, i.e., has no motion of the shadow at all.

The next step is the ophthalmometer. This instrument, in the majority of cases, is inaccurate, as it measures only the corneal astigmatism. However, it usually gives nearly a correct axis. If the axes are found to be different in the first and second positions, that of the second position is usually correct.

Next use the trial case to find the glass that gives the best vision.

In hypermetropia, never give the full correction except in case of squint. To correct the presbyopia,

give an addition that will range according to the work to be done by the patient. Try each eye separately. The one great fault is getting the range *too close*. There is no set rule, but the age of the patient helps you to know approximately. The addition is always the same in both eyes, except in pathological conditions, or when hypermetropia has not been fully corrected in each eye.

After finding the best glass for distance and near, then place a Maddox rod in front of one eye and a red glass in front of the other and test the muscle balance, first without the correction and then with it. Prisms act wonderfully well in a few certain cases, especially in hyperphoria. The prescribing of prisms requires great judgment, and I think they are too often prescribed. Do not forget that lenses can be decentered to get the prismatic effects. For the diagnosis of paralysis of the ocular muscles by means of the diplopia, through the courtesy of Dr. Wooton of the Mahattan Eye, Ear and Throat Hospital, I will quote his quick and easy method:

The Diagnosis of Paralysis of the Ocular Muscles by Means of the Diplopia.—Diplopia is termed homonymous when each image is on the side of the eye to which it belongs, the image of the right eye to the patient's right, the image to the left eye to his left. Homonymous diplopia always denotes a convergence. Diplopia is termed heteronymous or "crossed" when the images are not on the side of the eye to which they belong, the image of the right to the patient's left, that of the left eye to his right. "Crossed" diplopia always means divergence. The paralyzed eye is always the eye in the direction of whose image the diplopia increases, *e. g.*, red glass before the right eye, red image to patient's right, white image to his left, homonymous diplopia, convergent strabismus. If now, the patient's head be stationary, on moving the candle to his right, the distance between the images increases or, in other words, when he looks in the direction of the red image it is the "red" or right eye that is paralyzed. If the diplopia be vertical, the red image, let us say, being above the white, this rule still applies. If on looking up the distance increases it is the "red" or right eye that is paralyzed; if on looking down, the "white" or left eye. This rule has no exceptions and it makes no difference with which eye the patient may elect to fixate.

The paralyzed muscle is always the muscle that moves the paralyzed eye in the direction in which the diplopia increases. For example, the right is paralyzed, and the diplopia increases when the patient looks to the right. In this case, the paralyzed muscle is the muscle which moves the right eye to the right, namely, the external rectus. The right eye being paralyzed and the diplopia increasing as he looks to the left, the internal rectus is paralyzed, for that muscle moves the right eye to the left, the direction in which the diplopia increases.

Let us suppose the diplopia to be vertical, if, when the patient looks up the diplopia increases, an elevator is paralyzed, if it increases when he looks down, a depressor. With the vertical muscles the case is a little more complicated than with the lateral, for the reason that there are two elevators, the superior rectus, and the inferior oblique and two depressors, the inferior rectus, and the superior oblique. Let us suppose the diplopia has shown that an elevator of the right eye is paralyzed. We are now to determine which elevator is affected. If, when the paralyzed eye is made to follow the light in the direction of the temple, the *vertical* diplopia

increases, the superior rectus is the muscle; if it increases when the paralyzed eye is directed toward the nose, it is the inferior oblique. Similarly, if the diplopia has shown that a depressor of this eye is affected, and the diplopia increase as the paralyzed eye is rotated toward the temple, the paralyzed muscle is the inferior rectus; if it increases as this eye is turned toward the nose, it is the superior oblique. In the case of the vertical muscles, the tilting of the images is to be disregarded, as is also the homonymous or crossed character, if present, of the diplopia. These few rules are all that is necessary for the diagnosis of *recent* cases of paralysis of the ocular muscles, when diplopia is present.

Finally, it is a good plan to test the field for white and colors for any contractions or scotomata. This is readily done with the hands and small squares of colored paper, held on thumbnail while patient looks in the examiner's eye, or use the perimeter.

Unless the operator speaks all languages, the skiascope is indispensable, for by its use there is really no need of questions or mydriatics.

In cases of children, a mydriatic is not necessary unless you have them frightened. Take a little more time, and put them at ease.

Hypermetropia.—In measuring hypermetropia, I place a plus lens in front of the eye as near the amount as I can guess by means of a flash of the skiascope, and leave it there. If too strong cut it down by adding a minus lens until the pupil is blocked in that meridian. Then place the correct glass in the frame, having the patient keep *both eyes shut* while making the change. The same holds good if the first lens was too weak. Keep adding plus until the pupil is blocked and proceed as before. Then add the cylinder needed, if any. Be careful in myopia not to overcorrect, and it is not very good policy to give the full correction, or sometimes even a glass that will give 20/20 vision for the first glass. Your patient is apt to come back complaining he sees too much and is uncomfortable. You are supposed (in using the skiascope) to deduct plus 1 D in hypermetropia and add minus 1 D in myopia.

Verify your findings with the trial-case, carefully adding to or subtracting from your findings until the best vision and most comfortable glass is found.

Remember that homonymous diplopia means convergence and heteronymous diplopia, divergence.

Also, in writing for glasses, remember that you order .50 D less in toric lenses than in flat lenses, above 2 D.

If it is the patient's first pair of glasses, do not fail to tell him or her that things will appear differently. Sidewalks may seem higher or slanted; they will not see quite as well after dark, etc., but all these troubles will cease in about two weeks. It is a good plan to tell your patient to wear the glasses for two weeks before making any complaint, and at the end of that time to come to you for a verifying examination.

And finally, common sense and experience on the part of the operator are absolutely necessary.

1087 DEAN STREET

Chronic Cystitis.—Sinha says that santonin acts very promptly in chronic catarrh of the bladder, when given in $\frac{1}{2}$ -grain doses three times a day. The sensitiveness and feeling of fullness in the bladder disappear and a cure is generally effected in a very short time.—*Indian Medical Record.*

MEDICAL RECORD.

New York, June 24, 1916.

THE EGOCENTRIC FACTOR IN GENUINE EPILEPSY.

EPILEPSY is no more a perfectly distinct clinical entity than are other varieties of mental disturbance. Neither is egoism peculiar to this form of disease. The epileptic mode of reaction is present in other forms which do not show the definite symptoms belonging to genuine epilepsy. Even the normal person gives way occasionally to these reactions. These are always based on egoism, but it is the extreme degree of egoism in the epileptic which some believe gives rise to his special symptoms and leads to the complete deterioration which marks the final outcome of the disease. "The egoist is relentlessly pursued by the nemesis of intellectual degradation." Thus Dr. John T. MacCurdy strikes at the basis of epileptic reactions and the fundamental determinant of the epileptic fate in his "Clinical Study of Epileptic Deterioration," published in the *Psychiatric Bulletin*, Vol. IX, No. 2, April, 1916. The epileptic begins life with the extreme egocentric attitude, therefore he must pay the full penalty, unless indeed intelligent therapy turns to account this very weakness and utilizes it as a therapeutic measure. MacCurdy calls egoism "the keynote of epilepsy," but he also shows how this is successfully struck in order to direct the patient's interest toward his environment and to re-arouse it when it fails. Lasting success demands more than ordinary patience and appreciation of the symptomatic character of the manifest selfishness, indifference, and egotism of the individual. For the necessary initiative and perseverance must both be supplied by the physician or other helper. An ideal success is sometimes attained in which the patient reaches the point of self-sustained interest, but too often the original egoism asserts itself at each new difficulty met, with fresh loss of interest in the environment and renewed impulse toward regression. The supplying of a new interest at this point may not be sufficient to overcome the excessive egotistic withdrawal and in this way progressive deterioration occurs.

There are many signs of this extreme egoism in all stages of the epileptic decline. The individual begins life "at outs with his environment." There is always an absence of the emotional life. For this reason the attacks manifest themselves in the intellectual sphere and the deterioration likewise appears

in the gradual loss of intellectual acquisitions. The convulsions represent a sudden flight from the necessity for adaptation as the dementia represents the gradual withdrawal from the same thing, but in the intellectual and also in the vegetative nervous level rather than in the emotional sphere. The sexuality of the epileptic strikingly illustrates this in the purely physical nature of his desires and the absence of any love object. Expediency often leads the epileptic, still in the higher grades of deterioration, to a superficial profession of interest, notoriously in religion, which is in reality centered within the limits of his self-interest.

Even the patient who still preserves a considerable degree of insight and response shows a tendency to magnify the ego in conversation. His pursuits likewise must exalt himself as the center. He is reached and stimulated through reward and praise and equally disheartened and ready to relinquish task or pleasure at any failure or blame. It is just here that sympathetic therapy must step in and utilize the fundamental weakness as the one means of preserving or re-arousing the interest essential to the individual's salvation from the egoist's extreme fate.

The egocentric attitude stands out still more marked as dementia proceeds. Attempted replies to the examiner's questions center about some egotistic topic of interest with that perseveration characteristic of the true epileptic dementia. Further on the picture is that of a very young infant, indeed scarcely more than a biological entity, mental contact with environment all but obliterated, just enough of the infant's interest in its own body left to put a coin to its mouth or otherwise manifest the faintest semblance of any relation to its environment.

We are yet far from understanding epilepsy, but it is only by recognition of such profound functional attitudes and their typical reactions that the condition can be better understood, whatever other findings, functional or pathological, science may bring to light. At least this provides a working basis for clinical treatment which can be both prophylactic and curative by meeting the epileptic on his own ground and guiding him through his peculiar weakness to an efficient self-development.

THE HEALTH TRAIN IN FLORIDA.

THE State Health Department of Florida, although unable to fulfill entirely adequately all the functions normal to a body of that sort, owing to certain handicaps, according to the Public Health Reports for June 2, has undertaken very successfully the dissemination of information regarding health matters to the general public and is carrying out the idea in a manner which might well be emulated by other States. The Florida laws authorize the board to disseminate information concerning the cause, nature, and extent of communicable disease by lectures, exhibits, and printed matter. They also provide for a train containing health exhibits which shall travel about the State educating the people; this train carries lecturers and is conveyed free by the railroad.

The work done by the "health train" was formerly accomplished after a fashion by sending the public health exhibit of the State from city to city by express or freight, an expensive and tedious process. Quite recently, however, three cars were purchased and remodeled, one as a living car and two to house exhibits. The railroads by special arrangement haul this train about the State free of charge. It has been found advisable to follow a regular schedule in these trips so that each community is visited in regular turn; requests are frequently received from districts holding fairs or other local celebrations to have the health train visit them, but it has been impracticable to accede to these requests on account of the long irregular trips involved and the extra burden which such would put on the railroad companies, already so generous.

The exhibits comprise the "flies' air line," a sewage disposal plant; illustrations of the way in which underground contamination of water supplies may occur; an open-air house for the tuberculous; "the contrast room illusion"; the comfortable infant; and others. A moving picture apparatus is carried along, the screen being erected outside of the car and the picture projected through the open window. The health train has aroused a great deal of interest in Florida, especially in the smaller communities which are just the ones where it is most needed; in many of these districts fully 90 per cent. of the entire population turn out to view the health exhibits.

Besides the health train, the health officials of Florida are endeavoring to interest the public in other ways. They issue a monthly bulletin which is distributed to about 8,000 people, but as is so often the case, this is circulated largely among people who are well informed anyway. The same is true of the pamphlets which the board of health issue from time to time. Small circulars are distributed from the health train and by the public health nurses; these contain condensed information about such subjects as pellagra, hookworm, flies, and privies. Interesting and instructive posters are prepared in the health department by artists employed for that purpose from time to time and these are exhibited to the public where it can be done to the best advantage. Finally, a feature of the Florida health service, which is certainly unusual though not unique, is the preparation every week of an article on a public health subject which is sent free to every newspaper in the State with a request to publish it in the interest of the public health. These articles are written by an employee of the health department who is experienced in newspaper work and consequently able to write in a popular vein for the lay public.

The above described campaign for public enlightenment in these matters is certainly commendable. Florida has a high death rate, probably due to its 40 per cent. of negro population and to the flocking there of tuberculous cases, and as the State statistician estimated that in 1915 over half the deaths, 53.4 per cent. to be exact, were from preventable diseases, it is to be hoped and expected that the future will show diminution in these figures as the public becomes more and more alive to hygienic matters.

TUBERCULOSIS OF THE FOOT.

THE diagnosis of tuberculosis of the foot requires a considerable amount of care. According to Professor Kirmisson, writing in the *Medical Press*, May 31, 1916, the diagnosis of lesions of the tarsus and dorsum of the foot is based on two considerations: the nature of the osseous lesions and their distribution. The nature of the lesions is inferred from the clinical appearance, more particularly their pasty fungous consistency, and the discovery of enlarged glands. Tuberculous osteitis of the knee and foot is almost always associated with enlarged glands in Scarpa's triangle. This is a very important point to bear in mind. Again it is essential in order to gain a correct diagnosis to recollect that there are forms of osteomyelitis which are chronic *ab origine*, while tuberculous osteitis occasionally runs an acute course. Discovery of tuberculous lesions elsewhere favors the diagnosis of tuberculosis of the foot.

Exact anatomical knowledge is necessary to insure accurate diagnosis. Tuberculous lesions of the dorsum and tarsus are specially apt to occur in one or more of three spots, the tibiotarsal articulation, the posterior half of the tarsus, and the anterior half. In adults and in elderly persons all these joints may become involved simultaneously. In determining the exact seat of the mischief the site of the swelling must be taken into consideration. If the swelling is in the region of the malleoli, it is a case of malleolar osteitis involving the tibia or the fibula as the case may be. If behind the malleoli it may be a case of synovitis, but the involvement is more common by far in adults than in children. There are many other points to be considered in the diagnosis of tuberculosis of the foot, but space is lacking for discussing all of these. It should be remembered, however, that tuberculosis displays a marked preference for the calcaneum. This seat is recognized by the swelling in the depressions on either side of the bone and ultimately by reddening of the skin and fluctuation.

As for therapy, in a general way tuberculous disease of the foot and dorsum is amenable to treatment. It is apt to yield to conservative management, but if this fails it yields readily enough after operation. Kirmisson points out that when a patient comes with a foot in a faulty position, the first thing to do is to restore it to its normal relationship with the leg. Sometimes this can be done by mere reposition, but it may be necessary in certain cases to divide the tendo Achillis, after which the foot must be maintained in a proper position by means of a light plaster splint, leaving the lesions as far as possible uncovered. When the patient comes with abscess formation, the usual practice is to have recourse to deep impuncture, a method which is of veterinary origin, and has become safe and useful only since the introduction of asepsis and the thermocautery. In presence of suppuration the case must be dealt with as with an abscess of whatever origin, by puncture followed by the injection of iodoform ether. In more advanced cases tunnelization of the astragalus gives excellent results. Partial and total tarsectomy generally prove successful.

THE HANDY MAN ON THE BATTLEFIELD.

It has always been the experience of medical men suddenly called upon to do military service that they miss the well-stocked armamentarium which is available for them in their private practice. To the practitioner, well equipped with instruments, living on the same block with a modern drug store and attending cases in hospitals where dressing material appears as if by magic at the spoken word, it is somewhat disconcerting to find himself expected to improvise instruments and get along somehow. We have not all the sublime faith of the old-time obstetrician who considered himself equipped for a labor case if he had a penknife and a piece of string in his pocket. Certainly there is no harm in cultivating one's ingenuity occasionally by doing without accessories which we have been accustomed to regard as almost indispensable and if we have only a modicum of ingenuity ourselves, we can note down the contrivances of others more gifted, when we are fortunate enough to learn them. In the *British Medical Journal* for May 20, Dr. James MacMunn contributes some of his own makeshifts, the most interesting of which are as follows: To remove a foreign body from the urethra he passes an endoscopic tube to the body, then passes in a stick, pencil or pen-handle will do, the end of which has been dipped in liquid cement. This latter is given time to harden and then tube, stick and foreign body are all taken out together. To stop urethral, prostatic, or post-nasal hemorrhage, a condom is tied over a catheter, lubricated, passed and inflated. When rubber gloves are not available, a substitute not to be despised is a coating of iodine, followed by a coating of compound tincture of benzoin followed by a top layer of iodine. When no anal specula are to be had, Dr. MacMunn uses the handles of two toothbrushes, nasal specula are improvised by bending the loops of hairpins back at right angles. Doubtless other physicians and surgeons have their makeshifts which they have invented themselves or gleaned here and there. It would be interesting to compare notes through the medical press so that each might add to his stock of expedients and then in time some compilation could be attempted and issued in a form suitable for carrying about. Such a volume might prove useful to many physicians even in time of peace whose rounds often take them where the needed implements are not available, and in time of war would be invaluable.

News of the Week.

City Death Rate.—During the week ending June 10, the death rate in New York City was 12.79, or 1.39 lower than for the corresponding week of last year, the difference representing a saving of 149 lives. The total number of deaths during the week was 1,362. The reduction was secured chiefly through a decrease in the mortality of the acute infectious diseases, including measles, scarlet fever, diphtheria, and typhoid fever. There was a slight increase in the mortality from pulmonary tuberculosis, whooping-cough, and cerebrospinal meningitis. The mortality from heart disease was considerably lower than that of the same week last year, but this reduction was offset by the increased number of deaths due to Bright's disease. For the first twenty-four weeks of 1916 the death rate was 15.02 as compared with 15.28 for the corresponding period of 1915.

Hay Fever Ordinance.—Through the efforts of the American Hay Fever Prevention Association, the city of New Orleans has recently adopted a hay fever ordinance, which provides that the tenant or owner of any premises shall not permit weeds or grass over two feet in height to grow or stand on such premises, or permit weeds or grass over one foot in height to grow or stand on the sidewalk abutting such premises. In commenting on this ordinance, which has been hailed as the first of its kind to be adopted in America, the New York City Department of Health calls attention to Section 221 of the New York Sanitary Code, which was adopted a year ago and reads as follows: "Growth of poison ivy and rag weed prohibited. No person owning, occupying, or having charge of any lot or premises in the City of New York shall cause, suffer, or allow poison ivy, rag weed, or other poisonous weed to grow therein or thereon in such manner that any part of such ivy, rag weed, or other poisonous weed shall extend upon, overhang, or border upon any public place, or allow the seed, pollen, or other poisonous particles or emanations therefrom to be carried through the air into any public place."

Brooklyn Physicians Admonished.—The New York City Department of Health, in spite of its endeavors to obtain prompt and complete registration of all births occurring in the city and to impress upon physicians the importance of making such returns, has found that the reports from Brooklyn have been regularly incomplete or delayed, so that in comparison with a 100 per cent. registration in the Bronx and 99.2 per cent. in Manhattan, the registration in Brooklyn was only 96 per cent. As a result over a hundred physicians in the last-named borough have been brought to task by the Registrar of Records for failure to file birth certificates within ten days as required by law, and the cases of those who had repeatedly offended in this way and had been warned, have been referred to the Corporation Counsel for prosecution.

Civil Service Examinations.—The New York State Civil Service Commission will hold examinations on July 15, 1916, for the purpose of filling vacancies in the following positions:

Assistant bacteriologist, Quarantine laboratory, Department of the Health Officer of the Port of New York; men and women; salary \$1,200 per annum. Open only to candidates who have satisfactorily completed a systematic course in bacteriology and have also had not less than eight months' practical experience in laboratory work, including work in the bacteriology of cholera and plague.

Physician, State prisons and reformatories; men only; salary \$2,000 per annum without maintenance. Examination open only to licensed medical practitioners in the State, who since graduation have had at least one year's experience on the resident medical staff of a general hospital, have had at least three years' practice, and are not less than twenty-five years of age. One appointment will be made at Sing Sing in the near future.

Assistant physician, regular or homeopathic; open to men and women; salary \$1,200 to \$1,600 with maintenance. This examination is intended to provide eligibles for the position of assistant physician in the State hospitals and other positions of a similar nature in State and County institutions. Candidates must be licensed in this State,

graduates of a registered medical school, who since graduation have had one year's experience on the resident medical staff of a general hospital, or as medical interne or clinical assistant in a State hospital or institution, or have been engaged for three consecutive years in the practice of medicine.

Assistant physician, State prisons and reformatories; men only; salary \$1,500 per annum without maintenance. Examination open only to licensed medical practitioners in the State, who since graduation have had at least one year's experience on the resident medical staff of a general hospital.

Full details as to the examinations can be obtained on immediate application to the State Civil Service Commission, Albany, N. Y.

Association of Surgeons of the Southern Railway.—The following officers were elected at the meeting of the Society held in Chattanooga, Tenn., June 6 and 7: *President*, Dr. Cooper Holtzclaw, Chattanooga; *Vice-Presidents*, Dr. William H. Armstrong, Rogersville, Tenn.; Dr. T. F. Robinson, Bessemer, Ala.; Dr. Julius H. Taylor, Columbia, S. C., and Dr. Henry McHatton, Macon, Ga.; *Secretary-Treasurer*, Dr. Jacob V. Ray, Woodstock, Ala.

Medical Unit Sails.—The sixth medical war unit to be sent from the United States by the American Physicians' Expositions Committee sailed from New York on June 17, in the charge of Dr. Joseph R. Eastman, professor of surgery in the University of Indiana, Indianapolis.

Dr. Carroll Chase of Brooklyn sailed for France on June 4 to undertake hospital service under the auspices of the Association of American Relief for France and Her Allies.

For Investigation of Tuberculosis.—Announcement has been made of a recent gift to Johns Hopkins University, Baltimore, of \$95,000, to be used for the investigation of tuberculosis and the better teaching of physicians and medical students in the recognition and management of the disease and the care of patients. The giver is Dr. Kenneth Dows of New York.

Inspection of Restaurants.—During the first week of the inspection of restaurants, cafés, etc., now being conducted by the New York City Department of Health, 300 eating places in the city were visited, of these only one was rated "good," and only ten "fair" on first inspection.

To Investigate Yellow Fever.—The Yellow Fever Commission instituted by the International Health Board of the Rockefeller Foundation sailed from New York on June 14. The commission, of which Gen. William C. Gorgas, U. S. A., is chairman, will visit a number of ports in South America where the fever is still prevalent. General Gorgas has been given four months' leave of absence for the purpose of directing the investigation.

Dentists Graduate.—At the fiftieth annual commencement of the New York College of Dentistry on June 15 228 graduates, forming the largest class in the history of the college, received diplomas. A tablet in memory of the late Dr. Samuel Dunkin Weisse, former dean of the college, was unveiled.

Public Health Plank.—The platform of the Democratic party, adopted in St. Louis on June 16, contains the following plank: "We favor a thorough reconsideration of the means and methods by which the Federal Government handles questions of public health, to the end that human life may be conserved by the elimination of loathsome dis-

eases, the improvement of sanitation, and the diffusion of a knowledge of disease prevention. We favor the establishment by the Federal Government of tuberculosis sanitariums for needy tubercular patients." The second sentence is badly worded but intelligible enough; what is meant by the beginning of the first sentence can only be guessed at.

Recommend Tuberculosis Sanatorium.—The establishment of a sanatorium costing \$1,000,000 for the treatment of barbers suffering from tuberculosis, is recommended in a recent report of a committee composed of the president and general officers of the Journeymen Barbers' International Union of America. If the report is favorably acted upon by the union next September, it is probable that a site somewhere in eastern Tennessee will be chosen. The committee has also made an investigation of tuberculosis among barbers and will include its findings in a final report next September.

To Give Twenty Ambulances.—The members of the New York Stock Exchange have appointed a committee empowered to raise \$30,000 for the purpose of equipping and maintaining for one year twenty ambulances to be attached to the American Hospital in Paris. Excellent work has been done by the one ambulance already maintained by the Stock Exchange.

Fund for Biological Study.—The Biological Society of the College of the City of New York is raising a fund of from \$500 to \$1,000 to be devoted to the encouragement of biological studies at the Marine Station at Woods Hole, Mass., and at the experiment station at Cold Spring Harbor, N. Y.

Gifts to Charities.—By the will of the late Mrs. George G. Wheelock of New York, St. Luke's Hospital receives a bequest of \$10,000.

The Brooklyn Hospital, the Bushwick Hospital, the Brooklyn Home for Consumptives, and the Brooklyn City Dispensary receive bequests of \$5,000 each by the will of the late State Senator S. M. Griswold of Brooklyn.

Bequests of \$1,000 each to Mt. Sinai Hospital and the Montefiore Home, New York, are provided for in the will of the late Mrs. Rachel Lehmaier of this city.

The Mercer Hospital, Trenton, N. J., will receive \$150,000 as the result of the decision handed down on June 13 by the United States Supreme Court in connection with the settlement of the estate of Wesley R. Whittaker, formerly of Trenton.

Fordham Gives Degrees.—Forty-two graduates of the School of Medicine, Fordham University, New York, received the degree of doctor of medicine at the annual commencement of the university on June 14. Dr. James T. Walsh of New York, formerly dean of the school, received the honorary degree of doctor of letters, while the honorary degree of doctor of laws was conferred on Dr. Austin O'Malley of Philadelphia.

Alumni Association, Medical Department, University of Buffalo.—At the annual meeting of this association held recently, the following officers were elected: *President*, Dr. Walter D. Greene, '76, Buffalo; *Vice-President*, Dr. William H. Bergtold, '86, Denver; Dr. Henry A. Eastman, '92, Jamestown, N. Y.; Dr. Ross G. Loop, '97, Elmira, N. Y.; Dr. Henry A. Stadlinger, '97, Buffalo, and Dr. M. Louise Hurrell, '02, Rochester, N. Y.; *Secretary*, Dr. Julius Richter, '04, Buffalo; *Treasurer*, Dr. Frank E. Brundage, '09, Buffalo. At the annual dinner pledges amounting to \$10,000 were received as the nucleus of the Alumni Fund which is being raised

for the benefit of the medical department of the university.

Maine Medical Association.—The annual meeting of this association was held in Portland on June 8, officers for the ensuing year being elected as follows: *President*, Dr. Willis F. Hart, Camden; *Secretary*, Dr. John B. Thompson, Bangor; *Treasurer*, Dr. Edwin W. Gehring, Portland.

Obituary Notes.—Dr. IDA C. BENDER of Buffalo, N. Y., a graduate of the University of Buffalo, Medical Department, in 1890, died at her home on June 11.

Dr. SAMUEL LONG of New Brunswick, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1873, and a member of the New Jersey State Homeopathic Medical Society, died suddenly at his home, on June 11, aged 65 years.

Dr. FRANK DELOS GRAY of Jersey City, N. J., a graduate of New York University Medical College in 1883, and a member of the American Medical Association, the Medical Society of New Jersey, of which he was president in 1915, and the Hudson County Medical Society, died in Christ Hospital, Jersey City, on June 11, aged 59 years. Dr. Gray was also a member of the Practitioners' Club, and the Alumni Association of Christ Hospital, Jersey City, and was attending surgeon at Christ Hospital and the Jersey City Hospital, and consulting surgeon at the North Hudson County Hospital, Weehawken.

Dr. CHARLES M. TOBYNNE of New York, a graduate of the Eclectic Medical College of the City of New York in 1897, died in the Post-Graduate Hospital on June 13, aged 48 years.

Dr. ROBERT W. HUTCHESON of Freeport, L. I., a member of the Royal College of Surgeons, England, in 1857, a graduate of the University of St. Andrews, Dundee, Scotland, in 1858, and a Licentiate of the Apothecaries Society of London, England, in 1859, died at his home on June 13, aged 80 years.

Dr. SAMUEL MURLAND of New York, a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1883, and a member of the Medical Society of the State of New York, the New York County Medical Society, and the New York Academy of Medicine, died at his home on June 15, aged 66 years.

Dr. EDWARD J. ULRICH of San Jose, Cal., a graduate of the Cleveland University of Medicine and Surgery in 1871, died on May 31, aged 83 years.

Dr. THOMAS MILLER of Fincastle, Va., a graduate of the University of London, England, in 1859, died at his home after a lingering illness, on May 29, aged 79 years.

Dr. FRANCIS M. HARRINGTON of Providence, R. I., a graduate of the College of Physicians and Surgeons, Boston, in 1891, and a member of the American Medical Association, the Rhode Island Medical Society, and the Providence County Medical Society, died on June 7, aged 47 years.

Dr. HENRY HUGHES of Long Branch, N. J., a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1873, died in New York on June 14, aged 68 years.

Dr. S. CARRINGTON MINOR of New York, a graduate of New York University Medical College in 1892, and a member of the Medical Society of the State of New York, the Bronx County Medical Society, the Society of Alumni of Bellevue Hospital, and the Bronx Medical Association, died at his home on June 16, aged 66 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ANNUAL CONGRESS OF THE OPHTHALMOLOGICAL SOCIETY—WAR INJURIES—LEBER'S DISEASE—DYSMETROPSIA—CONTUSION HYPOTONIA—FOREIGN BODIES IN THE EYE AND ORBIT—ANATOMICAL RELATION OF THE EYEBALL—TREATMENT OF SYPHILITIC EYE DISEASES.

LONDON, May 27, 1916.

AT the Annual Congress of the Ophthalmological Society, the president, Mr. Walter Jessop, pointed to the fact that the society is now issuing its thirty-sixth consecutive annual volume of Transactions. The Bowman Library is the most complete library of the specialty in the world, and he hoped members would continue to cooperate in keeping it so. He asked, too, that they would notify changes which had occurred in cases that had been discussed, so that their sequelæ might be known. Two brilliant members had died during the year: George Coutts of London and Professor Straub of Amsterdam. Referring to the war, the president said the treatment of eye injuries had been satisfactory. He had found so far no case of sympathetic ophthalmitis; this he attributed to the precaution of removing every portion of a smashed eye. In the war of 1870 sympathetic eye trouble was reported in 55.6 per cent. of severe injury to eye or orbit. The war had taught them a good deal about papilledema. Trench nephritis he regarded as toxic and referred to edema of the retina, ocular hemorrhages and the formation of "white plaques." In the worst cases the blood pressure was high. He advised young ophthalmologists to conduct their examinations by daylight whenever possible.

Mr. Herbert Fisher read a paper on Leber's disease (hereditary optic atrophy) in which he suggested that its cause might be disturbance of the pituitary body, temporary in duration and moderate in degree, implicating the visual pathway. If it be so, he thought organotherapy might do good. During pregnancy the gland might enlarge to two or three times its normal size, and a milky secretion could often be squeezed out of it. The relationship between this and the sexual glands was well known, besides it was so close to the optic chiasma that any slight swelling would extend to it and be palpable there. He showed a skiagram casting a honeycomb-like shadow in the position of the pituitary. There was a full discussion on this subject, after which Mr. Foster Moore read a paper on the retinal circulation in arteriosclerosis. Thrombosis in an artery might cause starvation of tissues and if sudden obstruction a patient might awake to find he was blind: sometimes recovery was just as rapid.

Dysmetropsia was the title of another paper at this society, contributed by Dr. Kinear Wilson, who meant a defect in the capacity to appreciate the size and distance of objects. These cases he divided into (a) presumably peripheral, (b) probably central, and (c) psychical. In the last a hysterical young woman always saw the right half of any object larger than the left. Of two shillings placed side by side she took the right for half a crown. In a case of occipito-parietal tumor the objects seemed so near as to be practically touching the face.

Mr. Teacher Collins read a paper on "contusion hypotonia," pointing out that diminution of tension

was not infrequent after contusion of the eye apart from perforation of the globe. Normal tension was usually restored in a few days, but sometimes not for weeks, occasionally for so long as to threaten permanence. The causes he discussed under the heads: diminished secretion from (a) nerve inhibition, (b) vascular disturbance, and (c) epithelial damage.

Another discussion at this Congress was on foreign bodies in the eye and orbit, introduced by Messrs. Herbert Parsons and A. L. Whitehead. The prognosis and treatment must depend on a variety of factors; *e.g.* whether septic organisms were attached to the intruder and the size and nature of it as well as the site and degree of penetration. An injured eye without useful vision should be removed if there was any suspicion of the presence of a foreign body. If giving no pain or discomfort it should be left alone.

The anatomical relations of the eyeball were next discussed. Mr. Parsons urged more accurate study of the relations of the living eye to the bones by inserting slips of lead-foil in the cocainized conjunctival sac. Despite the heat generated in a high-velocity missile, the particles entering the eye were not always sterile. Diagnosis, pathology, prognosis, treatment, are depended greatly on the nature of the foreign body. Accurate localization was most important and skiagraphy might help this.

A debate on the treatment of the syphilitic eye affections was then introduced by Mr. J. B. Lawford and Capt. H. S. Browning. The former dated these methods from the introduction of organic arsenical preparations in the treatment. They had been extensively prescribed, but many cases of blindness led to their abandonment. Salvarsan seemed more promising. In reference to the ill effects of this reported by some observers he agreed with those who attributed them to fresh manifestations of the syphilitic virus. They improved under continued use of the drug. Captain Browning said in every case of suspected syphilis of the eye the patient's whole body should be subjected to thorough systematic examination. The Wassermann was one of the most reliable tests, but a negative result was not final. Kharsivan he found more toxic than salvarsan. The report of the committee cases of detachment of the retina was presented. It detailed eighty-five cases, half were British. The best visual results ensued when reposition occurred in four or five months, though one had a good result after eighteen months. No albuminuric cases were operated on. Major Cunningham, Professor de Lapersonne, Dr. Hawthorne, Captain Ormond, Mr. Clegg, and Captain Hird contributed further papers.

OUR LETTER FROM ALASKA.

(From Our Special Correspondent.)

TUBERCULOSIS AMONG THE NATIVE ESKIMO—HABITS—SANITATION.

ST. MICHAEL, April 18, 1916.

IN the ravages of the "great white plague" the Eskimo has not been overlooked. Just how or when this disease was introduced into Alaska no one knows, but it is obvious how its spread, increasing mortality, and morbidity are continued. There are various reports on the tuberculous percentage among the natives and these reports seem to have been formulated by writers other than medical men. This disease is so common in Alaska that every white man or white woman and most of the natives

themselves think first of tuberculosis as the cause of all ailments whether external or internal. The general opinion is that about 75 per cent. of the natives are suffering from tuberculosis.

With this in view the writer made a tuberculosis survey of the native children of St. Michael Island. This survey was conducted as follows: (1) Sanitary survey of the native villages so as to obtain an insight into their mode of living, food, percentage air space per individual, number of children under fifteen years of age, sewerage, and garbage disposal. (2) Physical examination of as many children below the age of fifteen as possible. (3) Testing these same children by the von Pirquet tuberculin reaction. (4) Sputum examination. (5) Making developmental measurements.

Sanitary Survey.—A person who has never visited an Eskimo village and has never come intimately in contact with the natives in their natural state has not the slightest conception of the most unsanitary surroundings they maintain. The villages from which these conclusions are drawn, are considered among the cleanest and most up-to-date villages in Northwestern Alaska. The houses are usually one room with a storm door entrance, low ceiling, and about fifteen feet square, made of plank, logs, grass, and scraps of tin, in fact anything that will keep the little heat they have within the building and keep out the cold. Every possible crack is closed so as to keep them warm, and no attempt whatsoever made at ventilation. In this little house will live the entire family and at times other families. In one house of the St. Michael village nineteen persons live continually and sometimes have visitors. The average cubic air space is about 350 cubic feet per person. The native also stores all of his belongings, except dogs, in his house; so we also find poorly tanned and foul smelling furs, seal oil, and fish that have been caught possibly many months before and in a decomposing state, a few dirty vessels of one kind or another, such tools or implements as they make their catch with, and sometimes a stove. The door into the house is usually covered by a piece of canvas, bagging, or a skin so as to aid in keeping out the draughts. Any form of table, chair, or bed is an unusual article. In fact in some of the villages the natives sleep seated on the floor with their backs against the wall. At one time the distinguishing feature between the Eskimo Indian and a citizen (in the legal sense) was based upon whether or not he ate off a table or on the floor.

Water is very scarce, particularly so in winter, as everything is frozen and all water is obtained by melting ice. Considering the above we can readily understand that the Eskimos rarely and in some cases never bathe. They also rub themselves with seal oil, and when you enter one of these houses you encounter an odor incomparable in intensity and offensiveness with anything that the writer ever before came into contact with. They sometimes catch fish in summer and bury it in the ground (possibly to keep the flies away); then will exhume this decomposed mass in winter and eat it as such, or perhaps cook it for themselves or their dogs. Should you enter this house now, the intensity of the smell will stifle you, but the native is placidly enjoying the aroma of these viands.

All waste is thrown out of the door, but as the natives eat all of the seal oil and the entire fish there is but little refuse from this source. The men urinate against the outside of the building, the

women and children defecate and urinate into such vessels as they have and throw this out of the door, the urine freezes and the dogs eat the feces. Is it surprising that communicable diseases spread among these people and that tuberculosis is threatening to destroy the Eskimo? It is only a question of time!

Some tuberculosis investigators have said that once we contract this disease the lesion remains, although at times in an inactive or walled off condition, the patient presenting no symptoms. Having this in mind it was thought best to examine the children. There are two schools at St. Michael, one called the "native school" which pure-breed natives attend, and the other the "white school," where there are a few children with Eskimo blood. The children in both schools were examined through courtesy of the teachers. The results of physical examination, tuberculin reaction, and sputum examinations are collectively tabulated as below:

	White School. (8 Children.)	Native School. (26 Children.)
Positive,	62.5 per cent.	61.5 per cent.
Negative,	12.5 per cent.	23.0 per cent.
Suspicious,	25.0 per cent.	15.5 per cent.

On further examination fully one-half of the suspicious cases would prove to be tuberculous.

This is a small number from which to draw conclusions and it is not intended to state that 61.5 per cent. of the native Eskimo children of Alaska under the age of fifteen years are suffering from active tuberculous lesions, but it does furnish an insight into the high percentage of tuberculosis in the natives even at an early age and in one of Northwestern Alaska's best villages.

During this survey there was occasion to examine eleven adults who were complaining of pain in their chests. All eleven showed advanced tuberculosis. These same adults are living in the above described houses with their children, brothers, and sisters. In all there are 27 houses in the village with 107 persons, 46 of whom are children under the age of 15 years. It was impossible to examine more than 26 of them as the parents objected in the remaining cases and antagonism was avoided wherever possible. The 26 children were all children from the native school, between the ages of 4½ and 14 years of age. Besides the 107 persons referred to above, there are 10 others who live in the village occasionally and a large number of others who live in other villages but visit here at St. Michael, living in the native village during their sojourn.

Although the percentage of positive cases from the white school was higher than from the native school, the physical signs were far more marked in the latter and there was a greater percentage of advanced tuberculosis in the native school. These eight mixed-breed children from the white school live under much better sanitary conditions, in fact all of them are at present living under conditions approximating those of white people and none of them live in the native village. These children intermingle to a certain extent and most of them have lived under conditions, during a portion of their lives, simulating Eskimo habits. Even the white man, in general, lives under poor sanitary surroundings at St. Michael.

It is stated that the Eskimo as a rule has little or no appreciation, but the writer believes he appreciates medical attention when approached in the

proper manner. He is a man that one cannot force into doing things, and to attempt to compel him to clean house (in the white man's sense) or to discard food that a civilized man would not eat, will soon gain his ill will and distrust. The field for medical and surgical work on the Alaskan natives is untouched. It is a field where medical missionaries can reap great harvests. The United States Bureau of Education has a small medical appropriation annually but it is far too little and only a very small percentage of the natives can receive much benefit from it. There are a few hospitals scattered over this enormous country and a few doctors here and there. They are undoubtedly doing valuable work, but there are too few of them. If the churches, religious societies, and benevolent organizations in general of that rich and wonderful country of ours—the United States of America—would turn only a part of their attention to Alaska and render financial aid, these poor and wretched natives, many of whom are without clothes and hungry to-day, could be elevated, mentally and physically, to a much better position.

1. Cholecystitis; Changes Produced by the Removal of the Gall Bladder. Edward Starr Judd.
2. Nephropexy. R. H. Gilpatrick.
3. Acute Perforation of Ulcers of the Stomach and Duodenum, with Case Reports. Martin T. Field.
4. Post-Operative Treatment. Harold G. Giddings.

1. **Cholecystitis; Changes Produced by the Removal of the Gall Bladder.**—Edward Starr Judd discusses the function of the gall bladder and the effects of its removal, and gives the technique of cholecystectomy, which he considers the gall-bladder operation of choice. The conclusions the author draws are as follows: The systemic circulation is probably the most important avenue through which infection reaches the gall-bladder. We are not yet able to recognize all cases of cholecystitis even with the abdomen open. The clinical history is most important in determining the existence of cholecystitis. Chronic cholecystitis without stones does exist as a definite pathological lesion and produces symptoms that will be relieved by the removal of the gall bladder. The only change in surrounding structures produced by removal is the dilatation of the common and hepatic ducts and possibly the stump of the cystic duct. This dilatation is most marked in the hepatic duct. Eventually this dilatation, with increased pressure, overcomes the action of the sphincter at the intestinal end of the duct, and the bile passes through the duodenum with very little resistance. The author believes that this mechanism explains why the removal of the gall bladder cures symptoms produced by inflammation of the pancreas, assuming that the inflammation in the pancreas is caused by bile from the common duct entering the pancreatic ducts. Finally, the changes in the ducts which follow cholecystectomy indicate that the gall bladder has a definite function.

2. **Nephropexy.**—R. H. Gilpatrick says that our study of the anatomy and physiology of the kidney and its means of support lead us to the conclusion that the organ is never a fixture and that mobility without symptoms may exist to a marked degree. It is therefore neither wise nor necessary to attempt to fix a pathologically moveable kidney in its exact anatomical position, an approach to within one inch being safe and sufficient, as well as much easier of accomplishment. The technique of various operations is given, with re-

ports of cases, and the writer makes a general summary of his position as follows: A mechanical problem is best solved under good mechanical principles. Success is dependent upon the degree to which normal anatomical and physiological conditions are approached. The kidney may not be wounded, fixed or constricted with impunity. Decapsulation, either partial or complete, does not impair kidney function. The most rational method of securing the kidney in position after it has become a wanderer to such a degree as to demand operation, is that of removing the cause and aiding in the reconstruction of natural support. Any permanent artificial support is dangerous if not completely destructive to the kidney's functional activity. The rolled-up and transfixed capsular flap offers a perfectly adequate hold for one end of the anchorage, and the muscular and fascial layers of the loin the same for the other end without sutures which emerge through the skin. If the anatomical relations of the kidney cannot be permanently readjusted without destruction of its functional activity it deserves to be either let alone or removed.

3. Acute Perforation of Ulcers of the Stomach and Duodenum, with Case Reports.—Martin T. Field has had the opportunity during the past few years to study ten cases of acute perforation of the stomach and duodenum. Six of these cases were his own and a brief report is made of them. The conclusions arrived at by the author are as follows: (1) Acute perforation of gastric and duodenal ulcers is not an uncommon accident. Early operation yields a high percentage of cures. Late operation gives a low percentage of cures, even when performed by a master surgeon. (2) It occurs most frequently in adult males giving a history of stomach trouble. Complete absence of dyspepsia (Case 1) should not preclude the possibility of this diagnosis. (3) The most important diagnostic guide is the occurrence of sudden, severe, epigastric pain immediately followed by signs of spreading peritonitis, which manifests itself by the presence of general tenderness and muscular rigidity (4) Early or first hour general tenderness and rigidity are very important signs in differentiating acute perforation from appendicitis and many other surgical lesions within the abdomen. (5) The points of maximum tenderness and rigidity are at first, especially in duodenal perforation, on the right side above and below. The rigidity later becomes board-like over the whole abdomen. This is quite distinctive of perforation, although in exceptional cases it may not be present. (6) Tympany over the liver is usually not present. It may occur, however (Case 4). Its absence should not militate against the diagnosis. (7) The abdominal pain as a rule is very severe and patients have an anxious expression, apparently realizing that something serious has occurred within the abdomen. The pulse, however, is often only slightly accelerated in the beginning. This is surprising, considering the gravity of this condition. (8) Early operation, implying repair of perforation with or without gastroenterostomy, should give a high percentage of recoveries. (9) Simple repair is apt to be followed by stomach symptoms, which later require gastroenterostomy for their relief. (10) In properly selected cases, gastroenterostomy, performed at the time of closure of perforation, is followed by most gratifying results.

2. Surgery of the Heart.—W. Wayne Babcock says that first it should be emphasized that the human heart is more tolerant of surgical manipulation than that of the cat or the dog, and apparently any operation that may be performed successfully on these lower animals, may, with even greater hope of success, be carried out upon the human heart. Local anesthesia or para vertebral nerve blocking with a 1, ½ or ¼ per cent. novocaine solution is to be preferred for the chest wall. No anesthetic is required for the heart proper. At times an associated moderate narcotism with scopolamine-morphine is desirable, or a slight ether narcosis, which is also to be preferred where haste is essential. An emergency operation upon a shocked and semi-unconscious patient may require no anesthetic. If the pleural cavities are to be invaded, intratracheal insufflation after the method of Meltzer-Auer has advantages. To restrict the inhibitory action of the vagus, a preliminary injection of atropine may be given subcutaneously, while cardiac massage and the intravascular injection of epinephrine are most valuable methods in starting the arrested heart. An excess of epinephrine, however, is dangerous, both from the vascular strain imposed and the danger of pneumogastric exhaustion. Gunshot wounds are more dangerous than incised wounds. Fischer in 1867, from a study of 452 heart wounds, found that from 7 to 10 per cent. are followed by spontaneous recovery. Lorson has reported nine recoveries after twenty-three needle punctures, eleven recoveries after nineteen stab wounds, and three recoveries after 110 unsutured gunshot wounds of the heart. Of operations for wounds of the heart, Vaughan has collected 150 cases, with 35 per cent. of recoveries compared with 15 per cent. of recoveries without operative treatment. Miller found 53 per cent. of recoveries in fifty-one more recent operative cases that he collected. The diagnosis of wounds of the heart may be difficult. In seven of Stewart's twelve cases, on exposing the heart no injury was found. The symptoms vary from instant death to a disability so slight that the patient continues to walk about, ultimately recovering or dying after several hours or days with the pericardium and possibly also the pleura filled with blood. Usually there is marked precordial anguish, pallor, shock, collapse, and at times unconsciousness. There is usually marked dyspnea, with rapid shallow respirations, and the development of cyanosis. The blood pressure rapidly falls, the pulse is weak and irregular, or lost. Method of operating for pulmonary embolism: 1. Dry shaving of the skin and disinfection by tincture of iodine. 2. The skin incision is carried along the left sternal edge from first to third rib, and from this a horizontal incision is made along the second rib. The skin and muscle flap is raised with a resection of the second and at times the third rib to a point well beyond the costochondral junction. Avoiding the internal mammary vessels, the pericardium is opened through the pleura in front of the phrenic nerve, which is to be avoided. 3. A rigid knobbed hook is curved around the aortic and pulmonary artery, a strong rubber tube affixed, and instruments withdrawn, leaving the rubber in place. 4. By the rubber tube both vessels are pulled forward and controlled. The visceral layer of pericardium and fat over pulmonary vessels is excised, so that the vessel cannot slip back into its serous covering. 5. Through an incision in the axis of the pulmonary artery two-fifths of an inch long, a fine curved dressing or polypus forceps is introduced into the branches of the pulmonary artery and the clots are

extracted. The aorta and pulmonary artery must not be constricted over three-quarters of a minute. If uncertain as to complete removal of all clots, the incision should be temporarily closed with a special narrow clamp, the constriction relieved, and later the procedure repeated. In suturing a small forceps springing outward and having a small hook projecting outward at each tip is introduced between the end of the slit, the vessel drawn forward and a flat hemostatic clamp is so applied behind the forceps that the edges of the incision project a little between the branches of the forceps. The blood stream then travels behind the occluded slit and the latter may be quickly closed by interrupted silk stitches. The removal of blood from the pericardium and suture of external parts without drainage complete the operation. In about fifteen cases no recovery has as yet followed the operation, but in one case the patient survived to the fourth day.

6. Epidemic Pneumonia in the Tropics.—J. Hobart Egbert points out that pneumonia is not limited to any particular climate, latitude, or altitude. In the spring of 1913, while the writer was serving as superintendent of the medical department of a large fruit company at Santa Marta, Republic of Colombia, pneumonia occurred, in virulent, epidemic form, among the Colombian soldiers in the Santa Marta barracks. Several cases proved rapidly fatal from mixed infection, with lung suppuration; in others the pneumococcus invaded the meninges, inducing pneumococcic meningitis, and was found in the cerebrospinal fluid. In a number of cases the pneumococcus was demonstrated in the general circulation. Post mortem examination in two rapidly fatal cases revealed extensive pyothorax. The mortality was high, death occurring in 57.9 per cent. of all the soldiers stricken with the disease between March 11 and April 24. Nearly all the cases that ended in recovery had a somewhat classic course, terminating, as a rule, through crisis, with but few important sequelæ. Santa Marta is a seaport on the northwestern coast of the Republic of Colombia in latitude 11° 15' N. and longitude 74° 14' W., or, in other words, is 675 miles north of the equator and due south of the City of New York. The town is low-lying and is situated upon the seaward portion of a circumscribed plain, surrounded, except to seaward, by the foothills of the Sierra Nevada. It has a population of about 8,000 and a dry even tropical climate. During the year 1913, the maximum temperature recorded by a standardized thermometer kept in the shaded portico of the office of the superintendent of the medical department was 92° F., and the minimum 79° F.—a variation of only 13° F. throughout the year. In the early period of the epidemic, two cases occurred among the soldiers which tended materially to complicate the situation, in that, while both were serious and important cases, neither presented characteristic signs of pneumonia, but in both the general symptoms corresponded closely to those observed in the first stage of yellow fever. In addition to this, one patient was found to have an enlarged inguinal gland. The cause of the outbreak among the soldiers was at least partly due to overcrowding and to improper accommodations in the local barracks. There were at that time 380 soldiers and about twenty officers quartered in a building that could not well afford proper accommodations for more than half that number. Many of the soldiers were raw recruits from the interior, and although the routine drills, etc., were, especially in view of the warmer climate of the coast, somewhat strenuous for these, all were well fed and under good, wholesome discipline. Local meteorological conditions also apparently favored the spread and virulence of the infection. The season was dry and there had been no rain for some months.

The trade winds then blew fresh, and the surface currents were freighted with the polluted dust and sand of the town.

1. Cases of Faulty Treatment of Superficial Malignancy.—H. H. Hazen states that during the past three years he has been consulted by thirty-two private patients for malignant conditions of either the skin or mucous membranes of the mouth. Of this number only six consulted him for early, untreated stages of cancer. The faults in handling the other cases naturally group themselves under three headings; first, neglect on the part of the patient; second, faulty diagnosis on the part of the physician, and third, improper or insufficient treatment by either physicians or quacks. In nine instances, patients had neglected themselves without seeking medical advice. One intelligent man had suffered from a cancer of the scalp for nineteen months, four patients had superficial growths of either the face or neck for over two years, one man had carcinoma of the lip for eight months, two had cancer of the face for six years, and one woman had five neoplasms of the face for seven years before seeking aid. Twelve cases were either improperly or sufficiently treated after a correct diagnosis was made. In several instances more than one faulty method of treatment was employed. Five patients had operations performed from which rapid recurrences took place. Four of the patients had been treated by small divided doses of the Roentgen rays. The new method of single heavy dose therapy has been in use such a short time that the writer and others have not as yet had a chance to study recurrences after it, although some will doubtless take place. The conclusions arrived at are as follows: 1. The public is not yet sufficiently educated as to the importance of attending to superficial sores that will not heal. 2. While it must be admitted that some cases of superficial malignancy are difficult to diagnose, still entirely too many of them are mistaken for other affections, even by experienced physicians. 3. Many cases are not treated radically enough; it should always be remembered that insufficient treatment of whatever kind is the worst possible thing for a patient suffering from a malignant condition. 4. Radium, even in large doses, and when administered by some of its greatest advocates, is by no means infallible in the superficial cases that it is stated to cure.

5. The Etiology of Iritis.—Ernest E. Irons and E. V. L. Brown have investigated all cases of non-traumatic iritis in one hundred patients. By a careful weighing of all the evidence, they were able to determine in most cases which infection was probably responsible for the disease of the eye; but sometimes the available evidence was insufficient and they have placed such

cases in a "combined" group. Some of these patients suffered from several infections. Syphilis, active tuberculosis, gonococcal infection, and alveolar abscess were repeatedly found in the same individual. Out of 100 successive cases of iritis, there were only twenty-three in which syphilis was the cause of iritis and sixteen others due to other causes in which syphilitic infection had occurred, making a total of thirty-nine patients in whom syphilis had to be seriously considered in the etiologic diagnosis. This left sixty-one cases in which a searching examination failed to reveal any evidence of past or present syphilitic infection and in which, therefore, the iritis could not be reasonably thought to be due to syphilis. So far as one may draw conclusions from this number of cases, it would seem that the widely accepted statement that 50 per cent. or more of iritis is due to syphilis may have to be revised. In eighteen patients the writers regarded the dental lesion as the source of the iritis. In fifteen patients the iritis seem to be clearly due to other causes, such as syphilis and tonsillar infection, and the dental infection relatively inactive so far as concerned the causation of metastatic lesions. In the remaining nine cases, the dental infection was associated with other infections, often two or more, including tonsillar, sinus, syphilitic or gonococcal, and they were unable to satisfy themselves which infection was responsible for the disease of the eye. The tonsil was clearly the source of infection in sixteen cases. In thirteen cases of the combined group, tonsillar infection was present with other infections; but as in the case of dental infections, they were not able to determine whether tonsillar or dental infection was the immediate cause of the iritis. Tonsillar and dental infections are frequently found together, and the question may well be raised as to whether the dental infection may not have developed in previous months and years by the same mechanism as the iritis, by repeated infections from the tonsils. Gonococcal infection was believed to be the cause of the iritis in nine patients, all males. In eight patients the iritis appeared to be tuberculous. In three patients the iritis was considered due to infection from the sinuses. In three cases the iritis was associated with non-venereal infections of the genitourinary tract, including two of the prostate. Diabetes was present in three cases, but in each instance, infections were also present, in one, alveolar abscess; in one, tonsillar abscess, and in one, tuberculosis, syphilis, and tonsillar infection. Several cases came to the investigators with a provisional diagnosis of "iritis from auto-intoxication." In none of these did they fail to find active infectious processes, such as tonsillar or alveolar abscesses, and the previously resistant iritis subsided on relief of the infection without measures specially directed toward the treatment of the supposed "gastrointestinal auto-intoxication." There were seventeen patients in whom several infections were present, or in whom there were several foci harboring the same or different infections in such combination that they could not with certainty determine which infection had given rise to the iritis. From the writers' clinical study and from their experiments thus far, it would appear that not one but several factors are concerned in the production of iritis, among which may be noted the presence of a focus of infection in which bacteria may live and multiply, partially protected from the resisting forces of the host; the periodic entrance into the blood stream of these organisms and that lodgment in the eye itself, either by reason of their great number as in sepsis, or by fortuitous embolism; changes in the eye itself, either in vascular anastomoses, or in susceptibility of the ocular tissues owing to previous injury; and finally

changes in the organism itself, whereby it becomes better able for a time to maintain itself in the tissues of the eye. Such adaptations on the part of the organism do not necessarily imply any demonstrable change in the morphology or cultural reactions.

8. **The Examination of Normal Gastric Secretion by the Fractional Method.**—Eugene S. Talbot examined about 150 cases by the fractional method in order to study the entire cycle of secretion during gastric digestion. These included a normal series on proved healthy medical students and nurses, and an abnormal series on private and clinical hospital patients. The technique employed was that of Rehfuess with a number of changes and additions. As a result of the work it is believed that the fractional method of gastric analysis should replace the old tube method. The true secretory curve of digestion can be determined only if the test meal is introduced into the empty stomach. A much larger quantity of residuum may be obtained from the symptom free fasting stomach by the Rehfuess tube than was formerly considered to be within the limits of normal. The intensity of appetite secretion is variably influenced by the Ewald meal in different normal individuals. The difference in the time of occurrence of the high point of secretion and the rapidity of the change in acid concentration make it impossible to determine the true secretory state of a stomach other than by the fractional method of analysis. A plateau type of secretory curve is no proof of the secretion of an acid of uniform concentration. There is no form of secretory curve common to all normal stomachs, although the vast majority of normal curves have certain characteristics in common. The contour of a given normal curve is dependent on the following main factors—the intensity and duration of appetite secretion as influenced by the test meal, the amount of gastric mucus, the concentration of food secretion, and the emptying time of the stomach. The emptying of the normal stomach is fairly uniform. Many phenomena associated with the normal gastric cycle of digestion as determined by the fractional method of analysis have yet to be explained.

1. **Links in a Chain of Research on Syphilis.**—I. E. R. McDonagh, in discussing chemotherapy, says that Ehrlich's principle in applying the "side-chain" theory to treatment was shortly this: To find drugs, the chemical groups of which would combine with the chemical groups of the parasites to be attacked, without combining with the chemical groups of the host's cells. The chemical groups of both the drugs and the cells received the name of "chemoceptors." The disease which Ehrlich hoped to combat was sleeping sickness, and as arsenic was the body which appeared to have the greatest influence upon the disease, experiments were undertaken with this metal. Ehrlich's views as to the mode of action of salvarsan, was that a union takes place between the drug and certain parasites, with a destructive action upon the latter. What the nature

of the union is, and why the death of only certain parasites should follow, are not explained. Summing up the points which stand out, with respect to the mode of action of salvarsan, the writer states that we can, in short, say that strongly absorbed metallic and non-metallic compounds become attached to the lipid-globulin molecules of the syphilitic parasite, the plasma cells, and the serum by virtue of their amino groups and of the peculiar physical properties of the protozoal lipid-globulin molecules. The metallic compounds attack those phases of the *Leucocytozoon syphilidis* in which reaction is most marked, especially the spirochetal phase, in virtue of its free hydroxyl groups. Both metals and non-metals act as catalysts, that is to say, they accelerate the complementary or oxidase-reducase action of the lipid-globulin molecules of the serum and of the plasma cells by increasing directly and indirectly the supply of active oxygen, which is necessary for the action of adsorption, a chemico-physical action which destroys the parasites. The writer wanted an element which had the following properties: 1. Of more than one valency; 2. An atomic weight of less than 75; 3. A non-metal; 4. A reducing agent. Only two elements occurred to him which would fulfill these conditions, and these were phosphorus and sulphur. He discarded phosphorus, owing to the fact that it can produce very toxic symptoms, such as fatty degeneration of the liver, so he conducted experiments with sulphur and succeeded in making a compound which has in some respects a more powerful therapeutic action than that of salvarsan. He prepared several compounds, but soon found that one was much superior to the others, and this one was di-ortho-amino-thio-benzene, or "intramine," as it is commercially called. As intramine is a new drug, some points with regard to its administration might with advantage be given. All intramuscular injections are apt to be painful; the intensity of the pain varies with different individuals, and is mostly due to the bulk of the injection and the edema and contraction of the muscle fibers which follow it. There are several ways in which pain can be reduced. First and foremost, the intramine should be well warmed before it is injected. Immediately after the injection pain is experienced; this lasts for a few minutes, then vanishes, to reappear some hours later when the edema and contraction set in. The patient should be well massaged after the injection has been given; he should walk about to aid absorption, and the moment the stiffness begins to set in he should have a very hot bath in which some soda has been dissolved. For the next two or three days the leg should be moved as much as possible, hot baths should be repeated, and the part should be well massaged. By the fourth day every trace of intramine will have vanished from the buttock, no induration will remain, and the patient should be able to move about in the normal way. There is usually a rise of temperature on the second and third days, the degree depending upon the severity of the case; the patient may perspire freely, and sometimes a few days later an erythema appears over the injected buttock, which either remains localized or spreads over the body, in every case to disappear twenty-four or forty-eight hours later. The erythema is probably due to the sulphur. However big be the dose, and however frequently it be repeated, McDonagh has never noticed any other ill-effects than those already described; therefore it may safely be assumed that intramine is an entirely innocuous drug. He cannot help closing his lectures with the prophecy that intramine, especially when alternated with powerfully adsorbed oxidizing agents, is going to play a very important part in the

treatment, not only of syphilis, but of all chronic infections, since it has already proved itself of considerable value in cases of tuberculosis and chronic gonorrhea. It is even probable that intramine may have a place in the treatment of malignant diseases.

4. Two Cases in Which the Lateral Ventricle Was Opened in the Course of Operations for the Removal of a Bullet and Indriven Bone from the Brain.—H. F. Woolfenden draws attention to the extreme fatality that follows the opening of a lateral ventricle during an operation for the removal of a foreign body, whether a bullet, shell fragment, or depressed bone, and records two cases in which recovery followed the operation. In about 200 cases that have come under his notice there have been some half dozen cases where, after the removal of the foreign body, cerebrospinal fluid has been found escaping from the depth of the wound, either at the operation or during the dressings some little time after the operation. In these cases the marked infection present had compelled an operation to be undertaken, although x-rays showed the likelihood of the ventricle being involved, and, further, this marked infection had reluctantly compelled one to leave in a drain. These patients mostly died from cerebral hernia following infection of the ventricle and basal meningitis, but one died from extreme emaciation and wasting due directly to the persistent escape of cerebrospinal fluid from a fistula that connected the lateral ventricle with the scalp wound. In view of this high mortality he ventured in the two cases recorded to depart from the general rule in early cases of always draining the track after the operation for the removal of foreign bodies or depressed skull fragments which were embedded in the brain. In these two cases the signs of sepsis were absent or slight, and so he felt justified in taking the risk of leaving a possibly infected track of the brain undrained to the risk of establishing a cerebrospinal fistula. Fortunately this procedure was justified, and either the wound was not infected or probably the patient's tissues were able to overcome the infection that was there. In the first case it is likely that the wound was clean, in the second case, a certain degree of infection appeared to be present. Both the cases occurred at a base hospital in France.

5. The Treatment of Hepatic Failure in Yellow Fever, Malaria, and Other Conditions: A Suggestion.—Andrew Balfour has had opportunities at Panama and elsewhere of studying sections of the liver from cases of yellow fever, toxic jaundice, blackwater fever, and malaria associated with icterus, and of noting the marked destruction of liver cells which occurs in these diseases. These studies have brought to his mind a case of malarial infection in the Sudan where, although quinine eventually cleared the blood from a heavy infection of *P. falciparum*, death occurred after a peculiar set of cerebral symptoms. At the time the medical officers in attendance on the case felt themselves between the devil and the deep sea, for they had difficulty in deciding whether these symptoms were due to the action of material toxins or were evidence of a tendency to quinine poisoning in a subject very susceptible to the effects of the drug. In the light of recent work and remembering the condition of the liver as revealed post-mortem, he has no hesitation in saying that the symptoms in this case were an expression of hepatic failure. Now what are the symptoms associated with the destruction of liver cells? They are chiefly of cerebral origin, pointing to a poisoning of the higher nerve centers. It will be found that these symptoms are common to delayed chloroform poisoning, yellow fever, severe cases of epidemic jaundice, the

so-called Mediterranean fever, Weil's disease—whatever that may be—blackwater fever, certain forms of fatal malaria, acute yellow atrophy, phosphorus poisoning, etc. The object of his note is to suggest that on the lines indicated by Colonel Hunter in cases of toxemic jaundice, etc., endeavor to prevent or at least cut short the rapid destruction of liver cells which seems to him plays so important a part in bringing about a fatal issue in such diseases as yellow fever and bilious remittent fever. Colonel Hunter thinks that in the destruction of liver cells there is, owing to the strain thrown upon this organ, increased fat metabolism with acidosis and acetoneuria, and the liver cell coming under the influence of its own ferments, undergoes autolysis and thus presents the characteristic appearances seen post-mortem. Colonel Hunter further thinks that ammonia, as a rule, keeps the ferments in check, and in the early stages of febrile diseases, purging the patient with calomel and withholding food prevent the formation of ammonia and thus the hepatic ferments have full play. Colonel Hunter's theory and researches would lead to one important practical conclusion, i.e. the necessity in cases of delayed chloroform poisoning and toxemic jaundice of keeping up the supply both of sugar and protein food, the latter in peptonized form.

1. **The Soldier's Foot and the Treatment of Common Deformities of the Foot.**—Robert Jones describes the deformities and disabilities of the foot, those to which the soldier is more especially liable, and their treatment. These disabilities and deformities include flat foot, acute flat foot, traumatic flat foot, flat foot from peri-arthritis, rigid flat foot, osseous flat foot, flat foot due to spasm of the peronei. The flat foot for clinical purposes may be divided into two classes. (a) The foot which the patient can invert. (b) The foot which he cannot invert. The first class will not respond to any mechanical treatment, such as a plate or alteration of the boot. It will not even suffer correction by means of a bandage to an outside iron from knee to heel. An operation of forcible manipulation and fixation under an anesthetic are essential preliminaries to the simpler mechanical methods. The second class will never require an operation. This simple clinical division should be helpful to the military surgeon. He has purposely avoided all mention of tiptoe exercise. These exercises are excellent, but they will not cure a flat foot if the patient is allowed to come down in the flat-footed position between the period of exercises. If the principle of deviation of body weight on to the outer edge be loyally adhered to every ordinary case will recover, even without special tiptoe exercise. Loyal adhesion to the principle stated means that the patient never sets foot on the ground except in a properly crooked boot, shoe or slipper. Even in his bath he must be careful to stand on the outer edge of the foot. The whole idea of treatment is to insure that uninterrupted

adaptive shortening of stretched structures shall take place. Massage, tiptoe exercises, electric stimulation of muscles all help to hasten the recovery, but a few minutes careless walking in stocking soles will undo all benefit from other treatment by again stretching recovering structures. Frequently the high arched foot is the most troublesome type when the tendons are strained and the ligaments begin to give. The strain upon the astragalo-scapoid joint in this type is, for obvious mechanical reasons, great, and the progress of the affection is often marked by a prominence about the scaphoid due to pressure osteitis.

5. **The Treatment of Puerperal Sepsis by Uterine Suction and Drainage.**—Norman Porritt is of the opinion that the suction tube has all the advantages with none of the dangers of the uterine douche. In at least two cases he has seen the uterine douche convert a smart sapremia into a rapidly fatal general infection, while in another case it set up acute, presumably chemical peritonitis. While he was administering the douche the woman was seized with agonizing abdominal pain, which was quickly followed by general collapse and rapidly developing abdominal tendencies and distention. The douching was at once stopped, but the patient died five hours after the onset of the acute pain. To illustrate the patulousness of the fallopian tubes, Dr. Goodall narrates a case of congenital atresia of the sigmoid. The abdomen was markedly distended, and dark liquid blood was coming in spurts from the vagina. On operating the abdomen was found full of blood and meconium, the sigmoid having ruptured. At the autopsy, four hours later, blood was still coming from the vagina. In the cadaver Dr. Goodall has injected methylene blue into the uterine cavity with douch can and cannula, imitating as closely as possible the technique of operative work. With a pressure of only two feet of elevation, and in some cases only eighteen inches, and with a temporary obstruction to the outflow, such as is frequently caused by clots and fragments of tissue, he was able to send fluid into the peritoneal cavity through the fallopian tubes. Hence, he says the risk of chemical peritonitis, not to speak of septic peritoneal contamination. Uterine suction tells us the conditions in the interior of the uterus. It is most instructive to watch the gradual alteration of the stuff withdrawn from a thick offensive fluid, loaded with semi-solid purulent masses, to a clear red liquid, and from that to an inoffensive mucus. Moreover, it prevents us from being misled, as we doubtless often are, but the deceptive character of what we find upon the diaper. The diaper may be covered with discharge, which may be only an overflow, or it may not come from the penthouse in the uterus at all, for there may be odorless discharge on the diaper, and foul, fetid fluid in the uterus. And efficient drainage of the uterus is the key to the successful treatment of puerperal sepsis.

Cleaning Vacuum Bottles.—Whenever a vacuum bottle gives any odor at the mouth of the bottle it should be cleaned. Hot water, soda (caustic soda or washing soda is more cleansing and quicker than baking soda, but the latter will do), and little clippings of clean paper will do the work, shaking from time to time for fifteen minutes with the bottle corked. Milk causes most of the uncleanness in a vacuum bottle, and bottles used for it should be cleaned often. Coffee with milk in it is apt to leave a sediment. Soup will sometimes leave an odor calling for a cleaning. Beer gives off a peculiar smell that soda also removes. Water will deposit a fine mud after a time, due to lime sediment, and soda will remove this when used as directed above.

(Special Report to the MEDICAL RECORD.)

SECTION ON DISEASES OF CHILDREN.

(Continued from page 1118.)

The Factor of Starvation in the Development of Acetonuria.—Drs. S. BORDEN VEEDER and MEREDITH JOHNSTON of St. Louis presented this communication. They emphasized the distinction that must be made between acetonuria and acidosis. Acidosis was now used in a more general way to designate a decrease in the alkali reserve in the blood. It was a question of practical value to the pediatrician to know how starvation influenced the acetone bodies in the urine. Observations were made on children of different ages and body weight. The diet on which they were fed before the period of starvation was one consisting of 40 or 50 per cent. carbohydrates. It was found that the total quantity of acetone varied directly with the period of inanition. The total output when the children were not starved was 3 mgs. per kilo body weight. During the first twenty-four hours of starvation there was little difference in the output of acetone bodies, but there was an increased elimination during the second day. If the period of starvation extended over only one day, the output of acetone bodies on the second day returned to normal figures. In eighteen cases in which there was a second twenty-four-hour period of starvation the output of acetone bodies increased from 20 to 410 mgs. per kilo body weight. On the day following the second day of inanition the output of acetone bodies was less than on the second day. In febrile and toxic conditions the figures were high, but not as high as during inanition. Folin and Denis had found that obesity was not a predisposing factor in increasing the total output of acetone bodies. The writers had made observations on children well nourished and on those undernourished, and found no relation between the degree of acetonuria and the degree of inanition. All the children were closely watched for clinical symptoms, particularly with reference to the symptoms of acidosis in childhood, but there was not a single child that appeared to be affected in any way, save for hunger, by the lack of food. It seemed safe to conclude that starvation could not be the cause of the symptoms of acidosis.

Dr. JOHN LOVETT MORSE said it seemed that after listening to these papers there were certain points which the practitioner might carry away with him. One of these was that the presence of acetone bodies was not proof of disease, and, vice versa, that the absence of acetone bodies was not proof that there was not an acidosis. If starvation caused the presence of acetone bodies in the urine when one was giving a child to starvation treatment, he could not tell whether the acetone bodies were due to the starvation or to the disease. Acetone bodies might be found in all the conditions of childhood accompanied by fever. It seemed that the physician must learn to examine the blood for acetone-mia and not trust to the presence of acetonuria. When they had all learned to tell whether a patient had acidosis by the examination of the blood they were still confronted by the fact that acetone-mia was not a primary condition, and before they could treat this condition satisfactorily they must find its underlying cause. Newspapers reported an epidemic of acidosis in Boston last winter. In most of these cases the urine was never examined and in some cases in which it was examined no acetone bodies were found. It seemed impossible to have an epidemic of acidosis, because acidosis was a secondary and not a primary condition. It had been his experience that a careful examination showed that these children had something else. There were places in New Hampshire where there were a great many cases of severe illness in children. The only thing found in these children outside of vomiting was the change in respiratory excursion and a diminution in the amount of urine. In these cases large amounts of acetone bodies were found in the urine. The large majority of these children got well, but some of them died. One could not deny that these were cases of acidosis. In cases presenting these symptoms the complications had all shown a bacterial infection of the blood and a local focus of infection.

Dr. CHARLES GILMORE KERLEY said he thought this subject was one of the most important that would come before the section at this meeting. He had been trying for five or six years to correlate these cases, showing a recurrent symptomatology. They found cases in which there was a distinct acetonuria and cases in which there was a distinct acidosis; it was not these but the borderline cases that gave the most difficulty in the attempt at classification. The type of case that showed the acetonuria were the children fed with too much milk. The majority of children of runabout age received too much fat and too much sugar. These were the children that showed acetonuria and high fever; about 60 or 70 per cent. of them showed acetonuria; a smaller percentage of cases of pneumonia, scarlet fever, and other conditions accompanied by a fever also showed acetonuria. In these children the power of assimilation of carbohydrates seemed to be held in abeyance and acidosis resulted. Dr. Kerley cited three cases of acidosis in which there seemed to be no definite complications.

Dr. JOHN JAHORSKY of St. Louis asked how the clinician was to distinguish these cases of acidosis from cases of gastrointestinal intoxication without having the tests accurately carried out. He wanted to know whether the hyperpnea could be depended upon, and when this was present whether it was better to give sodium bicarbonate. Should these cases of gastrointestinal intoxication be treated in the old way by barley water, saccharine water, etc., or should one begin right away giving large doses of bicarbonate instead of calomel?

Dr. HENRY D. CHAPIN of New York said that in answer to Dr. Jahorsky's question the treatment of the diarrhea was not different from that used ordinarily, giving castor oil, washing out the bowel, stopping the milk, and then giving carbohydrates.

Dr. JOHN HOWLAND of Baltimore, in closing the discussion, said that in the first place in the discussion there had been shown the same confusion in calling recurrent vomiting acidosis, which he had distinctly warned against in his paper. Cases of recurrent vomiting were not acidosis; an overwhelming majority of cases of recurrent vomiting had acetonuria, but this was not acidosis. One did not have acidosis until there was a diminished alkali reserve in the body, and in recurrent vomiting a diminished alkali reserve was almost the exception. One need give the alkali treatment only when the acetone-mia was severe and prolonged. There was only one symptom of acidosis, and that was the hyperpnea, the exaggerated breathing of the air-hunger type. Acidosis might occur without fever and without vomiting. The examination of the carbon dioxide tension of the alveolar air was not so difficult if the air was collected by the method devised by Dr. Marriott. In this way the air could be collected at the bedside.

Wednesday, June 14—Second Day.

Further Study of the Amino-Acid Content of the Blood.—Drs. C. J. PETTIBONE and F. W. SCHLUTZ of Minneapolis presented this paper, which was read by Dr. Schlutz. He reviewed the literature with reference to amino acids, which showed that the amount of amino acids in the blood varied widely, but there was little to show what relation the amount of amino acids in the blood might bear to various pathological conditions. The normal amount of amino acids per 100 c.c. of blood in infants was about 4 mgs. To find out what the variations from normal might be, a series of sixty children were studied, varying in age from one month to thirteen years. Among the pathological conditions present in this series were diphtheria, scarlet fever, bronchopneumonia, tuberculosis, atrophy, a number of nervous disorders, nephritis, rachitis, encephalitis, tonsillitis, and a number of other conditions. The blood examined was taken from the median basilic vein and the estimations were made by the method of Van Slyke and Meyer, 2 to 5 c.c. of blood being used. The analyses were made one-half hour after taking the blood. The figures ran lower for children than those of Van Slyke and Meyer for adults. In the diseased conditions the figures did not seem to differ from those found in health. There was no increase in the amino content of the blood in febrile conditions, as might have been expected; neither was there a decrease. There seemed to be no striking correlation between the amount of amino acid present in the blood and the length of time since the last feeding.

Symposium on Syphilis—The Frequency of Hereditary Syphilis.—Drs. FRANK S. CHURCHILL and R. S.

AUSTIN of Chicago presented this contribution, which was read by Dr. Churchill, who explained that the report on a series made by him in 1910, in which he found thirty-nine positive Wassermann reactions in a series of 102 infants, was open to criticism, because at that time he had taken a number of weakly positive Wassermann reactions as positive which in the light of their present knowledge would not be accepted as definitely positive. Dr. Austin had nothing to do with that part of the work. The present study was based on an unselected series of 695 patients coming to the Children's Memorial Hospital Clinic from November 1, 1915, to June 1, 1916. They had now learned that a weakly positive Wassermann reaction might be obtained in many conditions other than syphilis, as yaws, leprosy, tuberculosis, eczema, and some acute infections. In order that statistics might be considered reliable, there were two factors requisite: they must be based on the observation of a large number of individuals, and there must be accuracy in diagnosis. To meet this latter requirement in hereditary syphilis the family history of the patient and the laboratory findings must be taken into consideration. Owing to the transitory positive Wassermann reactions in other conditions it was well to have the test repeated. They had found positive Wassermann reactions in forty-two cases of eczema, sometimes a single and sometimes a double Wassermann. After describing the technique used the author stated that they had divided their reactions into three groups according to the degree of hemolysis. A single positive Wassermann reaction was regarded as of almost no value from a diagnostic point of view. A double Wassermann with physical signs of syphilis, of course, clinched the diagnosis. In the absence of clinical signs it was well to have the test repeated. A triple Wassermann reaction even without physical signs of syphilis was fairly good proof of the presence of lues. While this series of cases was too few to warrant definite conclusions, they had found that twenty-three cases could be considered as syphilitic. Sixteen of these twenty-three cases gave a triple Wassermann reaction. Six of the twenty-three cases showed no physical manifestations of the disease and the diagnosis was only based on the triple Wassermann reaction. The cases that were not considered syphilitic were grouped in definite classes. In 640 of these 672 cases there was nothing suggestive of syphilis. There was a certain number of cases in which there was a doubt as to whether they were syphilitic, and these cases should be regarded as syphilitic, treated, and kept under observation, both for their own good and for the welfare of society. A study of the incidence of hereditary syphilis as found in the literature showed a wide range of results and varied from 2 to 14 per cent. in Europe and in this country. In this series the incidence was 3.3 per cent., while in four of the largest studies made in this country it had ranged from 2 to 6 per cent.

The Clinical Course and Physical Signs in Hereditary Syphilis.—Dr. ABNER POST of Boston presented this paper, which was read by Dr. Philip H. Sylvester of Newton Center, Mass. He stated that there was an amount of irreconcilable variation in the descriptions of infantile syphilis found in the literature. A difference should be made between the child that was syphilitic *ab initio* and the one rendered syphilitic after life had begun. Hereditary syphilis had been confused with congenital syphilis. Hereditary syphilis occurred in a great variety of clinical forms, and there was a difference between early and late hereditary syphilis. In the early form the child was usually emaciated, suffered from impaired digestion, showed an eruption of the bullous type, had cracked lips which might ulcerate, and enlarged liver and spleen. In contrast to this severe type all gradations of symptoms might be found. Some of the children appeared apparently healthy until they developed something that indicated the condition. Obstinate wakefulness might arouse suspicion, and was particularly likely to occur in cases in which the disease affected the bones. Another symptom was the nasal catarrh, often leading to the belief that adenoids were present. Operation in such cases gave no relief. The nasal passages were decidedly narrowed. Aside from the fact that operation gave no relief to the patient, there was the danger that the operator might be infected. It was difficult to form an estimate of the incidence of infantile syphilis, as it was quite customary to give marasmus as the cause of death on the death certificate of many children in whom syphilis was the cause of the marasmus. Syphilis showed a marked

tendency to involve the lymphatic system; the enlarged glands of syphilis were often attributed to tuberculosis. In many subjects the skin was of a pale, sallow, yellowish hue. The eruption of hereditary syphilis was maculopapular. It usually was noticeable first on the heels and had a glistening appearance. There was sometimes desquamation. This condition might be observed on the palms of the hands as well as on the soles of the feet; it was also often found under the diaper. Other signs that were characteristic of early syphilis were shedding of the nails, thinning of the hair, and cranial exostoses. These latter were often attributed to rachitis. Other bone changes of syphilis might also be mistaken for rachitis, as osteochondritis. As to the treatment, salvarsan administered to the mother usually brought about a great improvement in the succeeding baby, but there still might be some stigmata of syphilis. It had been stated that in the case of twins one might show the stigmata of syphilis and the other not. Cases were cited which showed that a thorough search might often reveal the signs of syphilis in a child supposed to be healthy.

Comparative Studies of the Luetin and Wassermann Reactions.—Drs. L. R. DEBUYS and J. A. LANFORD presented this communication. They stated that in studying the symptoms of congenital syphilis they had found that there were not many classical symptoms. Moreover, it was important to recognize syphilis early in order to give the child the best possible chance in life. For this reason laboratory tests that could be depended upon were important. In making the Wassermann tests they had used the classical method of Wassermann, which was described in the paper, and in making the luetin tests they had used the technique of Noguchi, carried out minutely. They had made 350 Wassermann tests and 159 luetin tests in 179 cases. Thirty old cases studied with the Wassermann reaction several years ago were included. The period during which the cases were observed varied from one month to five and one-half years. There were seventy-nine children, sixty-three mothers, and eight fathers. The children varied in age from twelve days to just under puberty. In sixty-two families more than one member was tested by both the Wassermann and the luetin tests. The latest reaction in a mother was twenty-four days, and in another instance the reaction only showed itself after fourteen days. In some instances in which the Wassermann test had been negative, after the luetin test was made and was positive the Wassermann also became positive. It seemed that in some instances active anti-syphilitic treatment brought out a positive reaction where the reaction had previously been negative. The most violent luetin reactions occurred in a mother and nursing baby in whom there were no signs of syphilis. It developed that the mother had been given potassium iodide, and the interesting feature in this case was not only the effect of the iodide on the mother but also on the nursing baby. In this study they had found that the luetin test was more reliable than the Wassermann. In eighty-one children and parents the readings of the luetin test were dependable. In four instances there was a negative luetin and a positive Wassermann, and it was believed that there was an error in technique in these cases, as they all occurred on the same day, and none of them was considered clinically as luetic. The positive luetin reaction was found in many instances in which the Wassermann was negative. It was also found that a positive luetin test ran regularly in families, which was further evidence of the accuracy of this test. In the series of thirty old cases studied only by the Wassermann test, in which the luetin test had not been made, it was shown that thirteen out of twenty-nine would not have been recognized by the Wassermann reaction alone. It had also been observed that the Wassermann reaction varied from time to time, according to the activity of the disease. This was not the case with the luetin test. In concluding, the writers stated that the luetin test should not displace the Wassermann test, for the Wassermann reaction indicated the presence of anti-bodies in the blood. The luetin test showed the presence of syphilis even though it was inactive. However, the luetin test had the disadvantage that it was influenced by drugs, and again it should not be considered negative until sufficient time had passed to be sure that one would not have a late reaction.

Late Hereditary Syphilis.—Dr. P. C. JEANS of St. Louis presented this paper. He said the division of hereditary syphilis into early and late was not very

satisfactory, for the early changes might occur as late as the fifth or sixth year and the late changes might occur as early as at birth. This division must be relegated to its proper place. The only evidence of syphilis might be a positive Wassermann reaction. There was very little literature on the subject of latent syphilis, and the question arose whether such cases should be treated. It seemed to him that in such cases there was some advantage in carrying out the treatment just as though the manifestations of the disease were present, in spite of the possibility of developing a keratitis. If these cases were not treated there was a probability that the condition would manifest itself later anyway. The writer then reviewed Head's classification of syphilis of the central nervous system, and stated that it was the classification he would adopt in discussing syphilis of the central nervous system. He stated that certain authors had tried to correlate the symptoms of syphilis and chorea. He had had one case in which he thought the syphilis was the cause of choreic symptoms. In this instance salvarsan cleared up the choreic symptoms. About 20 per cent. of cases of epilepsy might be considered as due to syphilis. Multiple sclerosis proper did not occur in childhood. Hemiplegia was the most frequent acquired paralysis due to syphilis. Syphilis of the central nervous system was not as uncommon in children as had been supposed. Optic atrophy had been seen as early as four and one-half years of age; tabes was not so rare, but it was difficult to make a diagnosis of this condition in children. Paresis was more common than tabes. In young children the intelligence was not developed, so it was impossible to demonstrate the changes incident to syphilis of the central nervous system. It was often difficult to differentiate syphilitic from tuberculous processes, especially when the bones, joints, and lymph glands were involved. It had been the writer's experience that both the gross and microscopical picture might be indistinguishable. Many syphilitic processes were treated as tuberculous and support was even brought to the diagnosis of tuberculous by the laboratory tests. Hutchinson's triad was scarcely ever present. In a study of several hundred cases he had not found it present once. He had found keratitis present in 25 per cent. of his cases. Hutchinson's teeth in 6 per cent. and deafness in 1 per cent.

The Treatment of Hereditary Syphilis.—Dr. PHILIP H. SYLVESTER of Newton Center, Mass., read this paper. He said that a pregnant syphilitic woman had a much better chance of having a viable child if treated than if untreated. Since they had established their system of prenatal care in Boston he felt sure the percentage of viable children was greater and there were fewer abortions than before. Salvarsan was effective in the early cases, but salvarsan had been largely discarded in the new form in favor of neosalvarsan. After treatment by salvarsan or neosalvarsan alone the clinical symptoms returned after the cessation of the treatment, so that they had returned to the old treatment by mercury. Even if salvarsan was used at first it must be accompanied by mercury. There had also been a reaction in favor of inunctions of mercury. The tendency was to increase the dose of salvarsan rather than to diminish it and to give it in a concentrated solution. It could be very easily given through the longitudinal sinus. There were some new ideas advanced with reference to treating syphilis with antimony and mercury by inhalation, but thus far one could not say much of them. There was very little to show that the treatment of the mother influenced the child after birth. Some felt that breast milk contained antibodies and others attributed the improved condition of the child when the mother was under treatment to the better milk supply. Mercury should be given for several months and then, if at the end of six months the Wassermann was not positive, it might be omitted for a time, but it should be given at intervals over a period of two years, even though the Wassermann remained negative. If the child gave a negative Wassermann at the end of 2½ years it might be considered to be cured. Others believed that neosalvarsan should be given every two, three, or four months in addition to the older treatment. The late cases of syphilis in children might be divided into two groups. The one corresponded to the tertiary stage in the adult, and in these cases the results of treatment were more encouraging than in the adult, but less so than in the early stage. The second group included cases of syphilis of the nervous system. Some good results had been claimed for the Swift-Ellis method of treatment. Many cases in which nutrition was poor and

the mental development retarded were in reality syphilitic. Many of these children were not sick, but they were distinctly under par, and if the Wassermann reaction was positive they should be given routine anti-syphilitic treatment. Of fifty early cases treated by the writer eighteen presented clinical evidence of early syphilis. The dose of salvarsan that the writer used for a baby of one month was 0.1 of a grain; in a baby from one to six months, 0.2 gr.; from six months to one year, 0.25 gr. The writer described the treatment given different cases in this series and emphasized the importance of early treatment and a continuation of treatment over a period of two years. He said neosalvarsan was the most favorable arsenical preparation for use in children and thought that though the treatment of syphilis of the central nervous system had been disappointing it was not discouraging and all cases should be treated.

Dr. BORDEN S. VEEDER of St. Louis said there was one point he wished to emphasize, and that was the involvement of the central nervous system in hereditary syphilis. The statements made in textbooks that probably the involvement of the central nervous system in hereditary syphilis was rare was probably incorrect. The statement had been made that it was easy to give neosalvarsan intravenously. He did not think it was easy to administer it in this way. He had made injections of bichloride of mercury into the muscles and the cases cleared up more rapidly than with neosalvarsan. He usually gave 1 per cent. solution in four or five minims. In using this treatment one had to watch the kidneys very carefully, since one might activate a nephritis by the bichloride. He gave these injections every day for a period of ten days and then stopped it for a time, and later gave it again for a week. In syphilis of the nervous system he used mercury, as in these cases salvarsan did not seem to have the slightest effect. This was probably due to the fact that in syphilis of the nervous system the lesion was due to the death of nerve cells and nothing would do any good when syphilis of the central nervous system was well established.

Dr. HENRY DWIGHT CHAPIN said that as he recalled it Dr. Sylvester had stated that he gave large doses of mercury in little children. It should be remembered that in these young children gingivitis was not present to serve as a warning that a sufficiently large amount of mercury had been administered. The gastrointestinal symptoms of hereditary syphilis had been spoken of, but there was one other prominent symptom, and that was prolonged anemia. This was difficult to treat in some cases. It might also be mentioned that there was an impression that the breast milk might be affected by the arsenical preparations. He had attempted to prove this statement, but had never found arsenic in the breast milk, and had abandoned the idea of influencing syphilis in the child by treating the mother. Osteochondritis might be distinguished from rickets because it was unilateral, while in rickets the swelling was invariably symmetrical.

Dr. JOHN LOVETT MORSE of Boston said that enlargement of the lymph nodes in children was so common in disturbances of nutrition that he thought it should be disregarded as a sign of syphilis. He had been investigating the possible etiological relationship of syphilis to chorea, and his study seemed to show that syphilis could not be regarded as a cause of chorea. In his series of thirty cases he found only one with a positive Wassermann reaction, and that was a feeble reaction. Some French observers had treated chorea with very favorable results by the use of arsenic intravenously, so that the fact that the case reported was improved by salvarsan could not be taken as proving that the chorea was due to syphilis.

Dr. MARY DUNNING ROSE of New York related an instance in which a negative Wassermann reaction had influenced her to defer anti syphilitic treatment, with the result that there was a loss of six months time in a case that should have been treated.

Dr. STOLL of Hartford, Conn., gave a lantern-slide demonstration of the conditions found in Hutchinson's teeth and other deformities of the teeth resulting from syphilis and also of several other bony deformities.

A Case of Duodenal Ulcer—Operation and Improvement.—Dr. H. M. McCLANAHAN of Omaha reported this case. He stated that the patient was a girl 7 years of age who had been well until she was 5 years old. She then began to have recurrent attacks of gastric pain and vomiting, at intervals of from three weeks to six months. There was a peristaltic wave that could be

induced by drawing the fingers across the abdomen. There was tenderness in the region of the pylorus and a palpable mass. The case appeared to be one of partial stenosis of the pylorus or malignancy. The patient was operated upon by Dr. Jones of Omaha and the stomach was found much dilated and there was a very small pyloric orifice with a ring that could not be stretched. A posterior gastrojejunostomy was performed and recovery was prompt. The child was soon apparently well but was not sufficiently careful of her diet with the result that the symptoms reappeared. Dr. Jones found at the operation what appeared to be a healed duodenal ulcer. The case illustrated the need of proper post-operative care. The appearance of a peristaltic wave was very unusual in a child of this age and also the finding of the healed duodenal ulcer.

Dr. E. E. GRAHAM of Philadelphia said that pyloric stenosis in older children was not so uncommon as was supposed, but it was quite uncommon to meet with a duodenal ulcer in a child. The peristaltic wave and the typical tumor did not usually appear in older children, and in these particulars Dr. McClanahan's case was very unusual.

Dr. CHARLES GILMORE KERLEY of New York said it was unusual to find the peristaltic wave in older children; that was a symptom in infants but was rarely seen in older children. The palpable mass was also favorable to making a diagnosis. Just before coming away Dr. Downes had operated on a case of hypertrophic pyloric stenosis for him in an infant and they found a mass an inch in diameter and neither Dr. Downes nor he had been able to feel it. It was sometimes quite difficult to palpate these tumors, and if one did not find a tumor it did not mean that there was no hypertrophy.

Dr. V. W. TURNER of Des Moines, Iowa, described a case of pyloric stenosis which he observed which was operated on by the longitudinal incision of the tumor. This child, a three-months old baby, made a good recovery.

Dr. HARRY LOWENBURG of Philadelphia said he had had 30 or 40 cases of pyloric obstruction and nine had been operated upon. In all instances a gastroenterostomy had been done. Some were now performing a pyloroplasty, the operation known as the Ramstedt operation or its modification which Dr. Strass of Chicago had been using.

Dr. C. H. JOHNSON of Grand Rapids said that four months ago he had operated on a case of pyloric stenosis by the Strass method and the case had made a good recovery; since then he had three or four successful cases.

Dr. JULIUS H. HESS of Chicago said that he was familiar with Dr. Strass' work. Of the first 23 cases upon which he had operated, 21 were living. He reviewed the method of performing both the Ramstedt and the Strass operation and thought the Strass operation had certain advantages. If in doing the Ramstedt operation one accidentally cut through the mucosa he then had to resort to a posterior gastroenterostomy. The Strass operation had another advantage in that it left no raw surface.

Chronic Intestinal Disorders of Mechanical Origin in Children.—Dr. CHARLES GILMORE KERLEY of New York presented this communication. He stated that he wished to change the title of his paper so that it would include the chronic digestive disorders of the stomach as well as of the intestines. Digestive disturbances might be grouped into those due to bacterial infection, those due to perverted function, and those dependent upon chronic appendicitis. Certain cases showing recurrent symptoms of gastrointestinal disturbance, vomiting, fever, and sometimes respiratory symptoms, did not respond to the treatment that was usually effective in these cases. In seeking for the reason of his failure to treat these cases successfully he had resorted to the x-ray and this had opened up an entirely new field. Many of these cases had shown intractable constipation or constipation alternating with diarrhea. The x-ray had furnished the explanation. In some instances an elongated sigmoid was found and in others a ptosis of the stomach; there were others again showing a partial pyloric stenosis. These cases were treated by massage, gymnastics, Russian oil, olive oil, or fluid extract of cascara. If he wished to administer a teaspoonful of cascara in a day he gave it in three doses and in that way obtained a better effect than though it was all given at once. Massage and physical therapy had been of the greatest aid in dealing with the constipation due to

the long sigmoid. He regulated the diet by omitting white bread, crackers, and similar articles, and gave more green vegetables and fruits, except in cases in which there was diarrhea. In cases having a diarrhea he omitted the fruit and vegetables and gave boiled skimmed milk. These roentgenograms had demonstrated the possible dangers of enemas. The effect of the enema was to further irritate the bowel in these cases. The x-ray served the additional purpose of showing the parents just what was wrong with the child and made it easier to get their cooperation. When they were shown that there was an anatomical deformity they did not expect the child to be cured immediately. In many cases they had found that they were dealing with a ptosis. Ptoses in the adult were congenital or had their origin during child life. The child of five, six, or eight years ate a large meal three times a day and with each meal drank two or three glasses of milk, being urged to do this by his parents very often. The result was the stomach had more food to carry than was suited to its carrying power and as a result the child got a ptosis. The cases having ptosis of the stomach wore a Dr. Aaron band, modified for children, and having a transverse ridge which supported the stomach. He also had these children rest on the right side after meals. The vomiting, the asthmatic attacks, the eczema, the colitis, or the constipation had disappeared or been greatly helped in all of these cases by the recognition of the true condition and the treatment described.

Roentgen-Ray Findings of Chronic Intestinal Disorders of Mechanical Origin in Children.—Dr. LEON T. LE WALT of New York gave this demonstration which showed the conditions found in the cases which Dr. Kerley had described. The first series of pictures which he exhibited showed air that was present in the stomach of the infant normally. It was shown that when the baby was kept in a horizontal position the food in the stomach covered the esophageal opening so that this air could not escape; as a consequence it was forced into the intestines and caused colic. It was shown that if the baby was thrown over the nurse's or mother's shoulder an opportunity was given for the escape of this air. Roentgenograms of many of Dr. Kerley's cases were exhibited which showed the elongated sigmoid, or the ptosed stomach, or moderate pyloric stenosis. It was his rule to consider a case suitable for operation if no food passed through the pylorus at the end of an hour. He warned surgeons in doing a gastroenterostomy to always be sure that they had closed the pyloric end of the stomach. He had seen several cases in which a fatal pneumonia had resulted from neglect in this respect. The fact should be emphasized that ptosis was not a matter of anatomy but rather of function. Two instances of syphilitic lesions of the stomach were shown and Dr. Le Walt said it was becoming very evident that many visceral lesions were of syphilitic origin, not only gumma but interstitial changes. Operations that had been suggested as corrective of the elongated sigmoid were an anastomosis between the cecum and the sigmoid or a resection of the proximal portion of the sigmoid.

Dr. HENRY DWIGHT CHAPIN of New York said he had presented a paper on this subject at the Minneapolis meeting and had shown a series of x-ray pictures to demonstrate that the sigmoid flexure of infants was a very much larger and more complicated structure than was believed. There were several cases in which the sigmoid went above the umbilicus; in other cases it formed a figure eight and was very mobile and very large. These showed the utter uselessness of high enemas to babies. One could not pass a soft catheter into the sigmoid flexure of a baby, so we might be coming to a point where we could stop annoying babies by trying to pass a tube. If the tube was introduced two or three inches and the bag was placed about two feet above the baby's body one could wash out the whole large intestine, if the solution was allowed to flow in slowly.

Dr. L. R. DE BUYS of New Orleans advanced the theory that the pressure on the air ball in the stomach might be responsible for the projectile vomiting seen in pylorospasm.

Dr. HARRY LOWENBURG said he had been studying along the same lines as Dr. Kerley had been working and he would have liked it better if Dr. Kerley had told them more in detail with reference to the way in which he treated the case that he said was the severest case of colic he had ever seen. With the charcoal test and the x-ray one could tell whether a child was getting enough food to sustain life and one could speedily tell

whether he was dealing with an operative or a non-operative case, but one could not always depend on the peristaltic wave and a palpable pylorus to show whether the case was one for operation or not.

Dr. KERLEY said that, in answer to the question as to how he treated the cases with severe colic, he used massage and physical therapy. Sweet oil and olive oil were given in doses as large as one-half an ounce. He took away cow's milk and employed evaporated milk mixtures.

Familial Cyanosis.—Dr. JULIUS H. HESS of Chicago presented this contribution. He said he had used this name for the want of a better one to describe a clinical picture occurring in three boys, aged 11, 9, and 5 years respectively, all children of the same family. The study of these cases had led to the finding of a new method of diagnosis for congenital heart lesions. In these children the cyanosis of the skin and mucous membranes was constant, increasing under exertion, excitement, and more especially in the presence of inflammatory conditions of the respiratory tract, to which all three boys were subject. Very careful physical examination, roentgenograms, metabolic studies, blood examinations and analyses, and tuberculin tests were made. The spectroscopic examination in each case showed the absorption bands corresponded to oxyhemoglobin. The skin showed no pathological pigmentation. The spleen and liver were seemingly normal in size. The physical examination did not yield signs of heart involvement sufficient to account for the condition presented, and hence these thorough investigations were made in the endeavor to account for the condition. In the course of his observations he found that a determination of the difference between the arterial and venous blood in cyanosis and in a normal condition would be of value. He had devised a method of making this comparison which he demonstrated and which would be of material assistance in diagnosing congenital heart lesions.

Dr. WALTER M. BOOTHBY of Boston said that about a year ago at the Brigham Brent Hospital in Boston they had made a study exactly like the piece of work just presented and had reported four cases which were published in the *Journal of Physiology*. It seemed quite remarkable that this same work should have been going on in two laboratories at the same time.

Dr. E. L. HOOVER of Elkhart said he wished to say a word in approval of this method. Thus far all methods of studying the heart had dealt only with the mechanism. They had had no way of finding the systolic output of the heart and the systolic output of the ventricle; this method gave the desired information and it would also give an idea of the reserve energy in the heart, something that they had not had up to the present time.

A Study of the Deaths in Philadelphia During the Past Five Years from Scarlet Fever, Measles, Diphtheria, Whooping Cough and Typhoid Fever.—Dr. EDWIN E. GRAHAM of Philadelphia presented this paper. He said that a study of these statistics led to several interesting conclusions quite different from the general opinion as to the mortality of the diseases to be considered. The most effective way of showing these facts was by grouping the mortality rates of the different diseases according to age. In studying the death rate in infants under one year of age it was found that pertussis was responsible for the greatest number of deaths, more than measles, diphtheria, or scarlet fever. Measles had the next highest mortality, much exceeding the number of deaths caused by diphtheria. With the exception of typhoid fever, which was rare during the first year of life, scarlet fever caused the fewest deaths. Scarlet fever caused fewer deaths than any other disease in this series. The most deaths from measles among infants occurred between the first and second year of life. Pertussis was not as fatal after the first year though it also had a high rate during the second year. There were no deaths from typhoid fever under one year. Between the ages of two and five years of age, diphtheria caused far more deaths than all the acute infections combined. Scarlet fever showed the lowest mortality at this age, although it caused more deaths in children between two and five years of age than at any other period of life. At this age measles was a serious disease. Whooping cough caused almost as many deaths between the ages of two and five as in those under two years of age. Therefore it must be considered a serious disease during the early years of life. The mortality of typhoid fever increased year by year and did not reach its highest point until adult life. Between five and ten years of age diphtheria

caused more deaths than any other disease. At this age the mortality from measles and whooping cough decreased rapidly. There was no mortality from whooping cough between the ages of ten and fifteen years. On the other hand, typhoid fever now caused a higher mortality than any other acute infection and diphtheria ranked second. Between the ages of fifteen and twenty years there was an appreciable increase in the number of deaths from typhoid fever, while the mortality from scarlet fever was very low. From 1911 to 1915 the number of deaths from scarlet fever was 608 and of these 45 per cent. occurred between the ages of two and five years. Taking the death rates for all ages diphtheria was the most fatal disease in this group, having caused during this five-year period, 1,741 deaths. Typhoid fever had the next highest mortality, but in the last two years it had dropped, owing to an improved water supply and the pasteurization of milk. Measles at all ages caused more deaths than scarlet fever. The combined mortality of diphtheria was 11.8 per cent. This high mortality was attributed to the late recognition of the disease, for which parents were more often responsible than physicians. In the scarlet fever cases it had been noted that the mortality was lower when the number of cases was fewer. The points to be emphasized were the low death rate from scarlet fever, which was a much dreaded disease, and the high death rate from measles and whooping cough, against which children were less carefully protected.

Dr. ISSAC ABT said that the high mortality in diphtheria was a sad commentary on their method of dealing with diphtheria. That they should have such a mortality in a disease against which they possessed a specific remedy was because the disease was not recognized sufficiently early. It should be insisted that men learn to make a clinical diagnosis of diphtheria and should not depend too much on the laboratory. When the membrane was dense and covered the vulva and nares one was justified in suspecting diphtheria and should use antitoxin without waiting for a laboratory examination.

Thursday, June 15—Third Day.

Election of Officers.—The Section elected the following officers to serve for the coming year: *Chairman*, Dr. J. P. Sedgwick of Minneapolis, Minn.; *Vice-Chairman*, Frank C. Neff of Kansas City; *Secretary*, Dr. F. B. Gegenbach of Denver; *Representative to the House of Delegates*, Dr. H. M. McClanahan of Omaha.

Alkali Earth Equilibrium in Spasmophilia.—Dr. CLIFFORD C. GRULEE of Chicago read this paper. He discussed the literature on this subject and related the observations that he had made on six cases at the Presbyterian Hospital in Chicago. He found that giving large doses of calcium reduced the electrical irritability, while giving sodium and potassium salts increased the irritability. The increase in the electrical irritability was accompanied by a drop in weight. Three non-spasmophiliacs were given sodium and potassium without effect. Dr. Grulee said he did not feel that his observations had shown any definite relation between alkali earth equilibrium and spasmophilia, but the results spoke for an increased electrical irritability and a retention of the sodium and potassium salts. He had used sodium bicarbonates and sodium citrate, ten or fifteen grains every two hours, and calcium lactate given in large doses every four hours.

Dr. L. R. DEBUYS of New Orleans said that all were agreed that the calcium salts were the ones that controlled spasmophilia.

Dr. ALBERT BEIFIELD of Iowa City reported one case of spasmophilia treated successfully with calcium salts. The calcium salts produced practically a negative effect on the cathode. He gave sodium chloride, 15 grains every hour, and it lessened the irritability; the effect was shown within a few hours after the administration and disappeared within twenty-four hours.

Dr. HENRY F. HELMHOLZ of Chicago said he wished to recall an interesting report he had heard in Washington by Dr. Howland, in which it was shown that the calcium content of the blood during tetany was markedly reduced; this might explain some of the benefit Dr. Grulee observed during his experiments.

Dr. JOHN ZAHORSKY of St. Louis said he thought there was some more profound disturbance of nutrition in spasmophilia than simply a disturbance of salt metabolism and it was a question whether they would solve the problem by simply studying this phase of the subject.

Dr. T. C. MCCLEAVE of San Francisco asked Dr.

Grulee whether he thought calcium lactate was as effective as the other salts of calcium.

Dr. C. G. GRULEE of Chicago, in closing the discussion, replied that calcium lactate had seemed to give very good results in his hands. Much of this work must be reported with reserve. It was not what we gave but what a child absorbed that produced the result. He felt that the calcium treatment of spasmodophilia was a distinct advantage.

A Study of 226 Cases of Chorea.—Dr. ISAAC ABT of Chicago presented this report. He said that notwithstanding the voluminous literature on chorea, there were many phases still open for discussion, because they did not know the exact cause of the disease. Chorea was one of the most common diseases; their hospital records showed that they treated 226 cases since 1880. During these years they had had 80,000 patients, 10,150 of whom were children. The cases of chorea were therefore 2 1/5 per cent. of all cases treated. As to the age incidence, some claimed that they had seen congenital rickets; the usual age, however, at which the disease was most frequent was from five to fifteen years. Their records showed the highest percentage of cases between the ages of five and fourteen years. They had had two cases three and one-half years of age. The disease was more frequent among females than among males, many authorities finding the ratio about three to one; in their series they had found it two females to one male, that was, 151 girls and 75 boys. They had studied the seasonal incidence of chorea in this series and found that January had the highest number of admissions to the hospital of chorea cases and December next; October showed the fewest. These records did not confirm the seasonal findings of Gowers. The author then discussed the literature on the relation of rheumatism and endocarditis to chorea, and also the bacteriology of chorea. He stated that the relation of rheumatism to chorea had not yet been proven; however, it was his belief that chorea was of infectious origin. In 143 cases in which a special history of rheumatism was mentioned only 13 gave a definite history of articular rheumatism. In 119 of the cases there were no manifestations of rheumatism preceding the chorea. The findings were similar regarding chorea and tonsillitis; only 45, or 33 1/3 per cent., gave a history of tonsillitis. These records did not justify the assumption that there was any relation between chorea and acute infectious diseases. There had been a tendency to assume a relation between syphilis and chorea, especially on the part of French observers, and some even claimed that they had treated cases of chorea successfully with salvarsan or neo-salvarsan. In this series there were only two cases that showed any definite manifestation of congenital lues, so that these must be taken as a mere coincidence. Dr. Abt said that while he considered chorea as of infectious nature there was no question but that shock might bring on the symptoms of the disease. There seemed to be a tendency to localization of the choreiform movements. In 153 cases observed in this respect 46 showed a greater degree of involvement on one side than on the other. Of the 226 cases in this series, 73 showed cardiac affections, the majority being diagnosed as mitral. A few cases showed various other complications; two complications frequently observed were headache and vomiting. Some cases showed difficulty in speech and mental symptoms. In this series there was a total death rate of about 2 per cent., only one death being the direct result of the chorea. The average case remained in the hospital from five to eight weeks. There were 35 cases that had more than one attack. Some of the cases that received arsenic recurred and some that did not receive arsenic did not recur. Some of the cases were treated with large doses of arsenic; those cases treated without arsenic did as well as those treated with arsenical preparations. Arsenic might possibly have a deleterious effect of the heart muscle and innervation. It seemed unfair to treat a case of chorea with salvarsan unless syphilis was present.

Dr. HENRY F. HELMHOLZ of Chicago, Ill., said he would like to give the statistics from the Children's Memorial Hospital. They had had 138 cases of chorea, 33 1/3 per cent. of which gave a history of tonsillitis. Fifty-four per cent. of this series gave a history of either tonsillitis, rheumatism, or of cardiac involvement. From Rosenow's work, showing that the streptococcus had a tendency to localize in different parts of the body under different conditions, it might be that in chorea it localized in the brain. Even a single find-

ing of this kind would carry more weight than a series of cases with negative findings.

Dr. ABRAHAM JACOBI of New York said he had seen a great many cases of chorea and had written on the subject in 1875, at which time he had come to the conclusion that there was a close relation between chorea, rheumatism, and endocarditis, and that one frequently saw rheumatism first, endocarditis second, and chorea third; changes in this order, however, might take place. Rheumatism should not be overlooked in children who did not walk; it was easy to overlook it in such young children. Sometimes children showed a limp and sometimes they complained of pains which were likely to be called growing pains. In such cases one must think of rheumatism. As to arsenic, Dr. Jacobi said he did not believe that arsenic frequently had a deleterious effect. On the other hand, arsenic in young children and in the adult was a tissue builder, and he used it especially in myocarditis where there was a functional murmur, because, just like phosphorus, it built up the tissues. One should not lose sight of the value of arsenic in any disease in which there was anemia, as it influenced the development of muscle and tissue. Dr. Jacobi said that Dr. A. L. Goodman of New York had been working on the treatment of chorea and had proven that chorea was at least curable, not after weeks and months of treatment, but within a few days. Dr. Goodman's method of treatment was to withdraw from the patient about 40 c.c. of blood; then to take the serum of this blood, about 18 or 20 c.c., and inject that into the spinal canal. About 12 cases had been treated in this way and remarkable cures were demonstrated. If the first injection did not effect a cure a second and even a third injection might be made.

Dr. C. S. WAHRER of Fort Madison, Ia., said that it was supposed that rheumatism was an etiological factor in chorea. They had a therapeutical armamentarium against rheumatism and he wondered why this had not been applied in the treatment of chorea.

Dr. ISSAC ABT, in closing the discussion, said he believed that chorea was a symptom of nervous exhaustion in many instances and when it was due to this cause the child readily recovered with the rest treatment, hot baths, etc.

Obscure Fever in Infancy and Childhood.—Dr. EDGAR P. COPELAND of Washington, D. C., presented this paper. He stated that in considering fever of obscure origin one must bear in mind the structural and functional immaturity of the heat regulating mechanism, in every sense comparable to the immaturity of other systems in early life. The effects of such deficiency, invariably present to a greater or less extent in the very young, varied greatly, always being more pronounced in those individuals exhibiting other evidence of the instability of the nervous system, as expressed in convulsive attacks, tetany, etc. Under such conditions the responses to varied stimuli manifested themselves as unusual disturbances of body temperature. The recognition of these facts, however, did not obviate the necessity of the most diligent search for those definite pathological conditions giving rise to obscure fever in early life. The writer called special attention to dental caries as a cause of obscure fever and stated that middle ear diseases was also frequently a cause of fever, which might be overlooked by the most competent aurist, because middle ear disease might be present which could not be detected by inspecting the ear drum. It would sometimes be found that there was drainage from the middle ear into the pharynx when nothing could be seen by the ordinary aural examination. There might be an unsuspected infection of the tonsils which caused fever and in his opinion such an infection was more often the cause of obscure fever than was generally supposed.

Dr. F. M. POTTENGER of Los Angeles said he thought that the cases of obscure fever reported gave the syndrome of toxemia and the fever was part of the sympathetic disturbance. The toxemia might be produced by proteins broken up in the body. Proteins might be divided into poisonous and non-poisonous. It had been shown that a fasting animal got fever if protein was administered to it. This was illustrated by the fact that in typhoid fever, when after fasting the patient was given milk, there occurred a protein poisoning and a rise in temperature. The depressive emotional states did the same thing as toxemia through the action of the sympathetic nervous system which caused a vaso-motor constriction.

Dr. T. C. MCCLEAVE said he had been interested in what had been said about the tonsils because he had

had difficulty in getting the throat men to remove tonsils. The throat men did not know a great deal about the relation of general pathology to the condition of the tonsils; the pediatrician was a better judge as to the advisability of removing the tonsils.

Dr. ABRAHAM JACOBI said that in very few of these cases was it the tonsils that were at fault; even large tonsils were not at fault. The fault lay with the rest of the pharynx, the lymphoid bodies that surrounded the antrum and were between the nares and the throat were more often the cause of fever and toxic symptoms than the tonsils themselves. It had been his teaching that the nose must be kept clean, not by an atomizer but by irrigation. In giving irrigations emphasis must be placed on the danger of snuffing, a neglect to warn against snuffing might result in middle ear trouble.

Dr. ST. GEORGE T. GRINNAN of Richmond, Va., called attention to the possibility of having obscure fever as the result of over exercise. In certain children a blood examination might show a leucopenia and a low-hemoglobin percentage. He cited such a case in a child in which rest in bed for two weeks effected a cure.

Dr. JOHN LOVETT MORSE of Boston called attention to a great lack in our knowledge in that we did not know what were the normal variations of temperature in childhood. Again one had to be sure the thermometer was right before he said that a child had fever. As to the dental caries as a cause of fever, many dentists were two generations behind the time. A child might have an infection of the teeth and yet look all right. Teeth that were filled might have abscesses at their roots which were not suspected until the x-ray revealed their presence. The ears as a cause of fever must not be ruled out because the drum looked normal; one must remember that the child might have disease of the ethmoid cells or the antrum that might be the cause of symptoms. Nothing had been said about the urinary tract, the possibility of an infection here being the cause of fever must not be forgotten.

Dr. CHARLES GILMORE KERLEY stated that when the temperature was above 100° F. it could not be regarded as normal and should arouse suspicion. In many cases the cause could not be found. If a child with fever was put to bed, if the fever was of infectious origin the temperature would not come down, but if the child was neuropathic the rest would reduce the temperature.

The Natural Protection of the Child Against Tuberculosis, and Gradual Development of a Specific Cellular Defense.—Dr. F. M. POTTENGER of Los Angeles made this contribution. He emphasized the importance of recognizing that childhood was the time in which infection with tuberculosis occurred and that the prevention of adult tuberculosis was in the hands of the pediatricists. Most adult infection was simply the stirring up of a latent infection acquired in childhood. The question was how could we keep the child from becoming infected. The answer was that we must recognize the importance of the lymphatics. There were two kinds of defenses, humoral and cellular, and neither were specific. The child came in contact with various kinds of bacteria and gradually developed immunity by producing specific enzymes, and until this immunity was developed he must depend for protection on the lymphatic defense. The tonsil was the lymphatic structure for this defense. The fact that a tonsil was enlarged was no evidence that it should be removed, but rather that it was being overworked in exercising its function of defense. Hence tonsils should not be removed just because they were enlarged. They must be removed if they were diseased. The fact that a few tubercle bacilli were found in the tonsil did not indicate that the tonsil should be removed because the bacilli were destroyed before they passed through the tonsils to other tissues. In early life the bacilli passed readily through the tissues but when the cellular defense was established this did not occur, and, consequently, in the adult one got surface infection or clinical tuberculosis which did not involve the lymphatics but the tissues themselves, while in the child the opposite was true.

Dr. JOHN RITTER of Chicago expressed himself as much pleased to hear this attempt to stop the promiscuous removal of the tonsils. The lingual tonsil, the adenoids, and the tonsil proper were infantile organs whose purpose was to stop the entrance of bacilli into the body. Tuberculosis was a different proposition in a child from what it was in an adult. When one found a tuberculosis of the mediastinal glands in a child the bacilli had passed through the bronchus or trachea until they reached the mediastinal glands which set up a defense. One should be very careful in making a diagno-

sis of pulmonary tuberculosis in a child. Particular care should be exercised in guarding against the entrance of tubercle bacilli as far as possible. If there was disease of the tonsil it should be treated, but it should not be removed unless absolutely necessary. Dr. Ritter said he might make the statement that he had records showing that in cases in which the tonsils had been removed within six months or a year an active tuberculosis had supervened.

Dr. JOHN ZAHORSKY of St. Louis emphasized the statement that the tonsil was the first line of defense in the young child against infection, and if one removed much of the tonsillar ring there might ensue a bronchial pneumonia or a lymphadenitis. One should be very conservative in considering the removal of tonsils. The pediatricist was the one to decide when the tonsil was to be removed.

Dr. JAY I. DURAND of Seattle said the tonsil was a wide open gland while other glands were protected; this favored infection of the crypts of the tonsils which acted as culture tubes. It was difficult to tell when a tonsil should come out, but, in his opinion, it was better to err on the side of taking them out. A perfectly smooth scar tissue was a better defense than an infected tonsil. The general resistance of the child was improved by the removal of diseased tonsils and he had not seen a greater amount of infection after the removal of the tonsils. The bronchial glands were a means of defense as well as the tonsils.

Dr. T. C. MCCLEAVE expressed the opinion that it was safer to err on the side of removing the tonsils than on the other side. The tonsil doubtless had a protective function, but this was easily lost. He thought clinical experience justified the statement that in a large proportion of children readily infected tonsils were diseased. He had seen fewer infections supposed to have their portal of entrance by way of the throat in cases in which the tonsils had been removed and could not agree with the speaker who said that there were a greater number of bronchial infections after the removal of the tonsils.

Dr. ST. GEORGE T. GRINNAN of Richmond said that in Virginia one seldom saw tonsillitis in young negroes, yet these young negroes had a large amount of tuberculosis of the lung. It was extremely rare to see tuberculosis of the lungs in young white children but they had a large amount of glandular tuberculosis, and a large number of children who had it also had their tonsils.

Dr. F. P. GEGENBACH of Denver asked Dr. Pottenger how much importance he placed on the persistent enlargement of the anterior cervical glands and if there was any advantage in removing the tonsils in these cases, and also whether he would remove the tonsils in cases in which there was already a tuberculous adenitis.

Dr. CHARLES GILMORE KERLEY said he thought it was faulty teaching that would allow a diseased tonsil containing tubercle bacilli to remain in the throat. There was need of careful judgment as to what constituted a diseased tonsil. He believed that the tonsil had a function in the development and shaping of the throat and its removal should be avoided if possible until a child was three or four years of age. The removal of the tonsils resulted in adhesions between the pillars with a narrowing of the throat and a tendency to dryness of the throat. In contagious and infectious diseases, such as grip, measles, etc., the tonsil might furnish a site of infection as well as furnishing a method of prophylaxis against infection. Dr. Kerley said he had yet to see a case of tuberculous adenitis occur after tonsillitis when the child had been properly operated upon, and he had yet to see tuberculous glands as the result of operation when the tonsil had been thoroughly eradicated.

Dr. F. M. POTTENGER, in closing the discussion, stated that he would not allow a focus of infection to remain, but the point he had wished to emphasize was that the child had no other defense except the natural defense provided by the lymphatics, and that these had the function of building up a specific immunity against different varieties of bacteria. He would not remove a tonsil for tuberculous adenitis because he did not believe the tonsil was at fault.

Pediatric Nursing.—Dr. J. P. SEDGWICK of Minneapolis, Minn., presented this communication in which he discussed the influence which apparently minor conditions might have on the outcome of a case. He said that the present methods of charting a case had become so cumbersome that it consumed considerable time

to interpret a chart. He had devised a plan for graphic charting by which the condition of the child with reference to weight, temperature, feeding, etc., was shown by plotting the curves. There was a space for notes. A surprising amount of information in connection with the case could be quickly grasped by observing such a chart. By aseptic nursing in childhood a great deal of cross-infection could be prevented. In instances in which a nursing mother had a respiratory infection as grip, a cold, etc., she should wear a mask of two layers of gauze over the nose and mouth. Other members of the family and visitors were often a source of danger to the child. In order to prevent cross-infection in their hospital they placed the beds of the children seven feet apart. An experience with vulvovaginitis had taught them the importance of bathing female infants on a slab with running water. The writer cited instances in which the condition of premature and atrophic babies had varied directly with the attention that was given to a proper regulation of the temperature. In one instance too much warmth had caused a rise in temperature to 106° F. Other instances were cited in which insufficient warmth had resulted in a subnormal temperature. The importance of urinary analyses in infants was emphasized and a modification of the Lawrence apparatus for collecting the urine in female infants was demonstrated. In closing, Dr. Sedgwick stated that often the painstaking efforts of the physician were spoiled by incompetent nursing.

Report of Five Cases of Tertian Malaria Treated with Organic Synthetic Arsenic Intravenously.—Dr. FRANK C. NEFF of Kansas City, Mo., presented this report. He stated that synthetic arsenic had been given with satisfactory results in malaria of the tertian type but that it had little effect in the other types of malaria. He related the history of five cases showing a similarity in that after the administration of the diarsenal the plasmodium had disappeared from the blood. He gave doses of two or three decigrams of diarsenal and after two or three injections found that the plasmodium had disappeared. Several of the cases were not followed up; in others there has been a recurrence of the organisms and the treatment had to be repeated. There were no reactions that would contraindicate the use of salvarsan or neosalvarsan. While these agents had caused the disappearance of the organisms from the blood no conclusion could be drawn as to the permanence of the cure. Perhaps permanent results might be produced by different methods of administration or by the use of this treatment together with quinine as an adjuvant.

The Use of Boiled Milk in Infant Feeding.—Dr. JOSEPH BRENNEMANN of Chicago read this paper. He stated that the use of boiled milk in digestive disturbances was quite general and if it was good for the sick baby there seemed no reason why it should not be good for the well baby. The advantages of boiled milk were both bacteriological and physiological. The bacteriological advantages were understood by all. The physiological advantages depended upon the difference in the coagulability of the casein in boiled and raw milk. Boiled milk formed very hard curds which could only be broken up by peripheral digestion. In some instances the curds in raw milk were so large and so hard that they could not be gotten rid of even by vomiting. One of the reasons for the good results obtained with *eiweiss* milk was that it formed almost invisible curds. One never observed bad results in changing a baby from raw milk to boiled milk while the reverse was by no means true. The writer referred to the recent tendency to attribute all digestive disturbances in babies to the fats and carbohydrates in the food; he felt that the casein was also a factor in the production of symptoms of indigestion. The commercial pasteurization of milk was open to the objection that the milk was kept 24 hours after it had been pasteurized. Milk boiled at home was preferable to pasteurized milk; pasteurized milk might be considered as belonging in the raw milk class. If milk boiled at home was as popular as pasteurized milk there was every reason to believe that babies would suffer less.

Dr. C. G. GRULEE of Chicago said that scurvy had been held up as the scarecrow to prevent people from using boiled milk. He was in the habit of using boiled milk and boiled certified milk. He had never seen a case of scurvy that could be attributed to boiled milk.

Dr. HARRY LOWENBERG of Philadelphia said that if Dr. Brennemann needed anyone to come to his as-

sistance in advocating the use of boiled milk he was ready to do so. He was using boiled milk and even went so far in some instances as to use the old fashioned flour ball. As to the question of boiled milk as a factor in the production of scurvy he was ashamed to say that he had known of practitioners who failed to recognize the classical symptoms of scurvy, and even in cases in which superosteal hemorrhages were present were giving salicylates under the impression that they were dealing with rheumatism. He was in accord with the speaker in the belief that the protein of cow's milk could still be considered a factor in the production in indigestion in infants.

Dr. C. S. WAHRER of Fort Madison, Iowa, said he had been following this section for years and had come to a few conclusions. One had to be careful in drawing conclusions. He had heard of one man who made the statement that 33 1/3 per cent. of left-handed people were criminals, therefore left-handedness was a sign of criminality. Someone had replied, "Yes, but 77 per cent. of left-handed people are otherwise normal." This had its application to the feeding of babies. Most children did best on mother's milk; some did well on raw milk; some did well on pasteurized milk; others did well on goat's milk; others again on ass' milk, and some did well on anything.

Dr. JULIUS H. HESS said the disadvantages that were held against boiled milk might be obviated by giving fruit juices and vegetables earlier. Some children took more milk when it was boiled than when it was raw. He found that frequently boiled milk was being fed much in excess of the requirements of the child. This was not true of babies with a tendency to rickets; in these infants he had found that feeding cod-liver oil enabled the baby to handle more calcium. There was no question that there were fewer intestinal infections where boiled milk was used. They used boiled milk and had practically no gas bacillus infections.

Dr. L. R. DEBUYS of New Orleans said he had used first raw milk, then pasteurized milk, and now he was using boiled milk, but he always made it a point, whatever method was employed, to be sure that he first had good milk. He was now teaching that as soon as feeding with boiled milk was begun one must begin to add orange juice to the diet.

Dr. T. C. MCCLEAVE expressed the opinion that commercial pasteurization was a fallacy. Milk cooked in the home was better and from it one would get no infections.

Dr. CHARLES GILMORE KERLEY of New York said that one should not make sweeping statements, but must look upon this subject from the broad standpoint. Personally he preferred raw milk, but only a comparatively small part of the human family could have pure raw milk, inasmuch as it could not be provided. The next best thing was boiled or cooked milk. It was true that boiled milk was more easily digested than raw milk, especially was this true if the milk was boiled in the presence of starch. Dr. Kerley said he had never succumbed to the tendency to consider fats and carbohydrates the only cause of digestive disturbances; he had always believed that the casein played a part. There was no doubt that the feeding of cooked milk was a factor in the production of scurvy. Therefore, the speaker insisted, as soon as a child was put on boiled milk, orange juice or some other fruit juice should also be given as a precautionary measure.

The Use of Malt Soup Extract in Infant Feeding.—Dr. B. RAYMOND HOOBLER of Detroit read this paper in which he called attention to the failure of the prescribed formulæ accompanying the various preparations of malt soup to meet many of the indications in infant feeding. One great fault of some of these formulæ was that they called for wheat flour boiled but a very short time. The formulæ for the use of malt soup extracts might be greatly varied by adding it to a well cooked cereal, not necessarily wheat flour, but any other cereal that seemed best suited to the case. The cereal should be cooked at least one-half hour. One could then select any kind of milk that seemed indicated, boiled, pasteurized, certified, or raw. The writer presented a number of formulæ that illustrated how many of those for the use of malt milk might be made much more flexible, and he also explained the effect of different cereals with reference to fermentation and to the presence of different varieties of intestinal flora.

The Influence of Diet on the Development and Health of the Teeth.—Dr. JAY I. DURAND of Seattle presented this communication which consisted of an investiga-

tion of the incidence of caries in the teeth of 5000 children with reference to feeding during infancy. The highest percentage of caries was found in those fed on sweetened condensed milk. He cited statistics based on an examination of the skulls of a number of the primitive races which showed that caries was very rare in those races in comparison with what was found in modern civilized races. For instance, dental caries in Maori skulls had an incidence of only 0.76, while the Maori child in a civilized environment showed an incidence of 15 per cent. The foods that predisposed to caries were the sweet, sticky carbohydrates. These should not be eaten at the end of a meal as they lodged in the crevices of the teeth and even a thorough brushing failed to entirely remove them. There they fermented and caused caries. The foods which cleansed the teeth and prevented caries were the hard foods that required vigorous mastication, and raw vegetables such as lettuce and celery.

The Regulation of Children's Diet After Infancy.—Dr. J. H. M. KNOX of Baltimore presented this paper. He stated that the dietary needs of the infant during the first year of life were usually very carefully considered and in view of this fact it was rather surprising that so little attention was paid to the diet of children after infancy. But few studies had been made to ascertain the caloric requirements of the growing child at different ages or the relative amounts of the various food elements required for proper growth and development. It had been estimated that 100 calories per kilo or 45 per pound was the average requirement of a child one year old. Tables were presented which indicated the relative amounts of the various food elements required at different ages. After the first year of age the child could adapt itself to a wide variation in the proportions of the various food elements. These tables showed that as the age of the child advanced the amount of protein required decreased, and the proportion of carbohydrates increased. The quantity of fluid required varied widely and was dependent upon temperature, humidity, etc. The mineral requirements of the diet were usually fully met by the ordinary vegetable and cereal in the diet. The physician should be able to provide a well-balanced ration for a growing child and one that would be well digested. There was great danger of overfeeding growing children. A case illustrating the effects of overfeeding was cited, in which the child was getting 2500 calories per day, that was 150 calories per kilo body weight; the number of calories was diminished by one-half and the child rapidly improved in condition. Diet lists suited to children of various ages were presented together with a list of foods that could be used as substitutes for those given. The writer said he would not discuss the alteration of the diet in disease, but that by a careful adjustment of the diet in disease the child might be kept along without lowering the caloric value of its diet.

Report of a Committee on the Investigation of Diarrheal Diseases.—Dr. JOSEPH I. GROVER presented a statistical study of diarrheas in Boston for 1915 and Henry F. Helmholtz presented an analyses of the mortality for 1915 in the Infant Welfare Society of Chicago. The points brought out by Dr. Grover's statistics were that absolute humidity had a larger influence than any other one factor in infectious diarrheas. The proprietary foods, more especially those causing a great deal of carbohydrate fermentation, seemed to predispose to diarrhea and children with other diseases were more susceptible to the diarrheas of infancy than other children. Dr. Helmholtz's analysis of the Infant Welfare Work in Chicago brought out very clearly the relation of poverty to the mortality from diarrheal diseases and showed in a most striking manner that the visiting nurse was an exceedingly potent factor in lessening infant mortality among the poor foreign population. The mortality had been far higher in August than during any other month.

Dr. HENRY DWIGHT CHAPIN said he thought these statistics gave a wrong impression, in that they gave a much higher death rate in August than in July. He had made studies some years ago for five consecutive years and found that the mean temperature of July was 2 per cent. higher than that of August, and the mortality was higher for July than for August. Another unusual thing in these statistics was that the mortality rate from respiratory diseases was greater in August than in March. In New York he had found that the highest point in the mortality rate was not reached on the hot days, but a few days after the hot spell.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

REFRACTION OF THE HUMAN EYE AND METHODS OF ESTIMATING THE REFRACTION. Including a section on the Fitting of Spectacles and Eye-Glasses, etc. By JAMES THORINGTON, A.M., M.D. Published by P. Blakiston's Son & Co., 1012 Walnut Street, Philadelphia. 344 illustrations, 27 of which are colored. 407 pages. Price \$2.50 net.

A TEXT-BOOK OF FRACTURES AND DISLOCATIONS. With special reference to their Pathology Diagnosis and Treatment. By KELLOGG SPEED, S.B., M.D., F.A.C.S. Published by Lea & Febiger, Philadelphia and New York. Illustrated with 656 engravings. 888 pages.

DISPENSARY CONTROL OF TUBERCULOSIS. Eighth Annual Report of the Association of Tuberculosis Clinics of the City of New York. 39 pages.

GYNECOLOGY. By WILLIAM P. GRAVES, M.D., F.A.C.S. Published by W. B. Saunders Company, Philadelphia and London. With 424 Original Illustrations, 66 of them in colors. Octavo volume of 770 pages. Price, Cloth, \$7 net; Half Morocco, \$8.50 net.

EMBRYOLOGY, ANATOMY, AND DISEASES OF THE UMBILICUS, TOGETHER WITH DISEASES OF THE URACHUS. By THOMAS S. CULLEN. Published by W. B. Saunders Company, Philadelphia and London. With 269 original illustrations and 7 plates by MAX BRODEL and AUGUST HORN. Large octavo of 680 pages. Price, Cloth, \$7.50 net; Half Morocco, \$9 net.

LATERAL CURVATURE OF THE SPINE AND ROUND SHOULDERS. By ROBERT W. LOVETT, M.D. Published by P. Blakiston's Son & Co., 1012 Walnut Street, Philadelphia. Third Edition, Revised and Enlarged, with 180 Illustrations. 213 pages. Price, \$1.75 net.

BLOOD-PRESSURE. Its Clinical Applications. By GEO. WILLIAM NORRIS, A.M., M.D. Published by Lea & Febiger, Philadelphia and New York. Second Edition, Revised and Enlarged. Illustrated with 102 Engravings and 1 Colored Plate. 424 pages.

THE SEX COMPLEX. A Study of the Relationships of the Internal Secretions to the Female Characteristics and Functions in Health and Disease. By W. BLAIR BELL. Published by William Wood & Company, New York. Illustrated. 233 pages. Price \$4 net.

SURGICAL NURSING AND TECHNIQUE. A Book for Nurses, Dressers, House Surgeons, etc. By CHAS. P. CHILDE. Published by William Wood & Company, New York. Illustrated. 229 pages. Price \$2 net.

PLAGUE. Its Cause and the Manner of Its Extension—Its Menace—Its Control and Suppression—Its Diagnosis and Treatment. By THOMAS WRIGHT JACKSON, M.D. With Bacteriologic Observations by Dr. Otto Schobl. Published by J. B. Lippincott Company. Illustrated. 192 pages.

THE MEDICAL CLINICS OF CHICAGO. Vol. I, No. 6 (May, 1916). Published bi-monthly by W. B. Saunders Company, Philadelphia and London. Octavo of 229 pages, 22 illustrations. Price per year: Paper, \$8; cloth, \$12. (Index Number.)

MONOGRAPHS OF THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. No. 6, January 31, 1916. (Torula Infection in Man.) By JAMES L. STODDARD, M.D., and ELLIOTT C. CUTLER, M.D. Printed by Waverly Press. The Williams & Wilkins Co., Baltimore, U. S. A. Price, \$1. 98 pages.

COLLECTED STUDIES FROM THE BUREAU OF LABORATORIES. City of New York. Dr. WILLIAM H. PARK, Director. Volume viii, 1914-1915. Printed by M. B. Brown Printing & Binding Co., of New York. 435 pages.

FORTY-SIXTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS. (State Department of Health since August 6, 1914.) Printed by Wright & Potter Printing Co., State Printers, 32 Derne St., Boston. 781 pages.

THE GENERAL EDUCATION BOARD.—REPORT OF THE SECRETARY. 1914-1915. 82 pages.

THE KINETIC DRIVE. Its Phenomena and Control. By GEO. W. CRILE, M.D. Published by W. B. Saunders Company, Philadelphia and London. Illustrated. Octavo of 71 pages. Price, cloth, \$2 net.

Abbe, R., the legacy of the intemperate use of tobacco, 951; the tobacco habit, 177.

Abderhalden reaction, present status of, 285.

Abdomen, adhesions and bands in, 843; pain in, acute, prophylaxis in, 630; surgery of, care of cases, 759; surgery of, free omental grafts in, 562; surgical, acute, 648; typhoid, acute, 117; wounds, gunshot, of, 32; wounds, penetrative, of, 208, 887.

Abscess, appendicular, in infant, 232; gangrenous, of lung, 263; intraabdominal, 538; ischiorectal, from fish bone, 836; peritonsillar, radical treatment of, 115.

Accident insurance, 241, 707; operation for appendicitis, 445.

Accidents and arthritis deformans, 753.

Acetone bodies, production of abnormal quantities of, in infancy and childhood, 1118.

Acetonuria in relation to contagious diseases, 645; starvation in development of, 1156.

Achondroplasia, 1118.

Acid, hypochlorous, therapeutic value of, 1061; silicic, colloidal solutions of, 749.

Acidosis in children, 170, 1117; in diseases of childhood, 125; in nephritis, 981; studies in, 1018.

Acne, treatment of, 88.

Adamson, H. G., x-ray treatment of ringworm of the scalp, 525.

Addison's disease, 477; recent views of, 963.

Adenitis, tuberculous cervical, treated by x-ray, 579, 1058.

Adenocarcinoma of uterus, 537; of uterus and gall-bladder, 666.

Adenoids and ogival palate, 532; medical treatment for, 630.

Adenomyoma of rectovaginal septum, 1115; of round ligament and incarcerated omentum in inguinal hernia forming one tumor, 257.

Adhesions and bands, abdominal, 843.

Adrenal gland and dementia precox, 66.

Age, old, in relation to cancer, 425.

Agglutinins, inoculation, influence of febrile conditions on, 383.

Air passages, acute inflammations of, in infants, 840.

Alaska, practice in, 833.

Albee's operation for spondylitis tuberculosa, 972.

Albuminuria and trench fever, 572.

Alcohol, consumption, increased, of, in United States, 120; drinking in Germany, future status of, 334; effect of, on man, symposium on, 892; in relation to mental disease, 884; life insurance and, 890.

Alcoholic as seen in court, 1102.

Alcoholism, to combat, 46.

Alimentary canal, wounds, gunshot, of, 118.

Alopecia, seborrheic, treatment of, 352; syphilitic, 28; syphilitic, complete, 1061.

Amebas, dysenteric, in rats, 77.

Amenorrhea, 88.

Amino-acid content of blood, 1156.

Ammonia as an enema, 630.

Amputations at base hospitals in France, 838.

Amyloid degeneration in infection with *B. capsulatus*, 839.

Analgesia and anesthesia in obstetric practice, 570.

Anastomosis, intestinal, 165.

Anatomy, references to, in Rabelais' works, 812.

Andresen, A. F. R., the treatment of gastric ulcer with especial reference to its etiology as an infective process, 457.

Andrews, J. B., health insurance and the prevention of tuberculosis, 370.

Anemia, injections of whole blood in, 87; pernicious, etiology of, 716; post-hemorrhagic, blood transfusion in, 709, 711; splenic, surgery of, 1019.

Anesthesia, caudal, in genitourinary surgery, 259; local, observations on, 260; nitrous-oxide-oxygen, 1112; spinal, 840; spinal, with special reference to use of novocaine, 1060; spinal, with stovaine, 206.

Anesthetic vapors, warm, 251.

Aneurysm, cirroid, treated by direct application of boiling water, 104; subclavian, 581; traumatic and venous, 167.

Angina and rheumatism, articular, causal relationship between, 925; retronasal, 705; sepsis from, 374.

Angioma of larynx, 1084.

Aniline poisoning, industrial, in the United States, 922.

Anomalies, developmental, persistent, of position of large intestine, 353.

Anthropological studies, 155.

Anthropometric study in University of Porto Rico, 558.

Anticoagulants, use of, in blood transfusion, 183.

Antiseptic, brilliant-green as, 630.

Antitoxin for malignant edema, 33; tetanus after injections of, 168; tetanus, prophylactic use of, 914; therapy, quarter century of, 168.

Antivenine in snakebites, 242.

Aorta, abdominal, embolism of, aortotomy of, 198.

Aortitis, syphilitic, 340.

Aortotomy in embolism of abdominal aorta, 198.

Appendectomies, ineffective, 1009.

Appendicitis, acute, 339; acute, and pneumonia, differential diagnosis by x-ray, 592; acute, complicated by pericystitis, 196; can we diagnose? 469; complications, post-operative of, diagnosis and treatment of, 122; tuberculosis as cause of, 1121; salpingitis secondary to, 261; suppurative, treatment of, 84; unusual case of, 294.

Appendix vermiformis, abscess of, in infant, 232; biology of, 342; cysts of, 264; cysts, pseudomucinous, of, 262; fecal concretions of, demonstrable by Roentgen ray, 1069.

Apraxia, motor, bilateral, 794.

"Aqua viva", 287.

Army, report of Surgeon General, 108.

Arsenic and potassium iodide in bronchitis, 176; organic synthetic, in treatment of tertian malaria, 1163.

Arsenobenzol in syphilis, 385.

Arteries, degeneration of, 681.

Arteriosclerosis, 958.

Arteriovenous injury, 77.

Artery, pulmonary, extraction of thrombus from, 882.

Arthritis, chronic, uric acid in blood in, 389; deformans, 167; deformans and accidents, 753; dysenteric, note on, 839; rheumatoid, 630; rheumatoid,

radical treatment of, 295; treatment of, by intravenous injection of foreign protein, 1100.

Arthropathy, hypertrophic pulmonary, 489.

Ascites, treatment of, subcutaneous dermic fistula in, 263; veno-peritoneostomy for, 493.

Asthma, bronchial, dietetic treatment of, 87; bronchial, treatment with endobronchial spray, 574.

Atresia of duodenum, congenital, 106; of ileum, congenital, complete, 1039.

Atrophy, muscular, of scapulo-humeral type, 671; neuromuscular, progressive, Charcot-Marie-Tooth type of, 1010.

Atropine in eclampsia infantum, 384; in glaucoma, 1099.

Auer, E. A., phenomena resultant upon fatigue and shock of the central nervous system observed at the front in France, 641.

Aura, human, 334.

Auscultation in diagnosis of vascular injuries accompanying gunshot wounds, 923.

Austria, medical profession in, 487.

Autointoxication, acid, in infancy and childhood, 835.

Autolysis in mouse tumors, 165.

Autolysis, tissue, metabolism of, 250.

Autoserum in treatment of cancer, 730.

Aviators' sickness, 1093.

Avitaminoses, 245.

Axis, fracture of, non-fatal, 249.

B

Babies, are, worth saving? 37

Bacilli, diphtheroid, two unusual strains of, 240.

Bacillus capsulatus, amyloid degeneration in infections with, 839; *dysenteriae* as cause of infectious diarrhea in infants, 1098; *epilepticus*, 1010; *paratyphosus B.*, acute urinary infection with, 1061; *paratyphosus B.*, food poisoning by, 207; *tuberculosis*, in blood, 134; *tuberculosis*, in sputum, strains of, 838; *typhosus* carriers, iodine for, 352; *typhosus* carriers, search for among 800 convalescents, 660; *typhosus*, effect of emetinized blood on, 284; *typhosus*, infection by, use of stock vaccine in, 887.

Backache, chronic, 884; rôle of anteposed uterus in, 1113.

Bacteria of gangrenous wounds, 295.

Bacteriology of recent grip epidemic, 368.

Barnert, C., treatment of gonorrhea ophthalmia, 239.

Baronets, medical, 385.

Barrows, C. C., the late, 247.

Baruch, S., Nauheim baths at Saratoga, 1054; Nauheim method, 1074.

Basedow's disease, vagotonic type, thyrectomy for, 580.

Baths, Nauheim, in cardiovascular diseases, 233.

Battlefield casualties, 676.

Battle shock, clinical observations on, 388.

Bauch, S., a report on two cases of syphilis of the lung, 906.

Beekman, M., experimental study of the effect of emetinized blood on the typhoid bacillus, 284.

Benzol in leucemia, 1119.

Beriberi, 30; relapsing, 443.

- Best, W. H., intramuscular injections of mercury salicylate in the treatment of syphilis, 473.
- Bichloride of mercury as substitute for salvarsan, 389; intraspinal injections of, 1098; poisoning, mercury elimination in, 58.
